PME-NA History and Goals

PME came into existence at the Third International Congress on Mathematical Education (ICME-3) in Karlsrühe, Germany in 1976. It is affiliated with the International Commission for Mathematical Instruction. PME-NA is the North American Chapter of the International Group of Psychology of Mathematics Education. The first PME-NA conference was held in Evanston, Illinois in 1979.

The major goals of the International Group and the North American Chapter are:

- To promote international contacts and the exchange of scientific information in the psychology of mathematics education;
- To promote and stimulate interdisciplinary research in the aforesaid area, with the cooperation of psychologists, mathematicians, and mathematics teachers;
- To further a deeper and better understanding of the psychological aspects of teaching and learning mathematics and the implications thereof.

PME-NA Membership

Membership is open to people involved in active research consistent with PME-NA's aims or professionally interested in the results of such research. Membership is open on an annual basis and depends on payment of dues for the current year. Membership fees for PME-NA (but not PME International) are included in the conference fee each year. If you are unable to attend the conference but want to join or renew your membership, go to the PME-NA website at http://pmena.org. For information about membership in PME, go to http://www.igpme.org and click on "Membership" at the left of the screen.

PME-NA Local Organizing Committee

The local organizing committee for PMENA-37 in East Lansing, Michigan comprises volunteers from Michigan State University and other institutions in the United States:

Tonya Bartell, *Michigan State University*
Kristen Bieda, *Michigan State University*
Aaron Brakoniecki, *Boston University*
Kenneth Bradfield, *Michigan State University*
Sue Carpenter, *Michigan State University CREATE for STEM*
Higinio Dominguez, *Michigan State University*
AJ Edson, *Michigan State University*
Bob Geier, *Michigan State University CREATE for STEM*
Frances Harper, *Michigan State University*
Beth Herbel-Eisenmann, *Michigan State University*
Lateefah Id-Deen, *University of Louisville*
Kate Johnson, *Brigham Young University*
Lisa Keller, *Michigan State University*
Luis Leyva, *Rutgers Graduate School of Education*
Raven McCrory, *Michigan State University*
Scooter Nowak, *Michigan State University*
Amanda Opperman, *Michigan State University*
Amy Parks, *Michigan State University*
Joanne Philhower, *Michigan State University*
Ralph Putnam, *Michigan State University*
Amy Ray, *Michigan State University*
Jack Smith, *Michigan State University*
Eryn Stehr, *Michigan State University*
Shannon Sweeny, *Michigan State University*

We also acknowledge and are grateful for the volunteer support provided by many others during the conference including faculty and graduate students from Michigan State University, CREATE for STEM and the Connected Mathematics Project

Strand Leaders

The Local Organizing Committee would like to recognize and express appreciation to the following people for serving as **Strand Leaders**. In this role they managed the reviewing process for their strand and make recommendations to the Local Organizing Committee.

Dor Abrahamson, *University of California, Berkeley*
Julia Aguirre, *University of Washington, Tacoma*
Jeffrey Choppin, *University of Rochester*
Michelle Cirillo, *University of Delaware*
Dana Cox, *Miami University*
Robert Floden, *Michigan State University*
Mary Foote, *Queens College - CUNY*
Jennifer Kaplan, *University of Georgia*
Niral Shah, *Michigan State University*
Megan Staples, *University of Connecticut*
Anita Wager, *University of Wisconsin, Madison*

Preface

On behalf of the 2015 PME-NA Steering Committee, the 2015 PME-NA Local Organizing Committee, and Michigan State University, we welcome you to the 37th Annual Meeting of the International Group for the Psychology of Mathematics Education – North American Chapter held on the campus of Michigan State University in East Lansing, Michigan. The year 2016 marks 30 years since the conference was hosted by Michigan State University, and we hope it is the best PME-NA yet!

The theme of this year's conference is Critical Responses to Enduring Challenges in Mathematics Education. The theme of this year's conference invites mathematics education scholars to reflect upon and critically respond to enduring challenges in teaching and learning mathematics for all students. To ignite discussion within the field, we organized the conference around four focal enduring challenges, each of which is featured in one of four plenary talks: teaching as responsive to various conceptions of mathematics (Plenary #1, Dr. Jerry Lipka, Dr. Melfried Olson, Dora Andrew-Ihrke, Evelyn Yanez); addressing the needs of marginalized populations in school mathematics (Plenary #2, Dr. Robert Q. Berry III); (3) the impact of teacher evaluation and high-stakes assessment in teaching (Plenary Panel: Craig Huhn, Lisa Jilk, Marty Schnepp, Marie Smerigan); the role of assessment in teaching and learning (Plenary #4: Dr. Malcolm Swan). Our hope is that the conference will catalyze collective reflection, collaborative inquiry, and discussion about various means for responding to and addressing these, and other, challenges.

For this year's conference, we received 528 submissions. The overall acceptance rate was 64%. We are pleased to offer 92 Research Report sessions, 96 sessions, 136 Posters, and 12 Working Groups in our conference program.

We wish to acknowledge and thank the many people who generously volunteered their time in preparation for this conference to ensure a high-quality program, including proposal authors, reviewers, Strand Leaders, the PME-NA Steering Committee, and the 2015 PME-NA Local Organizing Committee. In particular, we want to highlight the extremely generous financial and personnel support provided by the MSU CREATE for STEM Institute. We are deeply grateful for the hard work and support of both Dr. Robert Geier and Sue Carpenter at the Institute. We also wish to thank the generous financial support of the MSU Program in Mathematics Education (PrIME), the MSU College of Education, and the MSU Department of Teacher Education.

Finally, we wish to thank this year's attendees for their hard work, passion and enthusiasm for addressing enduring challenges in mathematics education. You have inspired us to do our best to provide a venue for exchanging ideas and promoting ongoing reform in mathematics education. We hope you will enjoy the conference! Go Green!

This unlikely cast of characters, by working collaboratively in a trusting learning community, was able to identify an approach to teaching rational numbers through measuring from the everyday practices of Yup'ik Eskimo and other elders. "The beginning of everything," as named by a Yup'ik elder, provided deep insights into how practical activities were conceptualized and accomplished by means of body proportional measuring and nonnumeric comparisons. These concepts and practices shed light on the importance of measuring as comparing and the importance of relative units of measure, and helped us imagine a way to establish an alternative learning trajectory and school-based curriculum that begins with the insights gained from Yup'ik and other elders. This approach may well provide teachers a way to teach aspects of elementary school mathematics in an integrative and elegant way.

Keywords: Measurement, Number Concepts and Operations, Curriculum

Introduction

More than 30 years ago, Evelyn Yanez, Dora Andrew-Ihrke, and Jerry Lipka almost blindly began a journey to map the landscape of Yup'ik elders' knowledge, practices, and conceptions of mathematics. Evelyn and Dora were students in the Cross-Cultural Education Development Program (X-CED), University of Alaska Fairbanks, in Dillingham, Alaska, and Jerry was a field faculty member. Little did we know that insights gained from our long-term collaboration with Yup'ik elders and our more recent work with Indigenous Knowledge (IK) holders from the Yap Outer Islands, Greenland, Kamchatka, and Norway would result in a way to teach aspects of the foundation of elementary school mathematics. Nor did we realize that this would become our life's work.

From 1995 to approximately 2010, we worked with a dedicated group of Yup'ik elders and teachers. The most significant outcome of this phase of our collaborative work was the publication of the *Math in a Cultural Context* series—ten elementary school culturally based mathematics modules and ten accompanying storybooks. During this time, we also developed a culturally based and reform-oriented pedagogical approach (Lipka, with Mohatt & the Ciulistet, 1998), which incorporated aspects of Sternberg's theory of intelligence (Sternberg, Lipka, Newman, Wildfeuer, & Grigorenko, 2006). We shared our curricular and pedagogical approach in many teacher training institutes and workshops. This was our response to identifying conceptions and contexts of mathematical behavior and thinking based on Indigenous Knowledge and applying them to a classroom context. Quantitative and qualitative journal articles documented both teachers' pedagogical practices while implementing MCC curriculum and outcome studies on the efficacy of the curriculum (Kisker, Lipka, Adams, Andrew-Ihrke, Yanez, & Millard, 2012; Lipka, Hogan, Webster, Yanez, Adams, Clark, & Lacy, 2005).

Yet, we were not satisfied, as we were beginning to perceive a more cohesive approach to teaching elementary school mathematics based on Indigenous Knowledge (Lipka, Andrew-Ihrke, & Yanez 2011; Lipka, Wong, & Andrew-Ihrke, 2013). Could we identify and understand the embedded and encoded mathematics in everyday Yup'ik activities in a systematic way? We wondered what it is that enables Yup'ik and other elders to accomplish an array of everyday tasks without overburdening memory. Yup'ik people are generalists; individuals have needed to make clothing, build houses, fish racks, smokehouses, and kayaks, and orient themselves in various weather conditions when traveling on the tundra, in forests, and on rivers and open seas. Were there concepts that cohesively supported the performance of these tasks?

Our latest grants have enabled us to continue this exploration into mathematical concepts embedded in the everyday activities of Indigenous Knowledge holders among the Yup'ik and other cultural groups across the Arctic as well as an "outlier" group from Yap State in the Federated States of Micronesia. This work has allowed us to imagine what an elementary school mathematics curriculum would look like if developed from key aspects of Indigenous Knowledge. We began this phase of our research aware of the importance of symmetry and measuring in the everyday activities of Yup'ik elders (Lipka, Andrew-Ihrke, & Yanez, 2011). Measuring is the major conception of "mathematics" that elders have identified and use in their everyday activities (Lipka, with Mohatt & the Ciulistet, 1998; Lipka, Wong, & Andrew-Ihrke, 2013).This paper reports on what we have learned to date.

From the outset of our work, because numbers and operations represent such an overwhelming part of the curriculum, we were initially unable to see how a cultural group such as Yup'ik, which does not prize numbers in its daily activities, could provide us with key insights on how to teach the foundations of school mathematics. Yet, the information that follows is what we found, and it is what was right in front of us for years. Even though there are fundamental epistemological differences between Yup'ik practical activity and school mathematics, the embedded mathematical principles in everyday activity can generalize to the teaching of school mathematics. Because their measuring approach occurs in a nonnumeric environment, the embedded mathematical principles provide a generalized model for teaching aspects of rational number reasoning and other aspects of mathematics. In fact, rational number learning (fractions, ratios, and scaling) has been identified as a difficult topic for most U.S. students (Confrey, Maloney, Wilson, & Nguyen, 2010; Wu, 2011; Lamon, 1999), and rational number reasoning is considered a key concept in students' mathematical education (National Mathematics Advisory Panel, 2008).

This article describes how measuring can be perceived as a central and integrative concept across a wide range of everyday activities conducted by Yup'ik and other Indigenous Peoples. We will identify and describe a few cultural activities that highlight underlying generative cultural and mathematical principles. We briefly describe these principles and will argue that the principles embedded in activity provide an alternative pathway to teaching the foundations of mathematics. The key curricular and teaching examples demonstrated in this paper from Indigenous Knowledge connect measuring with the elders' halving algorithm and demonstrate how this can be an exemplar to teach place value in base 2.

Brief Methodological Considerations

Math in a Cultural Context (MCC) is a long-term project at the University of Alaska Fairbanks; federally funded grants have supported this work. A cohort of Yup'ik students enrolled in the X-CED Program and coauthor Jerry Lipka began working with elders in the late 1980s as a first step in understanding and connecting their everyday knowledge to elementary school teaching. This unlikely long-term collaboration (well documented in *Transforming the Culture of Schools: Yup'ik Eskimo Examples)* occurred among Yup'ik elders, Yup'ik teachers and now-retired Yup'ik teachers, and academics (mathematicians, mathematics educators, linguists, cultural anthropologists, and educators) to make teaching elementary school math more cohesive, accessible, and relevant. Critical to our long-term work has been the establishment of trust, respect, and continuity, as we have been working with some elders for over twenty years and, in the process, have become "elders" ourselves. Evelyn Yanez, a coauthor and retired Yup'ik teacher and current MCC faculty, stated that "elders trusted us enough to give us their stories and knowledge so that it may go into the future like an arrow. They knew we would prepare books for future generations; they were excited about sharing their work" (personal communication, June, 2015). The meetings were important to the elders as the following anecdote describes. Lily Gamechuk, an elder from Manokotak, Alaska, and now deceased, came to a meeting in Fairbanks some years ago. She needed to go to the hospital but refused to go until she told her story to the gathered group. Elders would often state to us how MCC was one of the few programs in which their knowledge counted.

Over these many years, insiders and outsiders have met three or four times a year for three to five days per meeting, when possible through grant funding. These meetings included storytelling, describing and performing everyday tasks such as making clothing and patterns, and discussing and simulating star navigation. Less often, we would practice these skills and knowledge *in situ*. However, more remarkable, our elder meetings at times have become Socratic in character as the discursive activities of the entire group demonstrate and refine the growing understanding of connections between Yup'ik cosmology, epistemology, and practice as a system, and as we relate this Indigenous Knowledge System to school mathematics. Koester (2014) describes the process as "getting to 'mathematical foundations' from oral accounts of activities, a discursive process that invokes metaphor, symbols, and various forms of discursive displacement."

Jerry Lipka, Principal Investigator of MCC and first author of this paper, cannot stress enough the absolute importance of the long-term collaborative inquiry, which has allowed exploration of topics in depth and in new ways and has allowed opportunity for serendipitous events to occur, ones from which completely new lines of inquiry developed. For example, a single geometrical construction performed by Dora Andrew-Ihrke, which she was not going to share because she "thought everyone knew this," led to a generalized way to construct many different planar shapes as well as three-dimensional shapes. (It is beyond the scope of this paper to explore in depth the methodological considerations or the geometrical constructions.)

The Beginning of Everything: Connecting Everyday Activity and Mathematical Reasoning

In one of our first meetings with Yup'ik elders many years ago, we asked Lily Gamechuk, a respected elder from Manokotak, Alaska, to share with the group how she made clothing. Lily asked one of the Yup'ik teachers-in-training in the room to stand. Without any instruments, and without touching her, Lily "measured" her. The measuring took place in her mind's eye. Minutes later, Lily had made a complete outfit out of butcher paper including a dress, belt, hat, and boots. The only instrument she used was a pair of scissors. How did she do this? How did she measure? She never told us directly, as it was more important from her point of view that we learn this skill in our way. What mental operations did she employ to transfer her visual perception to the practice of cutting and sewing proportionally? Little did we know that understanding how Yup'ik elders performed such everyday math would transform our own thinking.

In a recent elders' meeting with the Yup'ik cohort, Raphael Jimmy, an elder of approximately 90 years from Mountain Village, Alaska, slowly raised his hands above the table lifting them at eye level so that we could all see that he had crossed his left and right index fingers, forming right-angled axes referred to here as a plus sign: "+" (Figure 1). Simultaneously, he stated, "What was once hidden is now revealed" (personal communication, November, 2013).

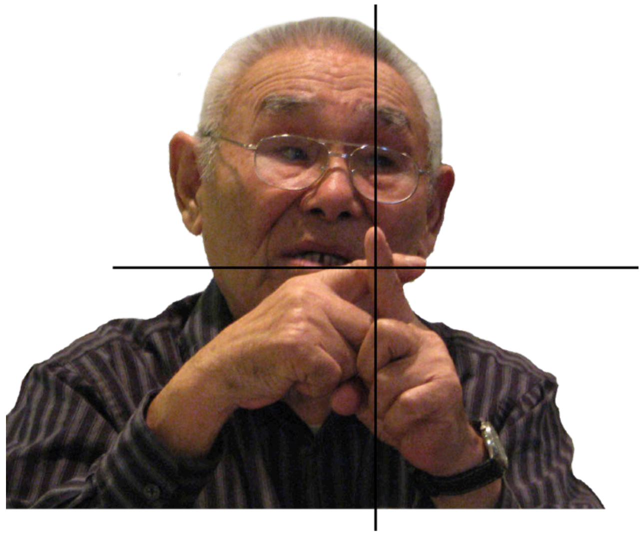

Figure 1: The beginning of everything

Mr. Jimmy explained that his crossed fingers represent "the beginning of everything." In a practical sense, this meant that the embodied abstraction was the starting point for many, if not most, practical activities. Even a length or a line segment has an implied center; folding material in half establishes a line of symmetry and two equal parts. Once Mr. Jimmy shared this concept, other members in our group realized that they too use this concept, heretofore unnamed, in their everyday constructions. We slowly realized that the concept reflected a culturally preferred way of perceiving, thinking, and performing across a wide variety of activities. Other members in our research group had also described this process, but until that moment, the process had gone unnamed. We have begun to observe the importance of "the beginning of everything" in other cultural groups with whom we are working, most notably the Yap Outer Islanders from the Federated States of Micronesia.

The cultural and mathematical activity-generating concepts signaled by Mr. Jimmy's action of crossing his fingers include the Yup'ik concepts of *qukaq* [center] and *ayagneq* [a place to begin], *avek* [halving], *tapluku* [to fold it, partitioning material], and *ayuquk* [testing and verifying congruence and symmetry or identifying equality]. This cluster of concepts and actions relate space, locating, and measuring space by invoking a line of symmetry that emerges through the action of folding material in half, or as a mental image in which the whole contains its parts, and a process of verifying equalities (is this side equal to the other side?). These words and actions establish a center and a place to begin many different projects performed by Yup'ik elders. The following few examples from Yup'ik cultural activity will illustrate how ubiquitous this concept is.

Although Dora Andrew-Ihrke, a long-term Yup'ik colleague and coauthor of this paper, did not have a name for "+," she uses the concept in her geometric constructions, such as for making a square out of irregular uneven material and in numerous other projects. Through body proportional measuring and folding, she establishes the center of the material. The "+" becomes the inner structure for a square, as shown in Figure 2. (The drawn lines are for demonstration purposes.)

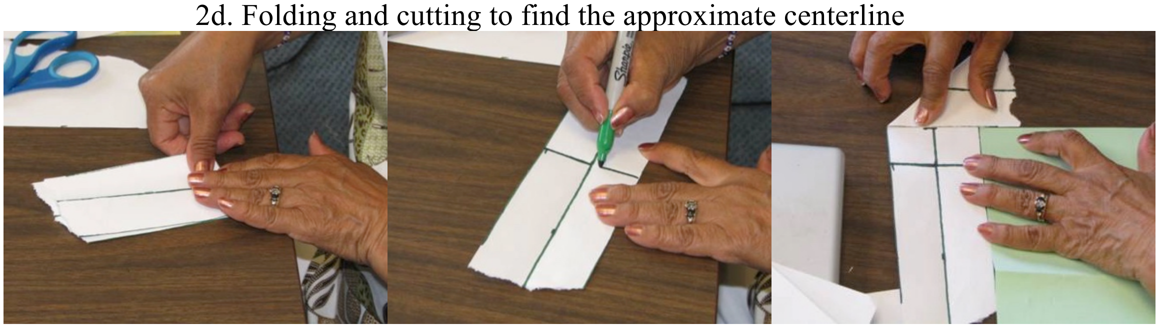
The square and its center are co-constructed, as Dora refers to the initial center point as "fake," meaning approximate. The square and its center become "real" when she verifies the congruence of each fold (vertical, horizontal, and diagonals).

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

Dora uses these same processes and the concept of the orthogonal center to create patterns. She folds a square in half from top to bottom and side to side twice. This produces smaller squares, all the while verifying that she has maintained the orthogonal center. Figure 3 shows an example of this

2a. Irregular material 2b. One fold creates an edge; 2c. Measuring from the edge

2d. Folding and cutting to find the approximate centerline



2e. Perpendicular fold 2f. The approximate center of the square is established and Dora continues to construct the square

Figure 2: Geometric constructions using the concept of "+"

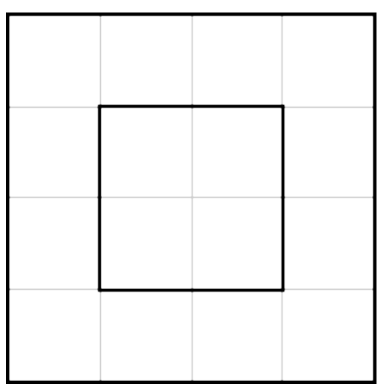


Figure 3: An example of geometrical similarity and scaling

similarity and scaling. Scaling is invoked through many everyday activities within the Yup'ik culture and is part of our school-based program.

The square is Dora's central geometrical shape, which she transforms through symmetrical folding into a circle or other planar shapes (Lipka, Wong, & Andrew-Ihrke, 2013). Aspects of the Yup'ik orientation system guide the transformation of a square into a circle by folding along lines of symmetry oriented by the winds, then the in-between winds, and once more between-those-winds until there are 16 points on the square (Figure 4).

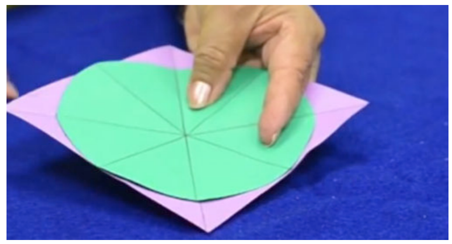

Figure 4:

When the square has been transformed into a many-sided polygon, Dora cuts a circle out of the square; the circle is inscribed in the square as shown in Figure 4 (Lipka, Andrew-Ihrke, & Yanez, 2011). All of these actions occur through the axial center.

Mrs. Nanalook, a respected elder from Manokotak, Alaska, has been a working member of the Yup'ik elders' cohort for a long time. Recently, she showed us step-by-step how she begins to weave a grass basket (Figure 5). A detailed ethnographic description is beyond the scope of this paper, but by referring to Mrs. Nanalook's key movements around the center point (see photographs in Figure 6), you can imagine how she begins weaving a grass basket.

Mrs. Nanalook takes a blade of grass, and if it is wide, she cuts it in half along its line of symmetry. As shown in Figure 6, she takes the two parts of the blade of grass and forms a cross, positioned in reference to the basket maker. Her actions of going up [*quletmun*] and going down [*acitmun*] along the vertical axes are coordinated by her actions of going left-to-right or right-to-left on the horizontal axes [*canitmun*]. She further orients the grass's motion in reference to her body as the grass is going inside toward her body [*ilutmu*n] and is going away from her body [*elatmun*]. The upward and downward and sideway folds form the loop at the center of the basket [*qukaq*]. The process is repeated along the horizontal plane, as these motions going inside/inward, and, going outward form another loop. The process is repeated six times until the beginning of the grass basket has been constructed.

Motions around the center, coupled with specialized demonstratives that aid orientation and location in reference to the speaker/weaver, reveal aspects of this generalized system. The Yup'ik language is exceedingly rich in demonstrative words that describe locating and orienting differentiating space (see Jacobson, 1984, pp. 653–662). Underlying this system is the central, bodily-situated orthogonal axis that functions as a cultural code of practical action and supports a wide range of activities from locating one's own self on the tundra or in the bays and surrounding waters, to orienting patterns and weaving the structure of a grass basket, to assisting a seamstress in measuring, cutting, and sewing clothing. In fact, even the Yup'ik counting system—base 20 and sub-base 5—uses movement across the spatially oriented four sectors of the body in relation to the axial center.

Figure 6: Mrs. Nanalook demonstrates basket weaving

The following examples are from both the Yapese and the Yup'ik context. These examples were chosen because they reveal how actions around the center (line of symmetry) contain both practical knowledge, used in making everyday products, and mathematical knowledge, applicable to teaching the foundation of mathematics. The illustration in Figure 7 shows Larry Raigetal, a Lamotrek (Yap Outer Islands) knowledge holder who lives on the main island of Yap, the state capital of fourteen widely dispersed atolls. Larry demonstrates to members of our research/study group how he transforms a coconut leaf into a "ruler." (Typically, a master canoe builder would use a pandanus leaf [personal communication, Cal Hachibmai, August 20, 2015].)

Larry first measures the desired length of the leaf by holding it between his thumb and index finger, stretching it over the top of the rest of his fingers and down the side of his hand until he reaches his wrist (proportional to his body) (Figure 8). He then constructs the tool by folding the measured leaf in half, and then he folds from one edge to the center and folds in half again. He repeats this process on the other side of the leaf and then folds each of the four segments in half again until there are eight segments in total. Master carvers use this measuring tool to build boats, and such tools are used to build traditional houses. We have observed others in the Yap Outer Islands as well as in Chuuk (also part of the Federated States of Micronesia, 1500 kilometers away from Yap, with a

Figure 7:

distinct although related language and culture) use repeated halving to create tools and build canoes and houses, and as a way to fashion loom-woven cloth. For the Yap Outer Islands, this process is well documented (Alkire, 1970).

Figure 8: Measured proportional to the hand

Dora Andrew-Ihrke similarly learned how to fold material as a young girl from her mother, Annie Andrew, a well-known seamstress. Mrs. Andrew demonstrated and explained to Dora that there are two kinds of folds: easy and difficult. Easy folds are the same as those demonstrated by Larry, using either serial or recursive half-folds, producing 2, 4, 8, and so on, number of parts. Difficult folds are odd folds that include 6 equal parts, as 6 equal parts are constructed by multiplying an odd and even number.

When Dora folds a strip of paper into three equal parts, she follows her mother's folding algorithm and principle—always use the simplest fold, the half-fold. The main difficulty we had in understanding this halving algorithm was in moving away from our habituated way of seeing three parts of the whole as thirds, when in fact Dora was consistently expressing the relationship between two parts: "Is this half equal to that half?" (See Figure 9).

Stating Mrs. Andrew's folding algorithm more formally, it is n-1, when n is an odd number. For elementary school classroom purposes, we demonstrate this process using small numbers as a model for the algorithm and managing the number of folds. Thus, with the single-digit prime numbers 3, 5, and 7 using the n-1 algorithm, the number of folds reverts to the simple half-fold. Subtracting 1 from those primes results in 2, 4, and 6 parts each, and these specific examples are achievable through the half-fold. The process is illustrated and described in Figure 9.

The halving algorithm represents movements around the center, as shown in previous examples. This algorithm provides a crucial part of Indigenous Knowledge that transfers to the teaching of

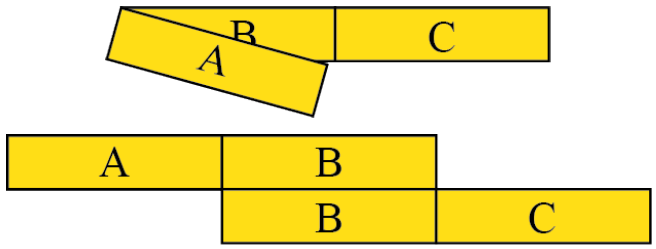

Figure 9:

school mathematics. Examples described below further develop the connection between Indigenous Knowledge and its potential in teaching rational numbers in a school context. Applying the n-1 folding algorithm to create three equal parts, we can either estimate Length A or Length C as the estimated third part. In the diagram shown in Figure 9, we estimated Length C as one-third of the whole. This leaves segment n-1, which is folded in half to create Length A and Length B. As illustrated, the halving algorithm is used twice.

When Lengths A and B were folded on top of each other, Dora treated them as a single entity and again referred to the notion: Are Lengths A and B with A folded on top of B equal to C? When we understood these actions and descriptions from her Yup'ik perspective, the centrality and the power of this halving algorithm (binary operation) became clear from within a Yup'ik cultural context. This realization opened a new and deeper understanding of how Yup'ik practical knowledge relates to fundamental aspects of numbers and relations.

The last cultural example is a variation of the halving algorithm, which both Mrs. Andrew and Dora use in their constructions. We observed other Yup'ik elders using the following algorithm, but clearly, Mrs. Andrew and Dora have refined this process at an expert level. In fact, other Yup'ik people learn from them. To find the difference between two quantities, for example Length A and Length B, Dora aligns them and then folds back the difference, Length C, so that Length A minus Length C equals Length B. (We have demonstrated this process in multiple workshops and institutes by comparing the length of Jerry's foot with that of Dora's. By finding the difference using the method shown in Figure 10, Dora eventually establishes a common unit that can measure both sets of feet.)

The difference between Length A and Length B is C. Dora uses C as the divisor. She now divides (or measures) Length A and Length B by the divisor, C. She folds until there is no remainder. In this simplified example, there is no remainder after two folds. C is now established as the common unit that can be used to measure Lengths A and B. Algebraically, B = 2C and A = 3C. This algorithm was developed in an Indigenous culture, but it is essentially Euclid's famous algorithm (https://en.wikipedia.org/wiki/Euclidean_algorithm), used to find the greatest common divisor of two numbers as well as the greatest common factor.

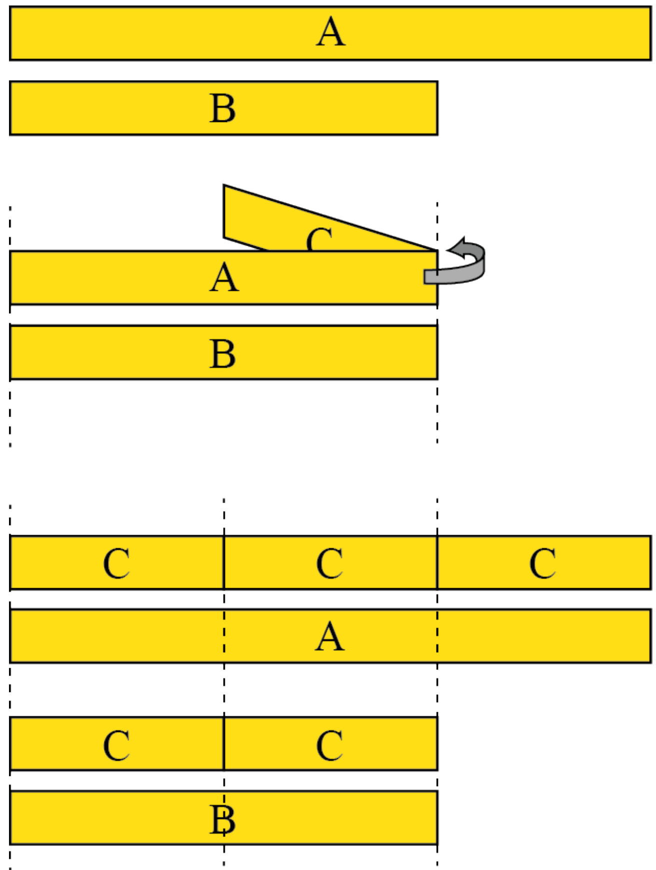

Figure 10:

Discussion: Indigenous Knowledge as a Basis for Teaching the Foundations of Mathematical Thinking

The above-described examples represent only a fraction of our data and provide evidence that in an Indigenous cultural context, measuring—as a means of comparing objects in practical activity—models the concept of ratios, expressed as rational numbers. When Dora creates a square from irregular material, or when Larry creates a measuring tool, both the square and the tool are constructed based on body measures and bodily techniques that establish ratios and proportions. The resulting products are made in proportion to the body of the person creating them. Everything is balanced between the user and the crafted product or clothing. The products and processes reflect relational thinking and relative units.

Mr. Jimmy identified the beginning of everything as a cultural code, which Mrs. Nanalook enacted while weaving her grass basket. This culturally grounded code is transferrable to the teaching of rational numbers in the elementary school. Dora's mantras are part of that cultural code: "What you do to one side you must do to the other side," and "Is this side equal to the other side?" Measuring as comparing (including body proportional measuring) reflects Lockhart's (2012) concept of measuring:

> How are we going to measure the length of two sticks? Let's suppose (for the sake of argument) that the first stick is exactly twice as long as the second stick. Does it matter how many inches or centimeters they come out to be? I certainly don't want to subject my beautiful mathematical universe to something mundane and arbitrary like that. For me, it is the proportion (that 2:1 ratio)

> that's the important thing. In other words, I'm going to measure these sticks relative to each other. (Lockhart, 2012, p.32)

We believe that it is through *measuring as comparing* that we can establish an integrative approach to teaching aspects of rational numbers. Measuring proportionally is about quantitative comparisons, comparing two or more lengths (or measurable attributes of quantities such as length, area, mass, and volume). A set of seemingly simple principles reflects the generative cultural practices and ways of thinking, which we then use to establish a mathematical starting point for developing school-based mathematics. The generative principles and processes can be expressed as:

- measuring as comparing
- relative units, ratios and rational numbers
- symmetry, halving, and verifying
- scaling

Applying Indigenous Knowledge to the Development of Rational Number Reasoning

These generative principles are the active ingredients that we have identified, and based on the knowledge of these principles and processes, we have begun the development of supplemental curriculum materials and a learning trajectory. Our work is informed by the *Measure Up* program, University of Hawaiʻi at Mānoa's Curriculum Research Development Group. The *Measure Up* program follows the experimental curriculum developed in Russia by Elkonin-Davydov (Dougherty & Simon, 2014), in which first grade students explore quantitative relationships through nonnumeric comparisons as a way to establish early algebraic reasoning including generalizing. Elkonin-Davydov's curriculum was influenced by Vygotsky's cultural-historical-activity theory (Engeström, Miettinen, & Punamäki, 1999). According to Davydov (2008), "the basic task of the school mathematics curriculum is to bring the students to the closest possible understanding of the conception of real number." Davydov goes onto to state, "the properties of quantities are discovered when a person works with real lengths, volumes, weights, time intervals, and so on (even before these are expressed in numbers)" (Davydov, 2008, p. 148). Moxhay (2008), who adapted the Elkonin-Davydov curriculum, and implemented and assessed it in the Portland School District in Maine, noted:

> All the children are exposed to the same, very high level of mathematical content, which at first view looks like high-school mathematics (use of algebraic notation, counting in bases other than 10). In particular, Davydov's curriculum has the goal of developing, in all students, a scientific, or theoretical, *concept of number,* from the very beginning of Grade 1. (Moxhay, 2008, p.2)

The developmental psychologist Sophian, at the University of Hawaiʻi at Mānoa, who collaborated with the *Measure Up* program, makes a persuasive argument for why the comparison-of-quantities approach should be considered a legitimate alternative to the "counting first approach." Sophian contrasts the concept of number and quantity as follows:

> In order to clarify the contrast between these two perspectives, the concept of *number* needs to be differentiated from that of *quantity.* In the senses most pertinent to the present discussion, *Webster's New World Dictionary* (Neufeldt & Guralnik, 1994) defines number as "a symbol or word, or a group of either of these, showing how many or which one in a series"; and quantity as … "that property of anything which can be determined by measurement." (Sophian, 2008, p. 3)

She notes an ontological difference between number and quantity by explaining that quantity is associated with physical things which can be compared in a variety of ways, while numbers are not physical things but are a mental operation (Sophian, 2008). She cites the work of Gal'perin and

Georgiev (1969), that numbers arise from the comparison of a quantity and a unit, and that different numbers occur if the unit size changes (Sophian, 2008). This approach leads to the recognition that "numerical values are essentially representations of the relation between the quantity they represent and a chosen unit" (Sophian, 2008, p. 7). The Davydov approach in some ways mirrors the cultural practices of some Indigenous People. Davydov takes measuring as comparing, as an alternative approach to establishing the foundations of mathematical thinking in a school context.

Measuring as Comparing Connects to Properties of Equality

Introduction to early algebraic thinking via the comparison of nonnumeric quantities. The measuring approach has allowed us to reverse and refine the sequence of introducing early algebraic thinking prior to the concept of number. In our approach, students compare and explore with quantities, understand, and slowly formalize algebraic operations (addition, subtraction, division, and multiplication) through the comparison of nonnumeric quantities, experimenting with length segments represented by strips. Elders' comparison of quantities lends itself directly to classroom application. Such experimentation organically leads to generating, representing, and verifying the basic algebraic properties of inequality and equality such as those noted below:

Properties of Inequality

- $quantity\ a < quantity\ b$
- $quantity\ b > quantity\ a$

Properties of Equality

- **Reflexive**: $a = a$
- **Symmetric**: $if\ a = b, then\ b = a$
- **Transitive**: $if\ a = b\ and\ b = c, then\ a = c$
- **Substitution**: $if\ a = b, then\ b\ can\ be\ substituted\ for\ a\ in\ any\ expression$
- **Commutative Property of Addition**: $a + b = b + a$
- **Associative Property of Addition and Multiplication**: $(a + b) + c = a + (b + c)$
- **Division Property**: $if\ a = b\ then\ \frac{a}{c} = \frac{b}{c}$

A Curricular Example: Halving, Comparing, and Place Value

The *Measuring Proportionally* curriculum construction process follows the lessons that we learned from working with Indigenous cultures. Measuring as comparing, the binary nature of the halving algorithm, and the concept and process of measuring by *dividing a quantity by a unit of measure* is ideally suited for modeling place value understanding. We believe that Indigenous practices that highlight halving and comparing lend themselves to modeling place value through base 2. The process of "halving," which is intuitively accessible to young students, becomes a powerful algorithm for furthering students' understanding of numbers. Research has shown that many students do not have a generalized understanding of place value systems (Venenciano & Dougherty, 2014). Recent work suggests that for students to understand a positional place value system, they need to compare base 10 to other systems (Schmittau & Morris, 2004; Slovin & Dougherty, 2004). We use measuring, halving, and properties of equality, particularly equivalence substitutions, as a way to conceptually develop this understanding. We describe this process below.

Place value example. Before engaging in these activities, students would have had ample opportunity to measure lengths by units of measures; to generate numbers from comparing a quantity and a unit of measure; and to explore through project materials many of the properties of inequality and equality enumerated above. Students are provided with an unnamed length, but for purposes of this discussion, we skip the processes involved in naming and representing quantities. We will name this example Length D. Students will be given a few different strips equal in length to Length D. They will be asked to keep Length D whole. With the other strips, through a series of recursive folds (1, 2, and 3 folds), they will create strips with 2, 4, and 8 parts. The strips will be labeled as shown in Figure 11.

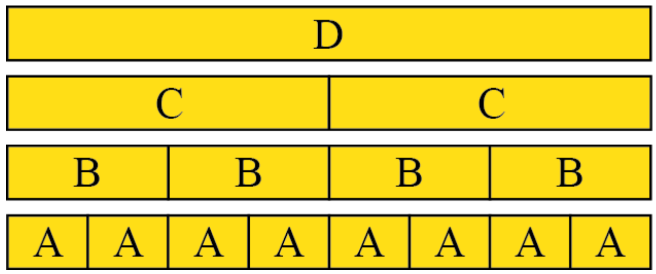

Figure 11:

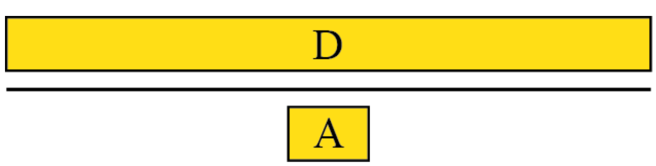
Students will generate numeric values as they measure a quantity such as Length D by a unit of measure such as Length A. After they have had a chance to explore and communicate mathematically, students will be told that they are developing a Measuring Kit (Figure 12) based, in part, on the ways that Larry and Dora create their own measuring tools. Each Measuring Kit will contain only one of each length. Students will be challenged to measure various objects simply by using these lengths.

Figure 12:

Students will create a table of values by using Length A to measure the other quantities. This method results in $\frac{D}{A} = 8$, $\frac{C}{A} = 4$, $\frac{B}{A} = 2$, and $\frac{A}{A} = 1$.



$= \frac{D}{A} = 8$ and so on

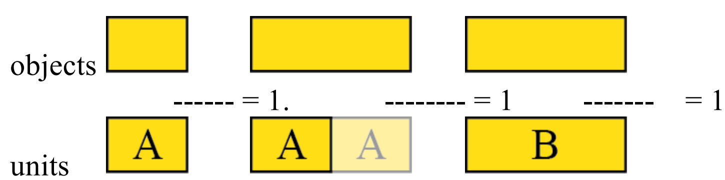
Students can either create or account for the units using a recording table as they measure the specific objects. There are only two numbers in this system: a unit of measure is used or a unit of measure is not used. Classes that have piloted these lessons have used 0 to indicate that they did not use a particular length, and they have used 1 to indicate that they did use a particular length. Some classes used “Y” for *yes* (they used a particular length) and “N” for *no* (they did not use a particular length). Each of these aspects of the activities on place value makes for interesting classroom discussions.

We challenge students to measure a set of objects. These objects are equivalent in base 10 lengths ranging from 1A to 16A. As students use their measuring kits to measure objects, they are faced with a few challenges, such as how to measure when your measuring kit has only one of each unit, and how to create a new unit of measure for your measuring kit when all of the units in the kit have been used. To facilitate solving these challenges, students receive a recording table (Table 1) and objects to be measured. For purposes of this presentation, we limited the number of objects to be measured.

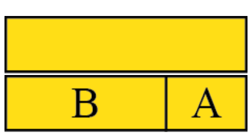
Table 1. Recording Table

Object to be measured	D	C	B	A
				1
			1	0
			1	1
		1	0	0

Length A (the length of A equals the length of the first object) is used to measure the first object one time. Students record 1 in the A column to show that one Length A was used. However, Length A is too small to measure the second object. Two Length A's would be needed to measure the second object. When students try to place 2 in the A column, they realize that there is space for one Length A and there is only one Length A in the kit. They can immediately observe that two Length A's = the second object, and that two Length A's = Length B. They can substitute two A's for Length B. Students record that they used 1 Length B and 0 Length A's. The specific measuring code for the second object is 10 (read as "one zero").



The next object is measured by (B + A) units, and thus it is recorded in the table as 11 (read as "one one").



The process continues as described above. Students measure multiple objects designed so that they continually experience the process of adding a unit, substituting the next unit from the tool kit, and moving from one place value column in a right-to-left direction.

Students continue this process until they reach a quantity that is exactly one unit longer than their entire set of measuring tools concatenated. They are then challenged to create a new unit of measure, Length E, that follows the system's exponential relationships: Length B is two times longer than

Length A; Length C is two times longer than Length B; Length D is two times longer than Length C. Now the students need to realize that Length E is twice as long as Length D. With these concrete objects and the structure of the recording table, the students are learning through measuring, building on prior knowledge related to properties of equality and equivalence substitutions. Only two numbers are allowed in each column (0 and 1), and each column to the left increases by a power of 2. In fact, this example models any positional number place value system, and may enhance understanding of base 10.

Discussion and Conclusion

This paper provides a glimpse into a long-term and continuing collaboration between Indigenous Knowledge holders—retired Yup'ik teachers who bridge Indigenous Knowledge and Western schooling—and academicians. We believe that the insights gained from everyday Indigenous activity and the ongoing intensive discussions among the Yup'ik cohort have enabled us to see how Indigenous Knowledge could have relevance for modern Western schooling. Measuring as comparing, and Dora's and Mrs. Andrew's folding algorithm, have implications for teaching aspects of the foundation of mathematics that go well beyond the scope of this paper. Our school-based curriculum development approach is attempting something not often done in academia or in the teaching of school mathematics: to use Indigenous Knowledge as a starting point for developing an approach to learning a core academic subject. Here we are building an elementary mathematics supplemental curriculum and learning trajectory from the perspective of Indigenous Knowledge. *Measuring Proportionally* is aided by insights gained from allied programs such as *Measure Up* and the work of Davydov and his colleagues. The halving algorithm and Euclidean-like way of generating the greatest common divisor are key aspects of our approach learned from Indigenous People, which distinguishes this approach from the work spearheaded by Davydov and his followers.

Yup'ik and Micronesian elders, in particular, use a process of *measuring as comparing and halving* to create tools and subunits across a wide spectrum of everyday activity. We are applying this process to our mathematical and pedagogical approach to teaching elementary school mathematics. Because the same processes are used in making the simplest of comparisons, such as direct comparisons of two quantities, to modeling place value, to comparing fractions and creating common units, our approach supports a cohesive way to teach aspects of elementary school mathematics. Similarly, our approach provides teachers with an integrative way of teaching foundations of mathematics. Measuring as comparing nonnumeric quantities establishes early notions of algebraic reasoning, and establishes relational units (as an early form of ratios). Proportional measuring and symmetrical folding are used in constructing geometrical shapes. The approach is both horizontally and vertically integrative. The same processes and halving algorithm used to compare two length quantities are also used to model and teach division of fractions, proportions, and scaling. Similarly, these cultural/mathematical principles are applied to Dora's and other elders' everyday construction of geometrical shapes and designs. Constructing a square and transforming a square into other planar shapes through symmetrical folding links the elders' knowledge to aspects of teaching geometry in school, including geometrical similarity (Lipka, Andrew-Ihrke, & Yanez, 2011). Scaling is invoked through many everyday activities within the Yup'ik culture and is taught in our program in the same fundamental ways as has been described for the comparison of quantities.

We believe that the mathematical pedagogical approach being developed by this project has potential to provide students and teachers with an elegant way to teach the foundations of mathematical thinking. This remains an empirical question.

The distance that this program has traveled—from its exploratory beginnings with elders to a more systematic collaborative study of everyday activity—continues to amaze and inspire those of us who are working in it.

ADDRESSING THE NEEDS OF THE MARGINALIZED STUDENTS IN SCHOOL MATHEMATICS: A REVIEW OF POLICIES AND REFORMS

Robert Q. Berry, III
University of Virginia
rqb3e@virginia.edu

Introduction

An examination of past research, policies, and reforms in mathematics education suggests that there have always been, and remain, tensions in conceptualizing the aims and goals of mathematics teaching and learning. These tensions have focused on addressing three concerns: (1) what mathematics students should learn; (2) how students should be taught mathematics; (3) who is qualified to teach mathematics? When examining how responses to these questions have addressed the needs of learners who are identified as marginalized (defined here as Black[1], Latin@[2], Indigenous, and poor) there is a constant pattern in which they are routinely given the least access to advanced mathematics content, the fewest opportunities to learn through methods other than memorizing facts and mimicking teacher-modeled procedures, and the least access to well-prepared mathematics teachers (Berry, Ellis, & Hughes, 2014). As a result, these learners experience the following conditions: a) reduced access to advanced mathematics courses that prepare them for higher education and improved career options; b) routine exposure to activities that focus primarily on rote, decontextualized learning through drill and practice with little to no engagement that promote reasoning and use mathematics as a tool to analyze social and economic issues, critique power dynamics, and build advocacy; and c) less access to qualified teachers of mathematics who both understand mathematics deeply and understand their students' cultural and community context deeply in order to give learners access to mathematical knowledge (Ellis, 2008; Flores, 2007; Gutiérrez, 2008; Martin, 2007). The effect of these conditions on marginalized learners' attainment in mathematics demonstrates well that such an approach constrains outcomes to a narrow range of proficiencies focused on basic skills.

While the disproportionality and conditions of marginalized learners is a cause for concern, it is important to understand that addressing the needs of these learners may not have been the primary goal of prior policies and reforms in mathematics education. Berry, Ellis, and Hughes (2014) argued that prior policies and reforms in mathematics education have failed due to having been developed to address the needs and interests of the larger dominant culture[3], not those of marginalized learners. In fact, many past policies and reforms in mathematics teaching and learning have come at the expense of the needs and interests of marginalized learners by framing policies and reforms based on economic, technological, and security interests of the dominant culture. There are statements such as "Mathematics has become a critical filter for employment and full participation in our society. We cannot afford to have the majority of our population mathematically illiterate: Equity has become an economic necessity" (NCTM, 1989, p. 4). This situates equity in mathematics education as serving economic interests of the dominant culture by situating participation as supporting the drivers of an economy. A consequence of this framing is that participation in mathematics education is based on ensuring that the dominant culture's economic, technological, and security interests are met rather than addressing the needs of learners. Examining the convergence of interests allows us to understand the motivating factors for policies and reforms that might lead to fortuitous benefits for marginalized students.

Derrick Bell, a former attorney with the National Association for the Advancement of Colored People (NAACP) during the Civil Rights Era, employed his interest-convergence principle to explain how the United States Supreme Court issued the landmark ruling in *Brown v Board of Education of*

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

Topeka, Kansas (*Brown I*) in 1954. The Supreme Court's ruling in the *Brown* case revoked the "separate but equal" doctrine, which legally sanctioned segregation in public education and all aspects of daily life. Bell (2004) argued that the *Brown* decision was not the result of America coming to terms with its democratic ideals or moral sensibilities. Rather, the Supreme Court was more interested in providing "immediate credibility to America's struggle with communist countries to win the hearts and minds of emerging third world people" than in doing what was morally right (p. 233). Thus, under the interest-convergence principle, the *Brown* decision is best understood as progress requiring the coincidence of a pressing issue, more than a commitment to justice (Donnor, 2005).

Brown provided the impetus for legislation, such as the Elementary and Secondary Education Act (ESEA) of 1965 and it reauthorizations Improving America's School Act of 1994 and No Child Left Behind Act (NCLB) of 2001 (Zion & Blanchett, 2011). These along with other legislations and mandates established requirements that address the need to ensure that all students in the United States are provided equal educational opportunities. Although not fully realized, the requirements of these legislative acts and mandates created pressure to address the historical inequity in educational opportunity, achievement, and outcomes. Zion and Blanchett (2011) argued that the reason why large scale improvement in outcomes for all students have yet to be realized is that the problem has not yet been framed appropriately. The problem must be framed as part of the history and legacy of racism, and as an issue of civil rights and social justice, viewed through a critical lens. This article use a critical lens to apply the interest-convergence principle informed largely by the work of legal scholar, Derrick Bell (1980 & 2004), to examine motivating factors of policies and reform efforts in mathematics education. Specifically, this article makes the case that policies and reforms in mathematics education were not designed to address the needs of marginalized learners; rather these policies and reforms are often designed and enacted to protect the economic, technological, and social interests of the dominant culture.

Theoretical Framework: Interest-Convergence Framework

Social institutions are set up by those in power and are organized to support and value the types of cultural and social capital held by those in power (Bourdieu & Passeron, 1990). Schools are institutions where power is controlled by the dominant culture's interests. In many schools we find values of individualism and independence, self-direction, competitiveness, decontextualized teaching, and passive methods of communication and learning (Stein, 2004). For many marginalized students, they must choose to engage using the values of the dominant culture or choose to resist becoming a part of the value set (Zion & Blanchett, 2011). Policies and reforms in education, and those particularly geared to marginalized learners, often portray these learners as deficient or in need of "fixing" to be more align with the values of the dominant culture (Stein 2004). Stein (2004) described the language of education policies as positioning marginalized people as being culturally deprived and deficiencies for marginalized learners are within their cultures, families, and communities. Consequently, policies and reforms frame marginalized students as problems to fixed through labels (i.e. Title I students; culturally deprived) then propose policies and reforms that are in the interests of those in power. That is, if marginalized students adopt the values of the dominant culture, then the economic, technological and security interest of those in power are maintained. Policies and reforms are more about the dominant culture's interest and less about needs and interests of marginalized students.

Interest-convergence is an analytical viewpoint for examining how policies and reforms are dictated by those in power to advance their political, social, and economic interests (Donnor, 2005). Bell's (1980; 2004) interest-convergence principle theorizes that any empowered group will not help any disempowered group unless it is in their best interest to do so. For Bell, the historical advancement of Black people's needs and interests is a result of being fortuitous beneficiaries of measures directed at furthering aims other than racial equity and social justice (Bell 2004). Bell states, "Even when interest-convergence results in an effective racial remedy, that remedy will be abrogated at the point that policymakers fear the remedial policy is threatening the superior societal status of Whites, particularly those in the middle and upper classes" (Bell, 2004, p. 69). Interest-convergence has its theoretical grounding in critical race theory (CRT) which draws from a broad literature in law, sociology, history, education and women's studies (DeCuir & Dixson, 2004; Ladson-Billings & Tate, 1995; Matsuda, Lawrence, Delgado, & Crenshaw, 1993; Solorzano & Yosso, 2001). Historically, its roots can be traced to legal studies. With respect to CRT's use in education, as Solorzano and Yosso (2002) explained, "critical race theory in education is a framework or set of basic insights, perspectives, methods, and pedagogy that seeks to identify, analyze, and transform those structural and cultural aspects of education that maintain subordinate and dominant racial positions in and out of the classroom" (p. 25). In education, interest convergence provides framework to discuss power dynamics as framed by systemic interests and a loss–gain binary (Milner, 2008). Interest-convergence has been used to examine policies and practices related to teacher education programs (Milner, 2008); practices for STEM education serving marginalized learners at universities (Barber, 2015); intercultural movements in multicultural education (Caraballo, 2009); inclusion and equity in special education (Zion & Blanchett, 2011); intercollegiate athletics (Donner, 2005); the development of historically Black colleges and universities (Gasman & Hilton, 2012); and postsecondary access for Latino immigrant populations (Alemán & Alemán, 2010). This body of work provides the lens for using the interest-convergence principle to examine the motivating factors for policies and reforms in mathematics education to understand whose interests are served and the resulting fortuitous beneficiaries.

Historical Perspectives in School Mathematics

In their review of the history of school mathematics, Ellis and Berry (2005) noted a tension that reforms in mathematics education focused on efficiencies with an emphasis on procedural learning coupled with a belief that mathematics beyond arithmetic should be reserved for those deemed capable of advancing to such heights. Efforts to improve mathematics education,

> …situated many learners in an a priori deficit position relative to disembodied mathematical knowledge—meaning learning mathematics was taken to be harder for certain groups of students due to their backgrounds and/or innate abilities—and failed to acknowledge the importance of mathematics for all students. (Ellis & Berry, pp. 10-11)

Throughout this history, systems of standardized assessment were developed as a means to justify the separation of students within and between schools by race, class, and ethnicity. The use of assessments to stratify was built on the assumption that a distribution of mathematical ability exists that can be fairly measured and meaningfully interpreted as the basis for separating students and providing unequal access to opportunities to learn mathematics. The conflation of this with societal beliefs about race and intelligence cannot be overlooked; the interest of those with power was preserved. This article documents some policies and reforms along the historical trajectory in mathematics education using the lens of interest-convergence to examine whose interests are served and whether there were any fortuitous benefits for marginalized students.

New Math, Sputnik, & Brown

The launch of the first artificial satellite, *Sputnik*, on October 4, 1957, by the Russians gave impetus to the drive to improve mathematics education in America. The launching of *Sputnik* brought heightened concern about America's national security as well as concern that America was lagging behind the Russians in mathematics and science. Influenced by the launch of *Sputnik*, federal funds for mathematics education became available through the National Defense Education Act (NDEA) of 1958 (Walmsley, 2003). Title V of the NDEA Act laid the groundwork for gifted programs and began the trend of using standardized testing in schools to measure competency (Walmsley, 2003). NDEA provided funds to identify "best and brightest" young scientific minds and was designed to fulfill defense interests in mathematics, science, engineering and foreign languages. The appeal to identify "best and brightest" was built on protecting national security and defense interests (Tate, 1997).

Approximately three years prior to the launching of *Sputnik*, the United States Supreme Court issued the landmark ruling in *Brown v Board of Education of Topeka, Kansas* which revoked the "separate but equal" doctrine. Black parents and community leaders sought desegregation based on the assumption that better school resources accompanied schools were White children were taught and that better resources provided greater opportunities. The *Brown* decisions occurred in the midst efforts to reform what mathematics should be taught and how it should be taught. This reform, the "new math" reform, offered teaching new mathematics content as well as new pedagogical approaches (Walmsley, 2003). One main idea of "new math" was to reduce focus on the drill and practice approach with approaches where students could develop conceptual understanding of mathematics. These pedagogical approaches included the use of manipulatives, guided-discovery learning teaching practices, and the spiral curriculum (Walmsley, 2003; Willoughby, 2000).

When we consider that many schools were still segregated and the process of desegregation was slow, and that schools serving Black children often received used textbooks handed down from schools serving white students (Snipes & Waters 2005), the reforms of "new math" did very little to address the needs of marginalized children, specifically Black children (Tate, 2000). That is, Black children did not have access to new content nor experienced the pedagogies to teaching associated with the "new math" reform. Within the interest-convergence framework, this era was characterized "benign neglect" (Tate, 2000; p. 201) for marginalized students because the needs and interest of marginalized students were largely ignored. This does not imply that these learners did not have access to quality teaching in segregated schools, in fact, there is a body of research that suggest that many teachers in segregated schools "made do" with substandard materials and provide high quality teaching (Foster, 1997; Siddle-Walker, 2000; Snipes & Waters, 2005; Standish, 2006). Rather, the "new math" reforms focused on identifying the best and brightest while ignoring the needs of marginalized students.

Great Society & Segregation

During the mid-1960s, President Lyndon Johnson had a vision for a "Great Society," which was an effort to address issues of civil rights, poverty, economic inequities, health care, housing, jobs, and education (Levitan & Taggart, 1976). Title I was enacted through the Elementary and Secondary Education Act of 1965 which allocated federal funds to schools with high concentrations of poverty in order to improve the educational opportunities of poor students (Wong & Nicotera, 2004). The Civil Rights Act of 1964 forbade job discrimination and the segregation of public accommodations; the Voting Rights Act of 1965 suspended use of literacy tests, other voter qualification tests, and stopped poll taxes; and the Civil Rights Act of 1968 banned housing discrimination and extended constitutional protections to Native Americans on reservations. These legislative acts provided greater opportunities for marginalized people but the activities of the Civil Rights movement facilitated these acts. In response to the radical protests of this period, the interest of those motivated by America's image to the world converged with the interests of the Civil Rights movement (Bell, 1980).

In 1966, the *Equality of Educational Opportunity,* commonly referred to as the Coleman Report, argued that school resources had little effect on student achievement and that student background and socioeconomic status are much more important in determining educational outcomes (Coleman, Campbell, Hobson, McPartland, Mood, & Weinfeld, 1965). The Coleman report was a challenge to President Johnson's policies on education that increased spending. One finding that received significant attention from policymakers was that peer effects had a significant impact on student achievement, meaning the background characteristics of other students influenced student achievement. This finding was interpreted to mean that marginalized children, specifically Black children, would have higher test scores if a majority of their classmates were white (Wong & Nicotera, 2004). This finding coupled with the tensions of desegregation was a catalyst for busing that occurred in many places in the United States. Busing was an effort to desegregate schools and marginalized children were more likely to be bused than white children. Thus, many marginalized children were displaced from their neighborhoods (Doughty, 1978). Busing was a policy sought to "fix" marginalized students because it existed primarily to assist these students by allowing them entrance to perceived superior schools that served white students; thus allowing marginalized students to receive the benefits of peer effect as described in the Coleman report. By displacing marginalized students from their communities, it positioned these students' communities as problem centers rather than as resources. In an effort to desegregate schools busing and peer effect policies served the interests of those who had power to make decisions about which children will be displaced from their home communities. Further, these policies assumed that immersion into schools serving white students will help marginalized students with better achievement and reap values that served the interests of those in power.

While busing sought to desegregate at the school-level, we must consider what happened at the classroom-level. In schools where significant numbers of marginalized children were bused, these children experienced resegregation for their mathematics instruction. In fact 70% of school districts had racially identifiable classrooms as a result of resegregation (Doughty, 1978). That is, because of the development of and placement in low-level mathematics courses, marginalized children were placed in mathematics classrooms that denied them access to high-level mathematics content and these students were in segregated classroom within integrated schools. Not only were students resegregated for mathematics instruction but a disproportionate number of marginalized students were placed in special education programs. Doughty (1978) estimated that 91% of Black children in special education programs during this period were incorrectly assigned on the basis of low expectations and inaccuracies in IQ scores. The misuse of a standardize test had negative consequences for many marginalized students. Michelson (2001) argued that resegregation in classrooms through tracking undermined any potential benefits of school-level desegregation. Given the consequences of resegregation at the classroom-level, it is plausible to consider that desegregation as policy for reform was a facade to hide the interests of those who wanted to maintain segregation but appease the interests who fought for desegregation.

Schools are as segregated today as they were in the 1960s and 1970s, and many schools are rapidly resegregating (Garda, 2011). In 2014, the percentage of public school students who were considered to be part of a racial or ethnic minority group was greater that the percentage of students considered being white (Hussar & Bailey, 2013). Yet, white children are the most racially isolated group of students in the United States; they have little contact with students from other ethnic groups. Nearly half of white students attend schools that are more than 90% white and approximately one-third of white students attend schools that are more than 95% white (Garda, 2011). These statistics suggest that *Brown* did not permanently integrate schools in the long-run; in fact the intended goal of racial balance and desegregation of *Brown* has not been realized.

“Back to Basics”

In the late 1960s and early 1970s, the “back to basics” reform movement in mathematics emerged in response to the perceived shortcomings of “new math” (Burrill, 2001). During this period, the National Science Foundation discontinued funding programs focused on “new math,” and there was a call to go back to the “core curriculum” which was understood to be basic skills in mathematics. The “back to basics” movement called for teaching basic mathematics procedures and skills and was closely connected to the minimum competency testing movement used extensively by states in the 1970s and 1980s (Resnick, 1980; Tate, 2000). Testing had a significant impact on the mathematics content that was taught and the methods used to teach mathematics. Typically, students were taught mathematics content deemed important for passing tests. Although the emphasis on skills did result in slightly improved standardized test scores for marginalized children, it did not adequately prepare these students for mathematics coursework requiring higher levels of cognition and understanding (Tate, 2000). Thus, marginalized students were underrepresented in the upper achievement distribution and in upper-level mathematics courses (Tate, 2000).

Considering the impact of desegregation and resegregation at the classroom-level coupled with an emphasis on testing, it plausible that the pedagogies and the curriculum offerings during the “back to basics” reform were similar for marginalized students during the “new math” reform. The pedagogies of “back to basic” were already apart of marginalized students’ mathematical experiences. The growing emphasis on testing during this period was used to legitimize the perception that many marginalized students are not capable of rigorous studies in mathematics (Perry 2003). The “back to basics” movement provided more focus of using achievement tests to pathologize marginalized students as being inferior, deficit and deviant. We find the first of many research studies focusing on the achievement gap in mathematics during this period describing marginalized students as deficient and in need of fixing (Perry, 2003). The analysis of achievement gap language advantaged the values of the dominant culture and ignored the ongoing experiences resegregation of marginalized students. If one considers the context of the late 1960s and 1970s and the persistent limited educational opportunities available to marginalized children, discussion of an achievement gap serves to reinforce an ideology about marginalized children’s intellectual inferiority. The focus on testing served the interest of those who focused on efficiency and stratifying learners to identify the “cognitive elite” (Hernstein & Murray, 1994) to protect the interest of those with power.

Increased Enrollments in Upper-Level Mathematics Courses

In 1983, the National Commission on Excellence in Education issued a report titled, *A Nation at Risk: The Imperative for Educational Reform*. The report suggested that education reform is necessary because competitors throughout the world are overtaking America’s preeminence in commerce, industry, science, and technology. Furthermore, the report stated, “If an unfriendly foreign power had attempted to impose on America the mediocre educational performance that exists today, we might well have viewed it as an act of war” (p. 1). The inflammatory rhetoric of *A Nation at Risk* heightened concerns about national security and America was lagging in mathematics and science when compared internationally. *A Nation at Risk* stated that through educational reform, American children’s promise of economic, social, and political security in the future would be earned by meritocratic ideals of effort, competence, and informed judgment.

As a reaction to *A Nation at Risk* Many states placed Algebra I as a high school graduation requirement. Between 1982 and 1992, students enrolled in Algebra I increased from 65 to 89 percent, in Algebra II from 35 to 62 percent, and in calculus from 5 to 11 percent (Raizen, McLead, & Rowe, 1997). Planty, Provasnik, and Daniel (2007) reported that the percentage of graduates who completed a semester or more of Algebra II rose from 40 percent in 1982 to 67 percent in 2004. This evidence suggests that the average number of mathematics courses at or above Algebra I taken by high school students has increased. The increased focus on maximizing students' performance on standardized tests has led schools to rethink course-taking patterns (Kelly, 2009). While there were increases in the enrollments rates of all students, the enrollment rates for marginalized students in higher-level mathematics courses was still relatively low (Jetter, 1993). Black students to be more likely to be enrolled in Algebra I and geometry but less likely enrolled in higher-level courses (Jetter, 1993). In the early 1990s, Bob Moses, a leader in the civil rights movement, argued that access to algebra is the "new" civil rights (Jetter, 1993). Moses contended that algebra served as a curricular gatekeeper tracking numerous students out of many in-school and out-of-school opportunities. Within an interest-convergence framework, Algebra I as a graduation requirement was to improve America's standing on internationally comparisons which lead to increase enrollments in for some marginalized students in high-level mathematics courses. These increased enrollments supported the economic, social, and political interests of those in power.

The increased enrollment in the upper-level mathematics courses did not influence instructional methodologies to meet the increase in the diverse learning needs of children (Porter, Kirst, Osthoff, Smithson, & Schneider, 1993). That is, for marginalized learners, instruction focused primarily on the acquisition of skills. Additionally, much of the increase in mathematics course enrollment occurred by simply placing students in Algebra I tracks. When the increased enrollment in mathematics courses seemed an insufficient means for increasing student achievement, policymakers and reformers began to investigate notions of systemic reform within the larger education system (Raizen, McLead, & Rowe, 1997). In the fall of 1989, President George H. W. Bush, the nation's governors, and other leaders held an educational summit in Charlottesville, Virginia. One result of this meeting was a call for national standards. Participants at the 1989 National Education Summit made a commitment to make U.S. students first in the world in mathematics and science by the year 2000.

Standards Movement

In 1980, NCTM put forth its *Agenda for Action*, which diverged from "back to basics." The *Agenda for Action* put forward recommendations that broadens the notion of basic skills as the acquisition of skills toward focusing on problem solving, use of technology, called for measures other than conventional testing, and an effort to meet students' diverse ne advocated for pedagogy and curriculum to accommodate the diverse needs of the student population. While the *Agenda for Action* was not a standards document, it was the foundation for the first standards document, *Curriculum and Evaluation Standards for School Mathematics* (*CSSM*), developed by NCTM (1989).

CSSM provided broad frameworks for mathematics content and processes across grade bands. Emphasis was placed on an inquiry-based approach to mathematics teaching and learning. The inquiry-based approach supported conceptual understanding as a primary goal and algorithmic fluency would follow once conceptual understanding was developed. Critics of *CSSM* argued that the primary goal of conceptual understanding through an inquiry-based approach did not help children acquire basic skills efficiently nor learn standard algorithms and formulas (Klein, 2003). *CSSM's* release came at a time when there were calls for national mathematics standards and it received support from the U.S. Department of Education and the National Science Foundation (NSF). Through the 1990s, NSF supported the creation and development of commercial mathematics curricula aligned to the standards in *CSSM.* Critics of the curricula objected to the inquiry-based approaches, claiming that not enough emphasis was placed on acquisition of basic skills and general mathematics principles (Klein, 2003). Tension between proponents and opponents of *CSSM* resulted in the "Math Wars." There were proponents for improving mathematics instruction for marginalized children on both sides of the "Math Wars." The primary tensions focus on mathematics content, pedagogical approaches, and student achievement, with both sides agreeing that reform is necessary for America's economic, technological, and security interests.

There is a long history indicating that during times of reform, the interests and needs of marginalized children are in many ways dismissed. The tensions of the "Math Wars" appear to have an underlying narrative focusing on the nation's technological interests, social efficiency, and perpetuation of privilege. There are intense debates focusing on curriculum, teaching, and assessment but little debate focusing on understanding the realities of children's lives. For marginalized learners, issues of race, racism, identity, and conditions were not under consideration in the "Math Wars." There is evidence from the *CSSM* to suggest that the standards were moving towards a democratic vision by including "for all" language. However, critics of the "for all" language argue that the use does not delve into serious considerations of the social and structural realities faced by Black children; rather the language suggests a myopic focus on modifying curricula, classrooms, and school cultures (Martin, 2003). Consequently, the underpinning of the "for all" message has done little to understand the variables that impact mathematics teaching and learning for marginalized learners.

The *CSSM* outlined four social goals for schools: (a) mathematically literate workers, (b) lifelong learning, (c) opportunity for all, and (d) informed electorate. These four goals derived from the fact that at the time society was moving towards an increase in technologies. These goals situated social justice issues in school mathematics within the framework of economic competition and national technological interests. Positioning social justice in mathematics education within the framework of economic competition and national technological interests situates mathematics education as being primarily utilitarian. Using the utilitarian perspective situates, increasing marginalized learner's participation in mathematics education is based on ensuring the economic and social interests of those with power. Consequently, the interests of marginal learners' needs are not given careful consideration; it was the interests of the broader American contexts that drove the implementation of standards. Within this context, mathematics is always situated as a utilitarian area of study, and the focus of mathematics education is on the needs of national interests rather than the needs of a democratic society.

NCTM revised it standards document in 2000 through the release of the *Principles and Standards for School Mathematics* (*PSSM*). The *PSSM* revision provided slightly greater emphasis on the importance of algorithms and computational fluency. *PSSM* was received as more balanced than *CSSM*, which led to some calming of but not an ending to the "Math Wars." *PSSM* highlighted equity as one of its six principles for school mathematics by stating that equity requires: (a) high expectations and worthwhile opportunities, (b) accommodating differences to help everyone learn mathematics, and (c) resources and support for all classrooms and all students. These points situate equity in a broad context but fail to recognize issues of social justice or understanding social, economic, and political context in which mathematics is learned. Martin (2003) is critical of *PSSM's* Equity Principle for not providing a sense of equity that considers the contexts of students' lives, identities of students, and conditions under which mathematics is taught and learned. He states:

> …the Equity Principle of the *Standards* contains no explicit or particular references to African American, Latino, Native American, and poor students or the conditions they face in their lives outside of school, including the inequitable arrangements of mathematical opportunities in these out of school contexts. I would argue that blanket statements about *all* students signals an uneasiness or unwillingness to grapple with the complexities and particularities of race, minority/marginalized status, differential treatment, underachievement in deference to the assumption that teaching, curriculum, learning, and assessment are all that matter. (p. 10)

Too often, race, racism, social justice, contexts, identities, conditions, and others are relegated as issues not appropriate for mathematics education when in fact these issues are central to the learning and teaching of mathematics for marginalized students.

No Child Left Behind & Common Core

In 2002, President George W. Bush signed the Elementary and Secondary Education Act better known as the No Child Left Behind Act (NCLB) into law with the declared intention of helping "all students meet high academic standards" (NCLB, 2002). NCLB required states to implement student testing, collect and disseminate subgroup results, ensure teachers are highly qualified, and guarantee that all students achieve academic proficiency by 2014. States were required to use sanctions to hold schools and districts accountable for their success in meeting adequate yearly progress (AYP) goals, set by the states, for both overall performance and performance in each subgroup. Similar to previous reforms, NCLB motives are cast in the interests of improving America's standing international measures and the interests of the future of the dominant culture maintaining power. NCLB narrows the definition of achievement, thus focusing on measureable outcomes and applying technical solutions, such as setting Standards and using tests to measure attainment of the standards. NCLB stated a desire to close the "achievement gap between high- and low-performing children, especially the achievement gap between minority and non-minority students and between disadvantaged children and their more advantaged peers" (NCLB, 2002; Sec 1001). To achieve these goals NCLB takes a position in instruction and measurement by insisting that instructional approaches be deemed based on "scientifically based research" (Stein, 2004). However, it is not clear in NCLB what constituted "scientifically based research." Given the language of measurement focused on closing the achievement gap and the language of standards, it is plausible that "scientifically based research" instructional approaches are approaches that can be measured and quantified. Through standards and assessment there are restrictions in the autonomy of teachers. Consequently, teachers are restricted in the ways to meet the needs and interest of students. NCLB assumed that members within a subgroup have static identities that are quantifiable in term of race, class, gender, language, etc. (Gutierrez, 2008).

NCLB unintentionally create incentives that encourages states to lower their academic standards, promote school segregation and the push out of poor and minority students, and reinforces the unequal distribution of good teachers (Ryan, 2004). The category of "failing school" was based on whether or not schools met a set of performance standards drafted by the states which were grounded in test-based measures of academic proficiency, states had incentives to lower their standards so that fewer schools are identified as failing (Ryan, 2004). Stein (2004) found that many states lowered performance standards rather than raised standards. To improve the chances that a particular school or schools within a district make AYP, administrators have an incentive to minimize the numbers of marginalized students. Since marginalized students traditionally do not perform as well as white and more affluent peers on standardized tests, the incentives to exclude these students are grounded on improving status (Ryan, 2004). Attaching consequences to test results creates incentives for teachers to avoid schools that are likely to not meet AYP. Thus, teaching will be less attractive in those schools where teachers must spend a great deal of time preparing for the tests.

In mathematics education, it is likely that marginalized students' needs and interests were served minimally by NCLB. As with previous reforms, these students most likely experienced mathematics as procedural and rote. This time of instruction appears to be consistent across all reforms. Similar to other reforms, the emphasis on testing was used to legitimize negative perception about marginalized students' capabilities in mathematics. As noted earlier, under NCLB schools serving predominately marginalized students were likely to be deemed as failing, have the least access to good teachers, and were stigmatized. The emphasis on testing does not recognize the external factors that contribute to testing results which could lead to a labeling that impacts the quality of mathematics that students experience. For students, in schools or subgroups labeled as failing the experience is focused on increasing test scores and for students in schools or subgroups that consistently meet AYP the experience may be more enriching.

When considering an interest-convergence perspective, we must consider whose interests are served under NCLB. If we consider one context in which NCLB was developed, there was public pressure on legislatures for competition in public schools through school choice and vouchers. These pressures lead to increase in public options for schooling, including the increase in charter schools. The interests of proponents of school choice were served. A consequence of NCLB has been the narrowing of the conception of what constitutes a ―good school. Judging schools simply based on standardized test scores had implications beyond the schools themselves. In a study examining property values and schools designated as failing because of NCLB, Bogin and Nguyen-Hoang (2014) found that the "failing" designations significantly decrease home prices and that low and moderate income neighborhoods were negatively impacted. Public schools are primarily funded through property taxes in most areas. This means that in neighborhoods with higher property values, the schools in that area get more resources. Similar to the peer finding of the Coleman report, proponents of school choice supported giving students options to be in "good" schools with the idea that placement in "good" schools would have positive effects. This conclusion ignores the external factors that contribute to failing schools.

A factor that contributed to the creation of the Common Core State Standards (CCSS) was the "known-yet-unacknowledged failure of No Child Left Behind" (Schneider, 2015; p. 20). One complication of NCLB was the lack of consistency among states and what constituted AYP. As a result there was agreement among the Council of Chief State School Officers (CCSSO) that consistent standards were necessary. In 2010 the *Common Core State Standards for Mathematics* (CCSSM) were released by the National Governors' Association and CCSSO. The mission statement for the Common Core makes clear these reforms are emerging from the same interests of college and career readiness by positioning American students to be able to compete in a global economy (National Governors Association Center for Best Practices and Council of Chief State School Officers, 2010)

Nowhere to be found is mention of the gross inequities within society that continue to be reflected in students' educational outcomes. Framing the reform from the position of economic interest, diminishes the needs of learners to focus primarily on the acquisition of mathematics content and practices.

Conclusion

The interest convergence principle provides an intellectual and political frame within which to question the motivating factors of policies and reforms in mathematics education to understand how they are designed to address the needs of marginalized learners. Employing the interest-convergence principles, I raise the following questions: (1) Whose interests are served by policies and reforms in mathematics education? (2) Where are opportunities for convergence?

Whose interests are benefited by policies and reforms in mathematics education? The review of policies and reforms suggest that economic, technological and security interests were the drivers of many policies and reforms. It is difficult to argue against ensuring students' competitive place in the global marketplace. However, a careful look at policies and reforms focused on labeling and identifying the "best and brightest," identifying high achievers, stratifying students based on characteristics, or identifying "failing" schools. Such labeling and identifying determines groups or populations as having merit and others as being deficit. Policies and reforms have typically not attended to or appreciated the social realities and needs of marginalized students in ways that lead to improvements in their life circumstances. This critique suggests that marginalized students voices and experiences within a broader context are either missing or are situated within deficit perspectives in mathematics education research, policy, and reform. In fact, patterns over time suggest that marginalized students have experienced mathematics instruction as a focusing on the acquisition of facts over the entire history discussed in this article. Thus, policies and reform have had little to no impact on the type of instruction these children receive.

Where are opportunities for convergence? The stage is set for convergence to occur, given the growing body of research focused on context, identities and conditions and the interests of practices and process in mathematics teaching and learning. There is a growing body of research that positions marginalized students (Berry, 2008; Boaler, 2014; Jett, 2011; Gutiérrez, 2010; Martin, 2000; Noble 2011; Stinson, 2010; Thompson & Lewis, 2005, Walker, 2006). This body of research considers issues of race, racism, contexts, identities, and conditions as variables that impact the mathematical experiences of marginalized. This body of research challenges the dominant discourse and pushes the field of mathematics education to consider sociological, anthropological, and critical theories. It encourages researchers to consider outcomes other than achievement as the primary measure of success. One finding that we find from this research is that educators must create opportunities for students to experience mathematics learning using the resources they bring to classrooms; teachers must know and understand learners' identities, histories, experiences, and cultural contexts and consider how to use these to connect students meaningfully with mathematics. There is a need of policies and reforms that focus on leveraging communities and community-members. Mathematics teaching and learning not only occurs in classrooms but also occurs in other spaces. By leveraging these resources, we situate mathematics teaching and learning as a way to structure experiences that are contextual and provide opportunities for exchange in mathematical ideas. The use of context in mathematics education can help learners to recognize and build upon the cultural and social resources they bring to the mathematics classroom.

Endnotes

[1]I use the term Black to acknowledge the Black Diaspora and to highlight that Black people living in North America have ancestry dispersed around the world. Black learners who attend schools and live in North America are racialized in similar ways regardless of country of origin.

[2]I borrow Latin@ from Rochelle Gutiérrez (2013) who stated that the use of the "@ sign to indicate both an "a" and "o" ending (Latina and Latino). The presence of both an "a" and "o" ending decenters the patriarchal nature of the Spanish language where is it customary for groups of males (Latinos) and females (Latinas) to be written in the form that denotes only males (Latinos). The term is written Latin@ with the "a" and "o" intertwined, as opposed to Latina/Latino, to show a sign of solidarity with individuals who identify as lesbian, gay, bisexual, transgender, questioning, and queer (LGBTQ)" (p. 7).

[3]A dominant culture is one that is able, through economic or political power, to impose its values, language, and ways of behaving. This is often achieved through oppression and political suppression of other sets of values and patterns of behavior.

DESIGNING FORMATIVE ASSESSMENT LESSONS FOR CONCEPT DEVELOPMENT AND PROBLEM SOLVING

Malcolm Swan
University of Nottingham
malcolm.swan@nottingham.ac.uk

Formative assessment is the process by which teachers and students gather evidence of learning and then use this to adapt the way they teach and learn. I describe a design research project in which we integrated formative assessment strategies into lesson materials that focus on developing students' conceptual understanding and their capacity to tackle non-routine problems. A theoretical framework for assessment task design is presented, together with an analysis of research-based principles for formative assessment lesson design. Particular aspects are highlighted: the roles of pre-assessment, formative feedback questions and sample work for students to critique. While there are some early signs that these lessons provide an effective model for teachers to introduce formative assessment into everyday classroom practice, the materials require a radical shift in the predominant culture within most classrooms.

Keywords: Assessment and Evaluation; Design Experiments

Introduction

There is little doubt that assessment has a profound impact on the nature of student learning, and that this is often detrimental in nature. Our assessment practices have the potential to convey our valued learning goals to students, but this is often unrealized because the tasks and methods we use do not reflect these values. It has been found, for example, that even when teachers clearly acknowledge the importance of eliciting students' understanding and of giving useful, qualitative feedback, the tests they use encourage 'rote and superficial learning' and appear more concerned with grading and record keeping than with developing learning (Black & Wiliam, 1998). The poor design of summative, high-stakes tests must take some of the blame for this. These are designed to be cheap, predictable and simple to grade and, in consequence, focus on fragments of mathematical performance. Policy makers tend to ignore their powerful backwash effect and continue to claim that tests are merely measuring instruments (ISDDE, 2012).

Assessment needn't be this way. High quality assessment, focused on important mathematics, can be a powerful lever for positive change. This requires a radical shift away from multiple choice, computer-based assessments of procedural knowledge toward assessments that focus on the mathematics we care about - understanding, reasoning and problem solving. More substantial assessment tasks are required and scoring must begin to assess the quality of students' extended reasoning. (This is possible even in high stakes assessment when human judgment, rather than machine scoring, is allowed to have a role. Point scoring rubrics of chains of reasoning, long established in other subjects, can give reliable scores on mathematics tests. Reliable qualitative methods, such as adaptive comparative judgment, are also now recognized as a possible way forward (Jones, Pollitt, & Swan, 2015). Further, when teachers are involved in scoring, suitably organized, it can have considerable value for professional development.)

In this paper, however, I have insufficient space for a thorough discussion of high stakes assessment. Instead I wish to focus on the potential of classroom assessment to produce significant and substantial student learning gains. This potential was brought to our attention by the research reviews of Black, Wiliam and others (Black, Harrison, Lee, Marshall, & Wiliam, 2003; Black & Wiliam, 1998; Black & Wiliam, 1999). In their original definition, the term 'formative assessment' is taken to include:

> … all those activities undertaken by teachers, and by their students in assessing themselves, which provide information to be used as feedback to modify the teaching and learning activities in which they are engaged. Such assessment becomes 'formative assessment' when the evidence is actually used to adapt the teaching work to meet the needs. (Black & Wiliam, 1998, p. 140)

This definition is wide-ranging, and includes both pre-planned and incidental assessment activities, such as diagnostic tests, oral questioning, collaborative tasks and observation of students. Improving the nature and focus of teacher-student and student-student communication is central. Most importantly, however, it must lead to adaptive action, not just the reteaching of the material concerned.

Since their work was published, this definition has often been mutated to mean more frequent testing, scoring and record keeping. In the UK, for example, one government initiative, "Assessing Pupil Progress" (APP) degenerated into the atomized profiling of pupils. This involved teachers in monitoring work, keeping files on pupils and regularly assessing progress against detailed criteria. Teacher workload was significantly increased and many teachers did not use the feedback to improve instruction. Recognizing such mutations, Black and Wiliam refined their definition a little differently in a later paper, laying more emphasis on the *agents* in the process: teachers, learners and peers, and the requirement for each of these agents to make *effective use* of the evidence obtained:

> Practice in a classroom is formative to the extent that evidence about student achievement is elicited, interpreted, and used by teachers, learners, or their peers, to make decisions about the next steps in instruction that are likely to be better, or better founded, than the decisions they would have taken in the absence of the evidence that was elicited. (Black & Wiliam, 2009, p. 9)

The interaction between these agents and the three main aspects of formative assessment: identifying where learners are in their learning, where they are going, and how to bridge the gap have been clearly articulated by Wiliam, and Thompson (2007), see Table 1. Within the matrix formed, are their five "key strategies" of formative assessment.

Table 1: Key Strategies of Formative Assessment

	Where the learner is going	**Where the learner is right now**	**How to get there**
Teacher	1. Clarifying learning intentions and criteria for success	2. Engineering effective class-room discussions and other learning tasks that elicit evidence of student understanding	3. Providing feedback that moves learners forward
Peer	Understanding and sharing learning intentions and criteria for success	4. Activating students as instructional resources for one another	
Learner	Understanding and sharing learning intentions and criteria for success	5. Activating students as the owners of their own learning	

Black and Wiliam launched programs of work that aimed at engaging teachers in these key strategies, but found that regular meetings over a period of years were needed to enable a substantial proportion of teachers to acquire the "adaptive expertise" (Hatano & Inagaki, 1986) needed for self-directed formative assessment. This is clearly an approach that is challenging to implement on a large scale.

The Mathematics Assessment Project

In 2009, the Bill & Melinda Gates Foundation approached us at Nottingham to develop a suite of "formative assessment lessons" to form a key element in the Foundation's program for "College and Career Ready Mathematics" based on the Common Core State Standards for Mathematics (NGA & CCSSO, 2010). In response, the Mathematics Assessment Project (MAP) was designed to explore how far well-designed teaching materials can enable teachers to make high-quality formative assessment an integral part of the implemented curriculum in their classrooms, even where linked professional development support is limited or non-existent. The lessons are thus designed, not only to provide teachers with diagnostic information, but to enable them use it to move each student's reasoning forward.

To date, we have designed and developed about a hundred formative assessment lessons to support US Middle and High Schools in implementing the new Common Core State Standards for Mathematics (CCSSM). Each lesson consists of student resources and an extensive teacher guide. The data we have does appear to support the assertion that these lessons have enabled teachers to integrate the key strategies for formative assessment, as identified in Table 1, into their normal teaching. The research-based design of these lessons, now called Classroom Challenges, forms the focus of this paper.

A Design-Based Methodology

Our methodology for lesson design was based on design research principles, involving theory-driven iterative cycles of design, enactment, analysis and redesign (Barab & Squire, 2004; Bereiter, 2002; Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003; DBRC, 2003; Kelly, 2003; van den Akker, Graveemeijer, McKenney, & Nieveen, 2006). In contrast with much design research, we worked to ensure that the products were robust in large-scale use by fairly typical end-users. This is, in fact why some prefer the term "engineering research" to design research (Burkhardt, 2006). Each lesson was developed, through two iterative design cycles, with each lesson trialed in three or four US classrooms between each revision. This sample size enabled us to obtain rich, detailed feedback, while also allowing us to distinguish general implementation issues from more idiosyncratic variations by individual teachers. As we were designing at a distance, revisions had to be based on structured, detailed feedback from experienced local observers in California, Rhode Island and the Midwest. We obtained approximately 700 observer reports of lessons, from over 100 teachers (over 50 schools) using these materials. We also observed many of the lessons first-hand, in UK schools.

In order for feedback to be useful in the revision process it had to be specific and reliable, based on a *detailed description* of what happed in each lesson. To meet this challenge, a protocol was developed. Two design questions permeated the protocol: How well did the materials communicate the formative assessment strategies to the teacher? How far was the learning experience profitable for students? The protocol was in three parts. The first part was descriptive, asking for the context, the nature of the students, the environment, the support given to the teacher, followed by a vivid description of the course of the lesson, illustrated by a sample of student work of varied quality. Significant events that might inform the designer were noted. The second part was analytical. Observers were asked for: their overall impressions; deviations from the lesson plan; quality of teacher questioning; quality of student reasoning, explanations, discussion and written work. They were also asked to provide evidence of learning. They were specifically asked about the relevance of the formative assessment opportunities. The third part sought the teacher's views, through an interview after the lesson. Teachers were asked about their lesson preparation, their views on the lesson plan, the lesson and the response of students, and implications for professional development. In developing 100 Classroom Challenges over the course of the project, about 700 such reports were obtained and discussed by the design team. This process enabled us to obtain rich, detailed feedback, while also allowing us to distinguish general implementation issues from idiosyncratic variations by individual teachers. On this basis the lessons themselves were revised, and ultimately published on the web: http://map.mathshell.org.uk/materials/index.php.

Theoretical Framework for Assessment Task Design

Our first priority was to clarify the learning intentions for *Classroom Challenges*. The CCSSM make it clear that the goals of the new curriculum are to foster a deeper, connected conceptual understanding of mathematics, along with the strategic skills necessary to tackle non-routine problems. A particular emphasis is the development of mathematical *practices* that should permeate all mathematical activity. We rapidly found it necessary to distinguish between tasks that are designed to foster conceptual development from those that are designed to develop problem-solving strategies. In the former, the focus of student activity is on the analysis and discussion of different *interpretations* of mathematical ideas, while in the latter the focus is on discussing and comparing alternative *approaches* to problems.

The intention was that concept lessons might be used partway through the teaching of a particular topic, providing the teacher with opportunities to assess students' understanding and time to respond adaptively. Problem solving lessons were designed to be used more flexibly, for example between topics, to assess how well students could select already familiar mathematical techniques to tackle unfamiliar, non-routine problems and thus provide a means for improving their strategic thinking.

The validity of any assessment scheme lies in the design of the tasks, which should reflect the intentions of the curriculum in a balanced way. We therefore begin by describing our task design framework. This is followed by a review of the research we used to design the formative assessment lesson structures within which the tasks are embedded.

(i) Assessment Task Genres for Concept Development

The tasks we selected for concept *Classroom Challenges* were designed to foster collaborative sense-making. Sierpinska (1994) suggests that people feel they have understood something when they have achieved a sense of order and harmony, where there is a sense of a 'unifying thought', of simplification, of seeing an underlying structure and that in some sense, feeling that the essence of an idea has been captured. She lists four mental operations involved in understanding: "identification: we can bring the concept to the foreground of attention, name and describe it; discrimination: we can see similarities and differences between this concept and others; generalisation: we can see general properties of the concept in particular cases of it; synthesis: we can perceive a unifying principle." To this, we would add the notions of representation. When we understand something, we are able to represent it in a variety of ways: verbally, visually, and/or symbolically. In the light of this, we developed four 'genres' of tasks for our concept development lessons (Table 2).

Space dictates that we only provide a few examples. For *Classify and define,* students were typically invited to sort a collection of cards showing mathematical objects using their own, or given criteria. The results of their sorting were then offered to other students, who would reconstruct the criteria that had been used. The objects ranged from geometric shapes to algebraic functions. As Zaslavsky (2008) has shown, this is a powerful way of enumerating properties of mathematical objects. Occasionally, students were presented with a mathematical object and were invited to list as many of its properties as possible. The task then became: "do any of these properties, taken individually, *define* the object?" or "do any *pairs* of these properties define the object?" (Figure 1). This resulted in a search for justifications and counterexamples. (This could be very demanding. For example, consider the pair of statements: "When $x = 0$, $y = 0$"; "When x doubles in value, y doubles in value". Do these statements *define* proportion? If not, then find a function that satisfies these statements but is not a proportion). Seeking definitions in this way lies at the very heart of mathematical activity (Lakatos, 1976).

Table 2: Assessment Task Genres for Concept Development

Assessment task genres	**Sample classroom activities.**
Classify and define mathematical objects and structures.	Identifying and describing attributes and sorting objects accordingly. Creating and identifying examples and non-examples. Creating and testing definitions.
Represent and translate between mathematical concepts and their representations.	Interpreting a range of representations including diagrams, graphs, and formulae. Translating between representations and studying the co-variation between representations.
Justify and/or prove mathematical conjectures, procedures and connections.	Making and testing mathematical conjectures and procedures. Identifying examples that support or refute a conjecture. Creating arguments that explain why conjectures and procedures may or may not be valid.
Identify and analyze structure within situations	Studying and modifying mathematical situations. Exploring relationships between variables. Comparing and relating mathematical structures.

Mathematical object	*A square*	*A proportional relationship exists between two continuous variables x and y.*
Properties	Four equal sides Two equal diagonals Four right angles Two pairs of parallel sides Four lines of symmetry ….	The graph of y against x is linear. $y \div x$ always gives the same result. When $x = 0$, $y = 0$ When x doubles in value, y doubles in value When x increases by equal steps then so does y ….

Figure 1: Observe, Classify and define: Listing properties and building definitions

For *represent and translate,* we developed activities that require students to translate between numerical, verbal, graphical, algebraic and other representations. Typically, groups of students were given collections of cards that they were asked to sort according to whether or not the cards convey equivalent representations. Common misinterpretations were foregrounded by including translations that are commonly confused. For example, students were given a collection of four money cards ($100; $150; $160; $200) and a collection of ten 'arrow' cards showing percentage increase and decrease (e.g. "up by 25%"; "down by 25%). They were asked to place the money cards in a square formation and place the percentage cards between them in appropriate places (Figure 2 shows just one side of the 'square'). Typically, students considered "up by 25%" and "down by 25%" to be inverse statements and placed them together between the money cards $160 and $200. Subsequently, the teacher introduced further arrow cards showing "decimal multipliers" (e.g. x 1.25; x 0.8). As students place these, they checked both with a calculator and by relating them to the percentage cards

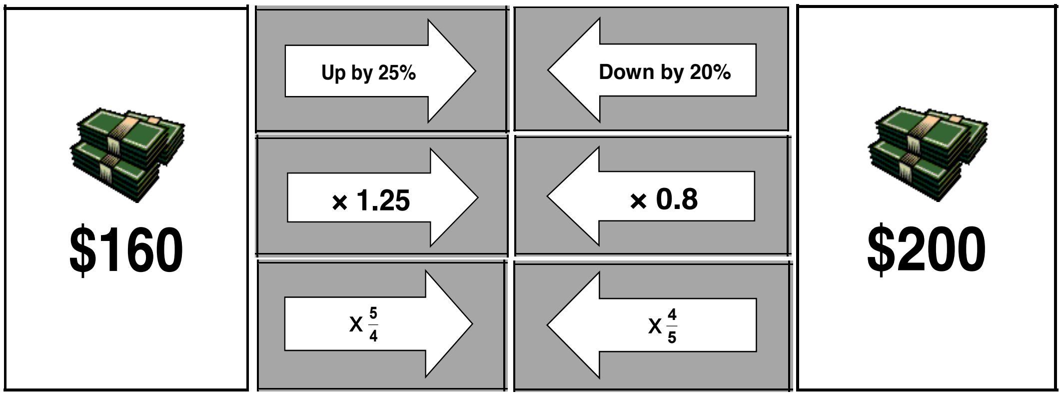

Figure 2: Represent and translate: Percentage increase and decrease.

already in position. This created "cognitive conflict" and discussion as inconsistencies were found. Later, further cards were added, as shown. Connections were drawn between all these representations and generalizations were made.

For *justify or prove* category, we designed collections of conjectures, and it was the students' task to determine their domains of validity. Figure 3 illustrates a typical selection of such assertions.

Pay rise Max gets a pay rise of 30%. Jim gets a pay rise of 25%. So Max gets the bigger pay rise.	**Fractions** If you add the same number to the numerator and denominator of a fraction, the fraction will increase in value.
Area and perimeter When you cut a piece off a shape you reduce its area and perimeter.	**Right angles** A pentagon has fewer right angles than a rectangle.
Diagonals The diagonals of a quadrilateral divide the quadrilateral into 4 equal areas.	**Right triangle** If a right-angled triangle has integer sides, the incircle has integer radius.

Figure 3: Justify or prove: A selection of conjectures to test.

Normally, a set of cards was related to a single mathematical topic, and contained some commonly held beliefs. Students were instructed: *"If you consider a statement to be always true or never true, then try to explain clearly how you be sure. If you think a statement is sometimes true, then try to describe all the cases when it is true and all the cases when it is false."* Thus students had first to identify the variables involved and then test the assertion by constructing examples and counterexamples. In some cases a formal proof could be sought. When students became stuck, the teacher pointed them toward particular cases to test. For example, in *Diagonals*, students often claimed that the statement is true for squares, but not for rectangles. The teacher needed to prompt them to re-consider and then go on to study a wider range of quadrilaterals to try to find *all* cases where the statement was valid.

Finally, we turn to *identify and analyze structure.* When students had tackled a conventional word problem, for example, they were invited to analyze its structure and in so doing construct further problems. The problem was rewritten as a list of variables together with their original values, including the solution to the original problem (see Figure 4). The task was to first describe how each variable might be obtained from the others, then to explore the effect of changing variables systematically. So the teacher erased the profit and asked: "How may this be constructed from the other variables?" (60x4-50 or $p=ns-k$). Then the profit was reinstated and the selling price was erased. How might this be found? ($s=(p+k)/n$). After working through each variable separately, the teacher considered variables in pairs. Suppose *both n* and *p* are erased? How will the profit depend on the number of cards made? Students could then generate a table and/or graph. Finally students might be asked to erase all values and describe the general structure algebraically ($p=ns-k$). This strategy could easily be used whenever students tackle word problems in order to focus more explicitly on structural relationships.

(ii) Assessment Task Genres for Problem Solving

These lessons were designed to assess and improve the capability of students to solve multi-step, non-routine problems and to extend this to the formulation and tackling of problems from the real world. We define a problem as a task that the individual wants to tackle, but for which he or she "does not have access to a straightforward means of solution" (Schoenfeld, 1985). One consequence of this definition is that it is pedagogically inconsistent to design problem-solving tasks for the

Making and Selling Candles

Original word problem

A student wants to earn some money by making and selling candles.
Suppose that he can make 60 candles from a $50 kit and that these will each be sold for $4.
How much profit will be made?

Rewritten problem

		k
The cost of buying one kit	**$**	**50**
		n
The number of candles that can be made with the kit		**60**
		s
The price at which each candle is sold	**$**	**4**
		p
Total profit made if all candles are sold.	**$**	**190**

Figure 4: Identify and analyze structure: Working with word problems

purpose of practicing a procedure or to develop understanding of a particular concept. In order to develop strategic competence, students must be free to experiment with a range of approaches. They may or may not decide to use any particular procedure or concept; these cannot be pre-determined. Problem solving is contained within the broader processes of mathematical modelling. Modelling additionally requires the formulation of problems by, for example, restricting the number of variables and making simplifying assumptions. Later in the process, solutions must be interpreted and validated in terms of the original context. Some task genres and sample classroom activities for strategic competence are shown in Table 3.

Table 3: Task Genres for Problem Solving Lessons

Assessment task genres	Sample classroom activities.
Solve a non-routine problem by creating an extended chain of reasoning.	Selecting appropriate mathematical concepts and procedures. Planning an approach. Carrying out the plan, monitoring progress and changing direction, where necessary. Reflecting on solutions; examining for reasonableness within the context. Reflecting on strategy; where might it have been improved?
Formulate and interpret a mathematical model of a situation that may be adapted and used in a range of situations.	Making suitable assumptions to simplify a situation. Representing a situation mathematically. Identifying significant variables in situations. Generating relationships between variables. Identifying accessible questions that may be tackled within a situation. Interpreting and validating a model in terms of the context.

The essence of a task in this category is that it should be amenable to a variety of alternative approaches, so that students may learn from comparing these approaches. An example of each type is given in Figure 5. The first is a pure mathematics ‘puzzle’ type problem set in an artificial context, that of a playground game. The second, a modelling task, is taken from a real-life context and involves the student in making simplifications and assumptions. Both however may be tackled in a variety of ways. *The playground game* may be tackled by practical drawing and measuring; by repeated use of Pythagoras’ theorem; and also by ‘pure, non-quantitative, geometric reasoning’. *Having Kittens* may be modelled with a wide variety of representations, and therein is its educational value.

The Playground Game

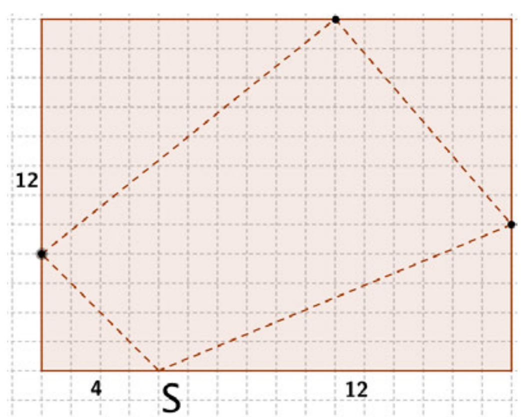
This is a plan view of a 12 meter by 16 meter playground.

The children start at point S, which is 4 meters along the 16-metre wall.

They have to run and touch each of the other three walls and then get back to S.

The first person to return to S is the winner.

What is the shortest route to take?



Having Kittens

Here is a poster published by an organization that looks after stray cats.

Cats can't add but they do multiply!
In just 18 months, this female cat can have 2000 descendants.

Figure out whether this number of descendants is realistic.
Here are some facts that you will need:

Length of pregnancy
About
2 months

Age at which a female cat can first get pregnant
About
4 months

Number of kittens in a litter
Usually
4 to 6

Average number of litters a female cat can have in one year
3

Age at which a female cat no longer has kittens
About
10 years

Figure 5: Tasks for assessing and improving problem solving processes.

Research-based Principles for Formative Assessment Lesson Design

Having discussed the mathematical focus of the tasks we used, we now turn our attention to how these tasks were incorporated into formative assessment lessons.

The principles that underpinned the design of our lessons were rooted in our "Diagnostic Teaching" program of design research in the 1980s. This was essentially formative assessment under another name (See e.g. Bell, 1993; Swan, 2006a). In a series of studies, on many different topics, we began to define an approach to teaching that we showed were more effective, over the longer term, than either expository or guided discovery approaches (Bassford, 1988; Birks, 1987; Brekke, 1987; Onslow, 1986; Swan, 1983). This approach consisted of four phases. The first involved offering a task designed that would expose students' existing conceptual understanding and make students aware of their own intuitive interpretations. The second involved the provocation of cognitive conflict by asking students to compare their responses with those of their peers or by asking them to repeat the task using alternative representations and methods. This feedback generated 'cognitive conflict' as students began to realize and confront the inconsistencies in their own and each others' interpretations and methods. Considerable time was then spent reflecting on and discussing the nature of this conflict and students were encouraged to write down the inconsistencies and possible causes of error. The third phase was whole class discussion aimed at resolving conflict. During this phase the teacher would introduce the mathematician's interpretation. Finally, new learning was 'consolidated' by using the newly acquired concepts and methods on further problems. Students were also invited to create and solve their own problems within given constraints, analyze completed work and diagnose causes of error for themselves.

From these studies it was deduced that the value of diagnostic teaching appeared to lie in the extent to which it assessed, identified and focused on the intuitive methods and ideas that students brought to each lesson, and created the opportunity for discussions between students; the greater the intensity of the discussion, the greater was the impact on learning. This is a clear endorsement of the formative assessment practices described in Table 1.

More recently, these results have been replicated on a wider scale. UK government funded the design and development of a multimedia professional development resource to support diagnostic teaching of algebra (Swan & Green, 2002). This was distributed to all Further Education colleges, leading to research on the effects of implementing collaborative approaches to learning in 40 classes of low attaining post 16 students. This again showed the greater effectiveness of approaches that assess and address conceptual difficulties through student-student and whole class discussion (Swan, 2006a, 2006b; Swan, 2006c). A particular design feature of these lessons was the use of a pre- and post-lesson assessment task that would allow both the teacher and the student to assess growth in understanding. The government, recognizing the potential of such resources, commissioned the design of a more substantial multimedia professional development resource, ‘Improving Learning in Mathematics’ (DfES, 2005). This material was trialed in 90 colleges, before being distributed to all English FE colleges and secondary schools. This material provided many of the resources that where subsequently redeveloped for the Mathematics Assessment Project.

In addition to our own research, we drew inspiration from the ways in which other researchers have structured the design of lessons. These include the Lesson Study research in Japan and the US (Fernandez & Yoshida, 2004; Shimizu, 1999). In Japanese classrooms, lessons are often structured into four phases: *hatsumon* (the teacher gives the class a problem to discuss); *kikan-shido* (the students tackle the problem in groups or individually); *neriage* (a whole class discussion in which alternative strategies are compared and contrasted and in which consensus is sought) and finally the *matome*, or summary, where teachers comment on the qualities of the approaches used. Formative assessment is clearly evident in the way in which the teacher carefully observes students working during the *hatsumon* and *kikan-shido* phases, and selects the ideas to be discussed in the *neriage* stage. The *neriage* phase is considered the most crucial. This term also refers to kneading or polishing in pottery, where different colours are blended together. This serves as a metaphor for the selection and blending of students’ ideas. It involves great skill on the part of the teacher, as she must assess student work carefully then select and sequence examples in a way that will elicit fruitful discussions.

Other researchers have adopted similar models for structuring classroom activity. They too emphasize the importance of: anticipating student responses to demanding tasks; carefully monitoring student work; discerning the value of alternative approaches; purposefully selecting ideas for whole class discussion; orchestrating this discussion to build on the collective sense-making of students by careful sequencing of the work to be shared; helping students make connections between and among different approaches and looking for generalizations, and recognizing and valuing and students’ constructed solutions by comparing this with existing valued knowledge (Brousseau, 1997; Chazan & Ball, 1999; Lampert, 2001; Stein, Eagle, Smith, & Hughes, 2008).

In order to illustrate how these principles, together with the key strategies in Table 1, have influenced the design of our lessons, we now illustrate the design of complete lessons.

Examples of Formative Assessment Lessons

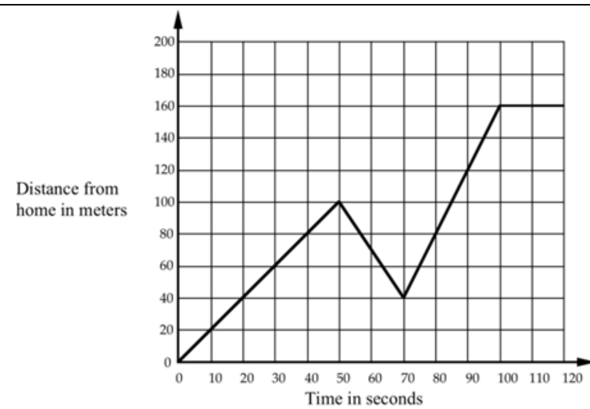
We now illustrate how this research has informed the lesson structure of the *Classroom Challenges*, integrating the formative assessment strategies of Table 1. A complete lesson guide for this and the other lessons may be downloaded from http://map.mathshell.org.

A Concept Development Lesson

The objective of this lesson is to provide a means for a teacher to formatively assess students’ capacity to interpret distance-time graphs. The lesson is preceded by a short diagnostic assessment, designed to expose students’ prior understandings and interpretations (Figure 6). We encourage teachers to prepare for the lesson by reading through students’ responses and by preparing probing questions that will advance student thinking. They are advised not to score or grade the work. Through our trials of the task, we have developed a "common issues table" that forewarns teachers of some common interpretations students may have, and suggests questions that the teacher might pose to advance a student's thinking. This form of feedback has been shown to more powerful than grades or scores, which detract from the mathematics and encourage competition rather than collaboration (Black et al., 2003; Black & Wiliam, 1998). Some teachers like to write their questions on the student work while others prepare short lists of questions for the whole class to consider.

Journey to the bus stop

Every morning Tom walks along a straight road from his home to a bus stop, a distance of 160 meters. The graph shows his journey on one particular day.



1. Describe what may have happened. Include details like how fast he walked.
2. Are all sections of the graph realistic? Fully explain your answer.

Issue	*Suggested questions and prompts*
Student interprets the graph as a picture For example: The student assumes that as the graph goes up and down, Tom's path is going up and down *or* assumes that a straight line on a graph means that the motion is along a straight path.	If a person walked in a circle around their home, what would the graph look like? If a person walked at a steady speed up and down a hill, directly away from home, what would the graph look like? In each section of his journey, is Tom's speed steady or is it changing? How do you know? How can you figure out Tom's speed in each section of the journey?
Student interprets graph as speed–time The student has interpreted a positive slope as 'speeding up' and a negative slope as 'slowing down'.	If a person walked for a mile at a steady speed, away from home, then turned round and walked back home at the same steady speed, what would the graph look like? How does the distance change during the second section of Tom's journey? What does this mean? How can you tell if Tom is traveling away from or towards home?

Figure 6: Initial assessment task: *Journey to school,* and an extract from the 'Common issues table'

The lesson itself is structured in five parts:

1. **Make existing concepts and methods explicit**. An initial task is offered with the purpose of clarifying the learning intentions, making students aware of their own intuitive interpretations, creating curiosity and modeling the level of reasoning to be expected during the main activity (Table 1, strategy 1). The teacher displays the task shown in Figure 7 and

asks students to select the story that best fits the graph. This usually results in a spread of student opinions, with many choosing option B. The teacher invites and probes explanations, and labels the diagram with these explanations, but does not correct students, nor attempt to reach resolution at this point.

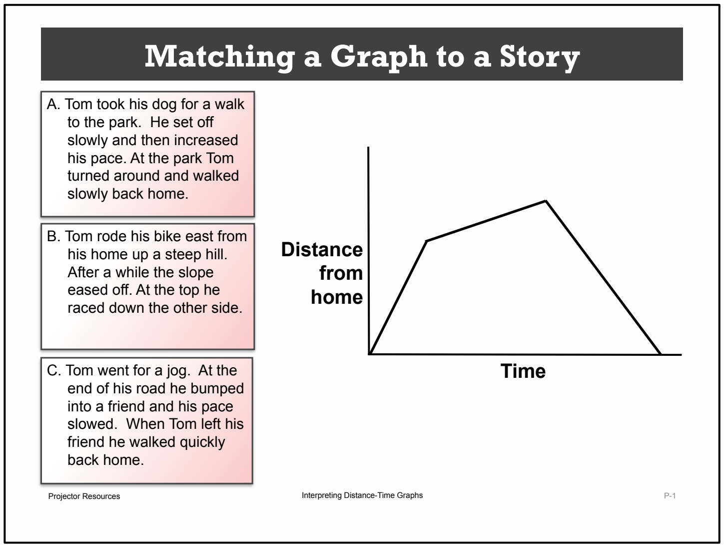


Figure 7: Introductory activity: Interpreting distance-time graphs

2. **Collaborative activity: Matching graphs, stories and tables**.
This phase is designed to create student-student discussions in which they share and challenge each others' interpretations (Table 1, strategy 2). Each group of students is given a set of the cards shown in Figure 8. Ten distance/time graphs are to be matched with nine 'stories' (the tenth to be constructed by the student). Subsequently, when the cards have been discussed and matched, the teacher distributes a further set of cards that contain distance/time tables of numerical data. These provide feedback by enabling students to check their own responses (by plotting if necessary), and reconsider the decisions that have been made. Students collaborate to construct posters displaying their reasoning. While students work, the teacher is encouraged to ask the pre-prepared questions from the initial diagnostic assessment (Table 1, strategy 3).
3. **Inter-group discussion: Comparing interpretations.** Students' posters are displayed, and students visit each other's posters and check them, demanding explanations for matches that do not appear to be correct (Table 1, strategy 4).
4. **Plenary discussion.** Students revisit the task that was introduced at the beginning of the lesson and resolution is now sought. Drawing on examples of student work produced during the lesson, the teacher draws attention to the significant concepts that have arisen (e.g. the connection between speed, slopes on graphs, and differences in tables). Further questions are posed to check learning, using mini-whiteboards. "Show me a distance time graph to show this story"; "Show me a story for this graph"; "Show me a table that would fit this graph". (Table 1, strategy 2)
5. **Individual work: Improving solutions to the pre-assessment task.** Students now revisit the work they did on the pre-assessment task. They describe how they would now answer the task differently and write about what they have learned. They are also asked to solve a fresh, similar task (Table 1, strategy 5).

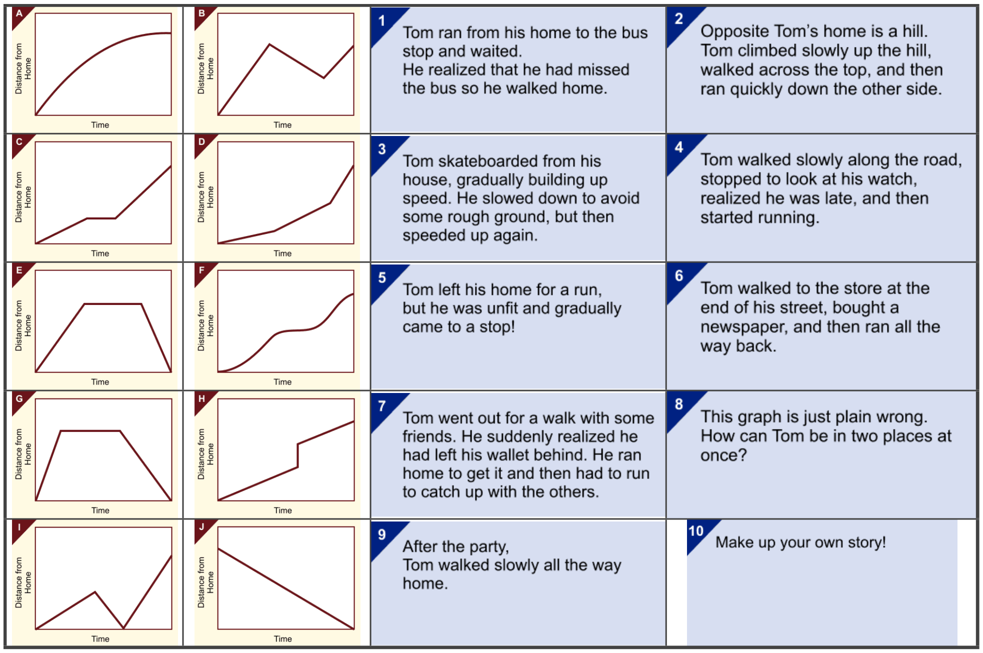

Figure 8: Matching cards: Graphs and stories.

A Problem Solving Lesson

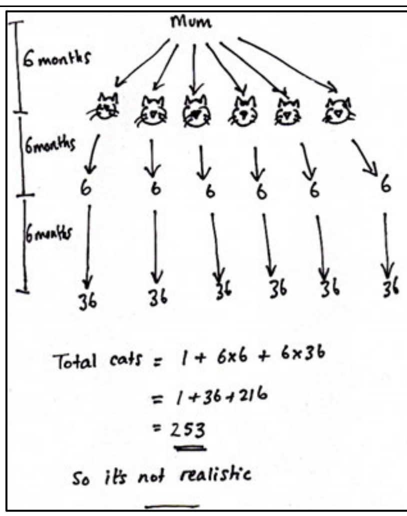
The problem solving lessons were constructed in a similar way, but with a different emphasis. Teachers found it very difficult to interpret, monitor and select students' extended reasoning during a problem-solving lesson. We therefore decided again to precede each lesson with a preliminary assessment in which students tackle the problem individually. The teacher reviews a sample of the students' initial attempts and identifies the main issues that need addressing. This time the issues focus on *approaches* to the problem. If time permits, teachers write feedback questions on each student's work, or alternatively prepare questions for the whole class to consider. Figure 9 illustrates some of the common issues and suggested questions for the task "*Having Kittens*" (Figure 5).

Issue	*Suggested questions and prompts*
Has difficulty starting	Can you describe what happens during first five months?
Does not develop a suitable representation	Can you make a diagram or table to show what is happening?
Work is unsystematic	Could you start by just looking at the litters from the first cat? What would you do after that?
Develops a partial model	Do you think the first litter of kittens will have time to grow and have litters of their own? What about their kittens?
Does not make clear or reasonable assumptions	What assumptions have you made? Are all your kittens are born at the beginning of the year? Are all your kittens females?
Makes a successful attempt	How could you check this answer using a different method?

Figure 9: An extract from the 'Common issues table' for *Having Kittens*

Now we come to the lesson itself. While the precise structure is problem-specific, these lessons are generally structured as follows:

1. **Introduction**. The teacher re-introduces the main task for the lesson and returns students' work along with the formative questions. Students are given a few minutes to read these questions and respond to them, individually (Table 1, strategy 3)
2. **Group work: comparing strategic approaches**. The students are asked to work in small groups to discuss the work of each individual, then to produce a poster showing a joint solution that is better than the individual attempts. Groups are organised so that students with contrasting ideas are paired. This activity promotes peer assessment and collaboration. The teacher's role is to observe groups and challenge students using the prepared questions and thus refine and improve their strategies (Table 1, strategy 2).
3. **Inter-group discussion: comparing strategic approaches**. Depending on the range of approaches in evidence, the teacher may at this point ask students to review the strategic approaches produced by other groups in the class, and justify their own. (Most will not have arrived at a solution by this stage). If there is not a sufficient divergence of methods, or more sophisticated representations are not becoming apparent, then the teacher may move directly to the next stage. (Table 1, strategy 4)
4. **Group work: critiquing pre-designed 'sample student work'**. The teacher introduces up to four pieces of "sample student work", provided in the materials (Figure 10). This work has been chosen to highlight significant, alternative approaches. For example, it may show different representations of the situation. Each piece of work is annotated with questions that focus students' attention. (E.g. "What has each student done correctly? What assumptions have they made? How can their work be improved?") This intervention is discussed further in the following section.
5. **Group work: refining solutions**. Students are given an opportunity to respond to the review of approaches. They revisit the task and try to use insights to further refine their solution (Table 1, strategy 4).
6. **Whole class discussion: a review of learning**. The teacher holds a plenary discussion to focus on the processes involved in the problem, such as the implications of making different assumptions, the power of alternative representations and the general mathematical structure of the problem. This may also involve further references to the approaches in the sample student work.



Questions for students

- What has Wayne done correctly?
- What assumptions has he made?
- How can Wayne's work be improved?

Notes from the teacher guide

Wayne has assumed that the mother has six kittens after 6 months, and has considered succeeding generations. He has, however, forgotten that each cat may have more than one litter. He has shown the timeline clearly. Wayne doesn't explain where the 6-month gaps have come from.

Figure 10: Sample work for discussion, with commentary from the teacher guide.

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

The above lesson description contains many features that are not common in mathematics teaching, at least in the US and UK. There is a strong emphasis on the use of preliminary formative assessment, which enables the teacher to prepare for and adapt interventions to the student reasoning that will be encountered. Students spend much of the lesson in dialogic talk, focused on comparing mathematical processes. The successive opportunities for refining the solution enable students to pursue multiple methods, and to compare and evaluate them. Finally, designed ‘sample student work’ is used to foster the development of *critical competence*. This aspect has become the focus of our recent research, and we now draw out some of the issues this raises.

Students Assessing Student Work

In Cobb’s terms, the products of design research are ‘humble’ theories that guide future designs (Cobb et al., 2003). As we have worked through successive refinements, many of the findings from the data have been incorporated into the designs themselves. Below we just one of the features of these lessons that we are continuing to study further (Evans & Swan, 2014); that of students critiquing pre-designed ‘sample student work’.

Researchers (e.g. Stein et al., 2008) have emphasised the importance of students assessing approaches to cognitively demanding tasks, but this has proved difficult for teachers to put into practice, particularly for problem solving, where student reasoning is extended, complex and often poorly articulated. In a busy classroom, teachers find it difficult to observe, interpret and select suitable work for sharing. In whole class discussions we frequently observe students presenting posters of their reasoning, to a sea of incomprehension. Teachers also find it difficult to quickly recognize and make connections between students’ ideas and draw out significant learning points. It is therefore understandable that, in practice, the sharing of ideas often degenerates into mere ‘show and tell’, with participation prioritized over learning (Stein et al., 2008).

In response to this challenge we are researching the potential uses of pre-designed ‘sample student work’ to focus classroom discussion on key concepts and processes, while at the same time developing critical competence. We construct this work by analyzing a sample of genuine student responses to a problem, then identifying conceptual difficulties or problem solving strategies that will provide significant learning opportunities for students. When problem solving, for example, very few students autonomously decide to employ an algebraic method (Treilibs, 1979). Given choice they tend to resort to more secure numerical or graphical methods. For this reason we may include an algebraic method among the sample work so that students will be confronted with methods they may not yet have considered. We present this work in clear, legible, handwritten form, to suggest that the work is tentative, open for criticism and improvement. We have found that students feel more able to criticize such work than the work of peers, where social pressures often come into play.

We have found that pre-designed sample student work has many potential uses. In problem solving, for example, it can be used to encourage a student that is stuck in one line of thinking to consider others, to enable comparison of alternative representations and to focus on the identification of modeling assumptions. In concept learning it may be used to draw attention to common mathematical misconceptions and alternative interpretations. Perhaps most importantly, the sample work may provide an opportunity for ‘clarifying our learning intentions and criteria for success’ (Table 1, strategy 1). By assessing the work of others, students become more aware of the criteria by which their own work is judged. Thus, for example, by asking students to compare four methods and judge which is most ‘powerful’, ‘clear’, or ‘elegant’, then they may come to understand what such terms may mean.

In our classroom observations (in the UK and the US), however, we found that there were frequent problems with implementation (Evans & Swan, 2014). These included: students commenting superficially, focusing merely on presentation and clarity; students being given insufficient time to engage with the reasoning presented in the work; students spending time correcting errors rather than focusing on strategy; students not using the work to improve their own solutions; students failing to make comparisons between approaches. In response, we established the following guidelines for the design of sample work:

- Discourage superficial analysis by students, by stating explicitly the purpose of the sample work, and by asking specific questions that relate to this purpose;
- Encourage holistic comparisons by making the sample work short, accessible and clear, and by excluding procedural and other errors that distract attention away from the identified purpose;
- Leave the work unfinished, so that students have to engage with the reasoning in order to complete it;
- Sequence the distribution of the sample student work so that successive pairwise comparisons of approaches may be made;
- Offer students sufficient time and opportunity to incorporate what they have learned from the sample work into their own solutions;
- Offer the teachers support for the whole class discussion so that they can identify and draw out criteria for the comparison of alternative approaches.

When these guidelines were followed, however, we found that critiquing work provides the potential to refocus students' attention away from 'getting answers' towards 'thinking about reasoning' and a deeper awareness of the learning intentions of the teacher and the criteria for success.

Concluding Remarks

In this brief paper, I have attempted to describe how systematic design research has enabled us to tackle a significant pedagogical problem: how might we enable teachers to embed formative assessment practices into their normal classroom practice? I have discussed the five strategies described by Black and Wiliam and shown how these have been integrated into the structure of the *Classroom Challenges*. In particular, I have attempted to show how:

- Learning intentions and criteria for success may be clarified by making use of task genres that *require* the mathematical practices that we seek to foster; by sharing these intentions and modeling the reasoning required at the beginning of lessons; and by encouraging students to focus on criteria for success as they critique and evaluate the work of others.
- Evidence of student understanding may be elicited through: pre-assessment tasks that offer students opportunity to engage with a problem individually, before group discussion takes place; and through group activities that require shared resources and dialogic talk in which students share interpretations and strategies. These give the teacher opportunities to reflect on student reasoning and to plan and make appropriate interventions.
- Common issues tables may be used to help teachers plan appropriate feedback that will prompt students to reconsider their thinking and move them forward.
- Students may become instructional resources for one another as they work collaboratively and review and comment on the work of their peers.
- Students may take a greater responsibility for their own learning as they become more aware of what they have learned and what they still need to learn through reflection at the end of lessons and through the matching of their own responses to the designed sample student work.

Of course, we realize that however carefully we design lesson structures, each classroom is unique and teachers will modify what we offer in their own way. Early evidence of their impact is, however, encouraging. Drawing on a national survey of 1239 mathematics teachers from 21 states, and interview data from four sites, Research for Action (RFA, 2015), found that a large majority of teachers reported that the use of the *Classroom Challenges* had helped them to implement the Common Core State Standards, raise their expectations for students, learn new strategies for teaching subject matter, use formative assessment; and differentiate instruction.

The National Center for Research on Evaluation, Standards and Student Testing (CRESST) examined the implementation and impact of *Classroom Challenges* in 9th grade Algebra 1 classes (Herman et al., 2015). This study used a quasi-experimental design to compare student performance with *Classroom Challenges* to a matched sample of students from across Kentucky comparable in prior achievement and demographic characteristics. On average, study teachers implemented only four to six *Challenges* during the study year (or 8-12 days), yet, relative to typical growth in math from eighth to ninth grade, the effect size for the *Classroom Challenges* represented an additional 4.6 months of schooling. Although teachers felt that that the *Challenges* benefited students' conceptual understanding and mathematical thinking, they reported that sizeable proportions of their students struggled, and it appeared that lower achieving students benefitted less than higher achievers. This they suggested, may be due to the great difference in challenge and learning style required by these lessons, compared with their previous diet of procedural learning.

Finally, Inverness Research (IR, 2015) in 2014 surveyed 636 students from 31 trial classes (6th grade to High School) across five states in the US. They found that the majority of students enjoyed learning math through these lessons, reported that they understood it better, had increased in their participation, listening to others, and in explaining their mathematical thinking. About 20%, however, remained unaffected by or disaffected with these lessons. This was because they didn't enjoy working in groups, they objected to the investigative approach, and/or they felt that these lessons were too long, or too difficult

In conclusion, it does appear that the *Classroom Challenges* provide a model for teachers as they attempt to introduce formative assessment into their everyday classroom practice, but they do require a radical shift in the predominant culture within many classrooms. The potential for improving learning through the integration of these formative assessment practices into everyday teaching is, however, clear. This project has shown that classroom materials with this focus can help teachers make it a reality in their classrooms. How far teachers transfer this approach into the rest of their teaching is the focus of ongoing research.

Acknowledgements

The Mathematics Assessment Program (MAP) materials were produced as part of a collaboration between the University of California, Berkeley and the Shell Center team at the University of Nottingham, with support from the Bill & Melinda Gates Foundation. The team works with the Silicon Valley Mathematics Initiative and school systems across the US and UK to develop improved assessment.

The Having Kittens task was originally designed by Acumina Ltd. (http://www.acumina.co.uk/) for Bowland Maths (http://www.bowlandmaths.org.uk) and appears courtesy of the Bowland Charitable Trust.

Special Session

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

FUNDING OPPORTUNITIES FROM THE NATIONAL SCIENCE FOUNDATION

Margret Hjalmarson
National Science Foundation
mhjalmar@nsf.gov

Finbarr Sloane
National Science Foundation
fsloane@nsf.gov

Karen King
National Science Foundation
kking@nsf.gov

This session will provide information about current funding opportunities in mathematics education research and development from the National Science Foundation. The following programs of particular interest to PME-NA participants will be included in the discussion: EHR Core Research, Discovery Research K-12, and CAREER. Program officers will also provide guidance and suggestions for preparing proposals for a variety of programs.

Currently, the National Science Foundation has a number of programs in the Education and Human Resources Directorate that provide opportunities for funding for the mathematics education research and development across K-12, undergraduate, and graduate education. In this session, program officers will provide information about current program announcements as well as suggestions for preparing proposals. The following programs of particular interest to PME-NA participants will be included in the discussion: EHR Core Research, Discovery Research K-12, and CAREER. Investigators should also refer to other opportunities in the EHR directorate for funding. Investigators should refer to the NSF website (www.nsf.gov) for current solicitation information when preparing proposals for submission. Investigators should also refer to the *Common Guidelines for Education Research and Development* when preparing materials and designing their projects (2013). In this session, we will present an overview of current programs (20 minutes) followed by time for questions from participants (20 minutes). New faculty and graduate students are particularly encouraged to attend.

COMMUNICATIONS IN CURRICULUM MATERIALS AND TYPES OF STUDENT AUTONOMY PROMOTED

Napthalin A. Atanga

achubang.a.naphtalin@wmich.edu

Ok-kyeong Kim
Western Michigan University
ok-kyeong.kim@wmich.edu

The interaction between types of communication and socio-mathematical norms on students' learning autonomy in five curriculum programs was investigated. Uni-directional, contributive, reflective, and instructive types of communications were present in curriculum programs studied. Investigations in Number Data and Space and Math Trailblazers provided opportunities for students to explain, justify, and compare solution strategies. Math in Focus and Scott Foresman Addison Wesley-Mathematics required explanations, justifications, and comparisons of solution strategies, but those were mainly provided by the teacher. The former and latter programs potentially foster intellectual autonomous and intellectual heteronomous learning in students, respectively, while Everyday Mathematics almost equally supports both.

Key words: Curriculum Analysis; Classroom Discourse; Curriculum

Classroom discourse is critical for sharing, reflecting upon, refining, supporting, and extending students' mathematical ideas (NCTM, 2014), and the ways in which teachers organize classroom discussion influence student thinking. Curriculum materials (CMs) communicate to teachers in ways that can position students as largely independent learners, as learners depending heavily on an authority, or as both types of learners during enactment. Yackel and Cobb (1996) described students who "make sense of explanations, compare solutions, and make judgments about similarities and differences" (p. 466) as intellectually autonomous and otherwise as intellectually heteronomous(i.e., relying heavily on an authority to lead and determine mathematically appropriate ways to act). These descriptions by Yackel and Cobb imply that kinds of engagement opportunities offered to students in the classroom determine the degree of independence provided to students in the learning process. Yackel and Cobb also recommended teachers establish what they call socio-mathematical norms—"normative aspects of mathematical discussions that are specific to students' mathematical activity" (p. 458) in their classroom so that students can decide for themselves what is mathematically appropriate and acceptable with minimal mathematical input from the teacher. Little is known about the interaction between communication types and socio-mathematical norms embedded in CMs and their impacts on students' autonomy. This study examines CMs for types of communication they promote and the kind of learning autonomy fostered. To investigate this, we asked a research question: *What are potential impacts of communication types and socio-mathematical norms embedded in written lessons?* Three reasons suggest that investigating the potential impacts of the interaction between communication types and socio-mathematical norms might benefit the mathematics education community.

First, students need to develop authority in the mathematics they learn, and teachers are in the position to foster desired "students' mathematical authority" (Stein, Engle, Smith, & Hughes, 2008, p. 332). Teachers might be able to do this when curriculum designers embed such practices in CMs. Examining the impact of communication types embedded in written lessons might explain the kind of mathematical authority teachers are expected to promote in students.

Second, Hiebert, Morris, Berk, and Jansen (2007) argued that teachers ought to learn from teaching in order to improve their practice. A possible way of doing this is by communicating to teachers through CMs what counts as a mathematical explanation and justification, which has possibility to develop "teachers' mathematical knowledge for teaching" (Ball, Thames, & Phelps, 2008, p. 394). As teachers understand what counts as mathematical explanation and justification, they might be able to orchestrate classroom interaction to develop mathematical authorities students need to be successful.

Third, Shulman (1986) recommended that teachers should understand both substantive and syntactic structures of mathematical ideas students are to learn. An understanding of ways CMs communicate, what is communicated, and the potential impact on students' mathematical authority may provide insights into whether teachers' learning of substantive and syntactic structures of mathematics is promoted.

Theoretical Perspectives

Researchers have investigated classroom discourse to identify ways in which teachers communicate and how these might affect students' mathematical thinking. Brendefur and Frykholm (2000) identified four hierarchical types of communication between two preservice teachers and their students: *uni-directional*, *contributive*, *reflective*, and *instructive*. They defined uni-directional communication as dominated by teachers; contributive as limited to sharing of ideas with minimal attention given to discussing them; reflective communication makes shared ideas objects of discussion; and instructive communication focuses on students' thought processes that reveal their strengths and limitations. Brendefur and Frykholm argued that classifying these four types is important because they affect classroom norms.

Cobb, Yackel and Wood (1989) and Yackel, Cobb, and Wood (1991) identified examples of socio-mathematical norms in classrooms as explanations, justifications, and argumentation. Yackel and Cobb (1996) argued that socio-mathematical norms focusing on "what counts as mathematically different, mathematically sophisticated, mathematically efficient, and mathematically elegant … acceptable mathematical explanation and justification" (p. 461) create additional learning opportunities for students and can develop their mathematical thinking.

CMs can contribute to teachers' classroom practice by promoting productive communications among teachers and students (Ball & Cohen, 1996; Davis & Krajcik, 2005) and supporting them to establish appropriate socio-mathematical norms in the classroom. As such, it is natural to ask whether CMs explicitly support teachers for effective classroom discourse, in terms of socio-mathematical norms and different types of communication. Because of the critical role CMs can play in influencing classroom practice, we drew on the works of Brendefur and Frykholm (2000) and Yackel and Cobb (1996) to identify types of communications embedded in CMs and potential impacts of communications types and socio-mathematical norms.

Methods

Data for this study were drawn from five curriculum programs used in a larger project, *Improving Curriculum Use for Better Teaching (ICUBiT)*. We selected written lessons from each of the five curriculum programs: (a) *Investigations in Number, Data, and Space*(*Investigations*);(b)*Everyday Mathematics* (*EM)*; (c) *Math Trailblazers* (*MTB*); (d) *Scott Foresman Addison Wesley-Mathematics* (*SFAW-Mathematics*), and (e)*Math in Focus*(*MiF*). The first three programs are reform-oriented and their designs were funded by the National Science Foundation; the fourth is commercially developed and widely used in U.S. classrooms; and the fifth, originally from Singapore, is gradually and steadily gaining prominence in U.S. classrooms. Teacher's guides of these five curriculum programs were analyzed, focusing on the guidance provided in the main portion of lessons—devoted to the main content, excluding routine practice. Fifteen written lessons in grades 3-5 (five per grade) randomly selected from each program were analyzed.

The main parts of each lesson were coded sentence by sentence and the analysis went through five stages. First, each sentence was associated with one of the following codes: (1) Uni-directional – directly speaking to teachers or students (through teacher); (2) contributing –explaining and demonstrating possible ideas; (3) reflecting – engaging students in making sense and generating meaning through use of representations, strategies, and discussions; and (4) instructing –posing situations that encourage students to compare and make judgments. Second, each sentence was again coded for socio-mathematical norms (i.e., forms of students' engagements): (1) making sense of explanations; (2) comparing solutions and strategies; (3) making judgments about similarities and differences; and (4) providing explanations, demonstrations, and justifications. Third, we made a summary for the number and percentage of sentences for each type of communication. Fourth, within each type of communication, we used socio-mathematical norms promoted to determine the degree of possible students' autonomy fostered in each program. When CMs communicate to teachers to engage students in making comparisons of solutions and strategies, providing explanations, demonstrations, or justifications, students appear to be supported to be more intellectually autonomous. Otherwise, they may be moving toward the intellectually heteronomous end, depending on the teacher or an authority to understand and articulate mathematical concepts or ideas. Fifth, for each program, we identified patterns in types of communication promoted and described the kinds of autonomy fostered, as described above, and compared the five programs in terms of kinds of communications and the type of student learning autonomy the programs tend to support.

Results

Table 1 shows that all four types of communications are present in all five curriculum programs, but with varying emphasis. For each program, the most dominant type of communication is *uni-directional*. *Contributive* communication is the least emphasized

Table 1: Percentages of Communication Promoted

Types of Communication	*INVESTIGATIONS*	*SFAW-MATHEMATICS*	*EM*	*MTB*	*MiF*
Uni-directional	60.0	80.5	76.9	84.1	70.2
Contributive	9.0	3.5	4.7	4.6	10.1
Reflective	16.1	5.6	10.7	6.2	6.4
Instructive	14.9	10.4	7.7	5.1	13.3
Grand Total	**100**	**100**	**100**	**100**	**100**

type in all of these programs, although *MiF* allocated a greater portion of its guidance to this type of communication, followed by *Investigations*. However, most of the contributions in *MiF* are from the teacher, whereas in *Investigations* they are from students. The proportion of sentences allocated for *reflective* communication is greatest for *Investigations* and least for *SFAW-Mathematics*. *Investigations* provide students opportunities to provide explanations, justifications, comparison of solution methods, and strategies presented, whereas in *SFAW-Mathematics* these are often provided by teachers. The proportion of sentences allocated for *instructive* communications is greatest for *Investigations* and least for *MTB*. In spite of this proportional difference, *Investigations* and *MTB* lessons guide teachers to use students' thinking to shape subsequent lessons. In other words, what students struggle with is used to design subsequent lessons.

The emphasis on types of communication propagated by each curriculum program indicates the kind of autonomy nurtured in student learning. Figure 1 shows a continuum from intellectually heteronomous to intellectually autonomous and the location of each curriculum program used for this study along this continuum.

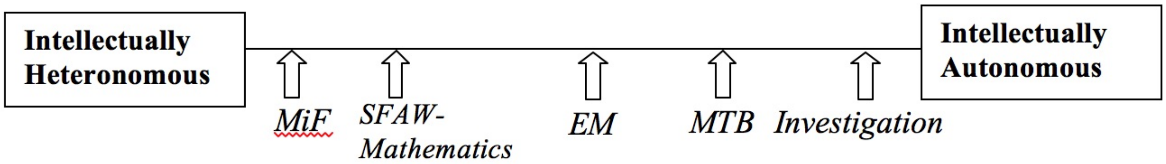

Figure 1: Intellectually Heteronomous-Intellectually Autonomous Continuum.

Intellectually Autonomous

All types of communications in *Investigations* provide students with opportunities to *justify*, *demonstrate*, and *make sense*. Contributive communications in *Investigations* position students to provide their solution strategies and methods, *justifying* and *demonstrating* to others. For example, *Investigations* provides an anticipated student's explanation of how a 120-degree angle is formed as "I put four 30-degree angles (on shape O) together to make 120, because 4 times 30 is 120," which also includes a *justification* of why the strategy and reasoning is mathematically appropriate. Students are also expected to demonstrate their solutions in class with others, as *Investigations* directs teachers to "ask students to demonstrate each of their strategies with the Power Polygon pieces they used." As students provide explanations, justifications, and demonstrations, other students are provided with opportunities to make sense, compare, and identify similarities and differences with theirs.

Instructive communication in *Investigations* provides questions to teachers to determine whether students are *making sense* and *justifying* their solutions. For example, "Do students correctly identify each angle? Do they use what they know about the measure of other angles, such as right angles, to help them find the measure of new angles?" These questions when posed to students provide opportunities to compare and make judgments. Therefore, *Investigations* seems to position students to rely more on their capability, thereby making them intellectually autonomous.

In *MiF*, instructive communication emphasizes *comparing solution methods* to determine which is simpler. During Guided Practice, *MiF* directs teachers to "Have students work in pairs to solve the problem. Have each pair choose a method to solve it. Then have students explain why their method is simpler." In this task, students are required to compare solution methods presented to them by the teacher and determine which is more efficient.

In *EM*, reflective communication suggests that students compare their work, such as "before turning in their work, have students compare their answers with a partner." This has the potential of moving students beyond just comparison of answers to reflecting on their solution strategies in case their answers are different or they have different solution methods to understand mathematical ideas in them. In *MTB*, reflective communication demands that students support their thinking. Questions are provided that asks for mathematical justifications from students for what decision they make. For example, questions such as, "Which fraction is larger: $\frac{1}{6}$ *or* $\frac{1}{4}$? How do you know? Show me with circles," are suggested to teachers to pose to students. *MTB* further asks teachers to "tell students that they are going to defend their choice to the class." These questions could potentially modify students' mathematical understanding by causing them to reflect on a representation and provide substantive arguments to support their reasoning. *MTB* directs teachers to position students to be reflective by letting them know that whatever choice they make needs to be defended. This, in a way, increases the "cognitive demand" (Stein, Grover, & Henningsen, 1996) of the tasks students are engaged with.

MTB supports the use of multiple strategies in classrooms but these come from students, in contrast to *MiF*. For example, *MTB* provides sentences such as, "Did anyone think of it in another way? Can you use another tool?" These different strategies contributed by students could enable them to build their confidence in doing mathematics. It also provides multiple entry points by which students come to understand a mathematical idea rather than depending on the unique approach usually provided by teachers. It also communicates to students that in the absence of the teacher's direct guidance, they could devise valuable and appropriate solution strategies and move their own learning forward.

In some cases, the authors of *SFAW-Mathematics* recommend that teachers provide reflective opportunities to students by asking questions such as, "Suppose the survey question in Example A had been asked to 50 people at a dog show. Would the sample represent the entire population well? Explain." Such questions position students to think about what a sample of a population means and whether the selected sample can adequately represent a population. It also positions students with opportunities to reflect on how a sample can be selected so that it adequately represents that population from which it is drawn. An important idea students must understand before making such a reflection is, what is a population? The authors of *SFAW-Mathematics* direct teachers to explain what an entire population is, in case students do not understand it (example provided under intellectual heteronomous). Although reflective opportunities are provided to students, the authors of *SFAW-Mathematics* often take away such moments and immediately hand them over to the teacher.

IntellectuallyHeteronomous

In *MiF*, contributive communication dominates, but solution strategies and methods presented are mainly from the teacher. For example, sentences such as "Show students how to rename a mixed number as an improper fraction using multiplication and addition with $3\frac{1}{2}$as an example" are used often, and this is followed by the methods which must be demonstrated by the teacher. In *MiF*, reflective communication emphasizes *comparison* of methods used, but the comparison is done mainly by teachers. For example, teachers are asked to "compare this method to the method in the previous *Learn*. Lead students to see that both methods involve multiplication followed by addition." The teacher is expected to *make judgments about similarities and differences*, and learning opportunities for students to develop these understandings themselves are lost. This implies that in *MiF*, students are not provided with opportunities to make sense of solution strategies presented and provide justifications why the methods work. Therefore, students seem to be frequently positioned in a way that makes them rely heavily on an authority, mainly the teacher.

In some situations, *EM* solely positions teachers to be the main authority in class, providing vital mathematical definitions and explanations, and demonstrating solution methods to students. For example, *EM* directs teachers to "explain that a map scale is a tool that helps to estimate real distances between two places shown on a map by relating the distances on the map to distances in the real world." Also, *EM* asks teachers to "model the following solution methods in your discussion." At other times, *EM* provides a step-by-step approach for teachers to lead students through to their solution. The methods teachers are asked to model above for students illustrate this approach. Although these are instructive, most of it comes from the teacher, communicating to teachers that students must depend on them.

In *SFAW-Mathematics*, instructive communication is mainly for teachers to direct students on what to do or provide explanations of mathematical concepts for student learning. The authors of *SFAW-Mathematics* speak to teachers about possible modifications that should be made to foster students' learning of mathematics. For example, they communicate to teachers that "if students do not understand what is meant by the entire population, explain that this is the whole group of people being considered by those who are conducting the survey. For example, it might be everyone living in the United States over the age of 18." Also, the authors of *SFAW-Mathematics* identify possible errors students might make and suggest ways teachers might engage students in fixing them, instead of recommending an instructive approach that positions students to depend on the teacher's authority. For example, *SFAW-Mathematics* authors suggests that "if students cannot decide whether statements are fact or opinion, then point out that words such as best, good, and favorite are clues that a statement is probably an opinion." In this way, the teacher is positioned as the main classroom authority students must look up to in times of difficulties or challenges on certain mathematical ideas. As such, these students might be given the signal that the teacher must evaluate every response as correct or incorrect before they can proceed. Students exposed to this kind of approach might not develop the ability to determine for themselves whether an approach or argument is mathematically sound and accurate.

Discussion/Significance

Many researchers have described curriculum materials as carriers of educational reform because whatever ideas for improvement are conceptualized, they must pass through these materials to get into classrooms. One of the goals of reform efforts has been to make students independent learners. In other words, reform efforts seek to develop students' understanding of mathematical concepts as they reason and provide justification for why an explanation is accurate, decide for themselves what is mathematically correct and acceptable, and critique the reasoning of others students (NCTM, 2000) to learn independently and be certain progress is made. In order for this to happen, teachers need to create such a learning environment. NCTM (2000) recommended that teachers should create environments "in which intellectual risks and sense making are expected" (p. 197).

In this study, some curriculum materials have been found to communicate to teachers in ways that make intellectual risk taking a substantial part of classroom discourse, while others have minimally done so. For example, the authors of *Investigations* and *MTB* have provided teachers with ways students might be thinking about particular mathematical concepts and the depth of the ideas embedded in students' thoughts. The authors of these two curriculum programs have also provided questions teachers might ask to help engage or motivate students to take intellectual risks. In other words, these two programs have communicated the risk-taking environments by providing what students may say and how ideas presented can be deliberated upon. These programs have opened up opportunities for students to justify whatever they say and embrace critique from their peers. These two programs have the potential to empower teachers to support students in figuring out their difficulties and making judgments while depending less on the teacher. Hence, when teachers implement suggestions from curriculum programs similar to these two, focusing on learning goals, students in such classrooms are likely to develop intellectually autonomous habits of mind, monitoring their own progress and making substantial claims of what they understand and what challenges them.

Other curriculum programs such as *MiF* and *SFAW-Mathematics* have attempted to provide opportunities for explanations and justification, but mainly by the teacher. As mentioned above, these programs often require teachers to explain mathematical ideas and strategies to students as well as provide justifications for why approaches they demonstrate are mathematically accurate. These programs implicitly communicate to teachers to take absolute control of the mathematics taking place in their classes. As such, students are to follow, depending heavily on the teacher to "show" them what is correct to copy. Such students are likely to depend greatly on the teacher or any other authority, possibly making them intellectually heteronomous. This does not mean students taught this way might never become intellectually autonomous, but that it might take them a much longer time, thereby achieving this retrospectively and delaying learning of other mathematical concepts. Cumulatively, delays of this sort might have a long-term negative impact on students' learning, causing students to be discouraged about mathematics.

Although many studies have emphasized the kinds of resources CMs make available to teachers (e.g., Ball & Cohen, 1996; Davis & Krajcik, 2005), the study reported here extends our understanding of the kinds of resources that CMs offer to teachers. In addition to overall organization, development of content, and how this content should be taught (e.g., Davis & Krajcik, 2005),mathematics CMs also offer ways teachers might communicate to students to support their learning of mathematical content. Brendefur and Frykholm (2000) identified four types of communication teachers use in their classroom to interact with students. The study reported in this paper found that these four types of communications are provided in all CMs mentioned above. Although Brendefur and Frykholm did not indicate the kind of curriculum materials used by teachers in their study, it is possible the teachers may have been drawing on resources/guidance from their CMs to communicate with their students. Teachers are therefore encouraged to pay close attention to ways CMs communicate with them and how CMs expect them to communicate with students in order to promote student learning, as the communication types identified by Brendefur and Frykholm have been found to create learning opportunities for students if judiciously used.

This study found that CMs can foster both kinds of learning autonomy, although some may strongly propagate one type or the other or even both in some significant proportion (like *EM*). Reform efforts (e.g., NCTM, 2014) support intellectual autonomy for students by recommending that effective teaching provide opportunities for students to share ideas, clarify mathematical understanding, justify their approaches, and also critique ideas of others. This recommendation underscores the importance of autonomous learning that students might achieve and teachers need to support to effectively make student learning of mathematics autonomous. One way to support teachers to gain such knowledge to promote students' autonomous learning of mathematics is by embedding such moves in the teachers' guide. Although some curriculum programs have begun doing this, as the results of this study indicate, it is important to note that curriculum designers may make use of this finding to develop better ways of promoting students' learning autonomy and communicate these to teachers effectively. Hence, these findings are potentially useful for curriculum designers to deliberately position students on the path of intellectual autonomy.

These findings are also potentially useful for teacher educators. Although during teacher training preservice teachers often take a look at curriculum programs, they have done so mainly in the light of preparing lessons to teach during field work. Rarely have preservice teachers been focused on examining the curriculum in the direction of promoting students' learning autonomy. Teacher educators might use these results to engage their preservice teachers in examining curriculum programs for how teachers are positioned to promote learning autonomy in students beyond simply asking students to engage with tasks. This can potentially support teachers to gain skills in assessing curriculum materials for use in schools based on which kind of learning autonomy is fostered.

Providing students opportunities to share their solutions, explain their work, make comparisons, and justify their thinking might not automatically develop the needed intellectual autonomy for students. Although this study has revealed the relationship between types of communications and desired intellectual autonomy and identified the pathway to sustained intellectual autonomy, the following questions still need to be answered: How can teachers effectively foster students' intellectual autonomy in the classroom environment of sharing, comparing, explaining, and justifying reasoning? This question is important because teachers must be able to assess and conclude that their students can work independently and still make sense. Further research involving many classroom observations over an extended period of time might provide results that can fully describe and characterize intellectual autonomy.

We describe two metaphors that we hope can be used to better understand the contemporary mathematics curriculum context in U.S. middle schools, to see how this new context is both similar to and different from prior curriculum contexts. We explain the role and positioning of middle school mathematics curriculum materials over the last century or more and build from learning theory to develop the metaphors. The first metaphor, curriculum as delivery mechanism, builds from technical rational or scientific discourses and encompasses perspectives that are so pervasive they are often unstated and unquestioned. The second metaphor, curriculum as epistemic device, posits that role of curriculum is to provoke interactions that generate understanding. In this metaphor, the role of tasks in curriculum materials is to provoke and progressively refine student thinking, individually and collectively.

Keywords: Curriculum Design; Middle School Mathematics; Learning Theory

Purpose

The U.S. curriculum context is rapidly changing with the increased use of digital and open source materials, the introduction of the Common Core State Standards, and the expansion in the numbers of individuals and organizations involved in curriculum development. In an effort to better understand how this new context is both similar to and different from prior curriculum contexts, we explore two curriculum metaphors that encompass broad trends in the role and positioning of middle school mathematics curriculum materials over the last century or more. The first metaphor, *curriculum as delivery mechanism*, encompasses perspectives that are so pervasive they are often unstated and unquestioned. This dominant metaphor appeals to modernist discourses of science and technical rationalism that permeate educational and other policy contexts (Datnow & Park, 2009) in spite of decades of work to deconstruct such discourses (cf. de Alba et al., 2000). Language referencing the dominant modernist or scientific perspective is often used to market products ostensibly developed using rigorous scientific methods. We deconstruct this metaphor and its manifestations in curriculum materials to highlight its influence on learning opportunities in middle school classrooms. Our goal is to highlight the nature of teachers' work and decisions when working with these materials and the impact of those decisions on the educational experiences of middle school mathematics students. We then describe an alternative metaphor, *curriculum as epistemic device*, which is implicitly if not explicitly evident in some curriculum programs, including those developed as a result of National Science Foundation (NSF) funding in the 1990s and 2000s.

Perspective: Curriculum as Tool

In order to explore how curriculum design gets taken up by various stakeholders, we employ a perspective that considers human cognition in terms of action that is mediated by resources and tools situated in particular contexts (Engestrom, 1999; Pea, 1993; Wertsch, 1998). That is, human knowledge and understanding are manifest in action, which is mediated by the available tools and resources in ways that align with a person's goals and purposes. This contrasts with the idea of cognition as something that strictly happens inside the head of individuals and which has universal attributes. The context in which human action / cognition takes place influences the nature and goals of activity, division of labor, mediating artifacts, and discourse channels (Engestrom; Gee, 1999). With respect to curriculum, resources are deployed or mobilized in relation to the characteristics of the teacher and the curriculum program, prior teacher-curriculum interactions, and the curriculum goals of the teacher (Brown, 2009). Given the situated view of cognition from which we operate, we see teachers as curriculum designers, in that they exercise agency as they draw from resources in curriculum programs to design lessons, inevitably altering the resources in ways big and small (Ben-Peretz, 1990; Remillard, 2005).

The nature of curriculum materials influences the actions of the teacher and transforms both the goals and the activities of the teacher, while simultaneously the teacher employs the resources within curriculum programs according to a given history (personal, organizational, and political) and context that mediate how the resources are taken up (Remillard, 2005). Curriculum resources include representations of mathematics, representations of mathematical tasks and instructional activities, articulation of instructional goals, recommendations for lesson structure and requisite materials, and so forth. Because the enacted curriculum is a dynamic and interactive process of co-constructed activity between teachers and students (Ball & Cohen, 1996), curriculum resources are transformed as they are enacted in classrooms, with the enacted curriculum varying in ways both anticipated and unanticipated by the designers or teacher. The intended written curriculum is thus an inert form of curriculum that becomes 'lived' when enacted in classrooms (Guedet, Pepin, & Trouche, 2012).

Methods/Modes of Inquiry

This paper is primary conceptual and theoretical in nature; nevertheless, we describe the process by which we came to consider these metaphors. First, we turned to prior research which suggests that, in most U.S. middle school classrooms, the typical lesson consists of teachers explaining a topic, modeling a particular procedure or skill, and then having the students independently work on sets of problems around that problem or skill, with minimal solving of complex or novel problems (Jacobs, et al., 2006; Stigler & Hiebert, 1999). This pattern reflects the presentation of mathematics in most middle school curriculum materials, which follow a similar explain-model-independent practice-problem solving (predictably applying the skill just practiced) sequence. This pattern also reflects the delivery metaphor.

The curriculum as epistemic device metaphor emerged from a five-year study of teachers using the Connected Mathematics Program (CMP) curriculum program (Lappan et al., 1998, 2006), conducted by the lead author. In this study, two of the teachers used the materials in ways quite distinct from their counterparts (Author, 2009, 2011a, 2011b, 2011c). These two teachers attended closely to student thinking, typically using the initial tasks in an instructional sequence to elicit students' informal reasoning. Subsequent tasks were used to refine and develop students' reasoning and the language used to describe mathematical concepts and relationships. In short, these teachers used the tasks in the curriculum materials as a means of eliciting and refining students' reasoning, language, and strategies.

A current project involving all four authors and a national sample of middle school teachers using materials from six different curriculum programs has provided corroborating evidence that these metaphors can be used to describe the practices of many of these teachers. However, the metaphors needed a stronger conceptual treatment in order to be useful for developing analytic categories to describe teachers' understanding and use of curriculum materials. In order to develop the metaphors, we have been reviewing literature on the history of mathematics curriculum trends in the U.S., on teachers' understanding and use of curriculum materials, and on theories of learning. Our ongoing synthesis of these literatures is presented below.

Dialogic and Monologic Functions of Text

The two curriculum metaphors are distinguished largely by the extent to which their primary goal is to transmit information or to promote dialogue. Wertsch and Toma (1995), citing Lotman's work, discuss the dual functions of text as monologic and dialogic. The monologic function follows the delivery or conduit metaphor (Reddy, 1979, as cited in Wertsch and Toma), in which the main functions of text are encoding, transmission, and decoding. The monologic function is the primary function of curriculum as delivery mechanism, with an implication that messages as encoded in text or curriculum can be delivered with fidelity. Lotman describes the dialogic function of text in terms of text as *thinking device* in which the "main structural attribute of a [dialogic] text is its internal heterogeneity" (Lotman, p. 37, as cited in Wertsch and Toma) and second is that of a *generator of meaning*. Internal heterogeneity refers to the extent to which different approaches or interpretations are afforded. These different approaches or interpretations are generators of meaning when their differences and underlying similarities are made explicit, in the process generating new understanding or meaning in that community. We thus consider that the dialogic function of curriculum materials is to promote *interactions that generate understanding* and consequently emphasize the term interactions rather than dialogue in our discussion below. Although all texts simultaneously have monologic and dialogic functions, Wertsch and Toma (1995) state that "communication models based on the unidirectional transmission of messages cannot be amended in any simple way to deal with the issue of texts as thinking devices" (p. 166), suggesting that there need to be a priori decisions made about which function to emphasize. Thus, curriculum can be thought of as text that primarily serves as a generator of interactions or as a conduit to transmit information or knowledge, with the design situated near one pole or the other.

Two Contrasting Curriculum Metaphors

Below, we unpack each metaphor in terms of its broad historical and epistemological foundations. We then describe how each metaphor is manifest in existing U.S. middle school curriculum programs. We then describe each metaphor in terms of task design, how teachers are positioned, and the underlying principles of curriculum development. First, we discuss the nature of tasks and how they provide opportunities to initiate dialogue and then we describe how teachers are positioned in this metaphor. We conclude with implications regarding learning experiences engendered by materials from each metaphor, the curriculum features essential to each metaphor, and the kinds of teacher understanding entailed by each metaphor.

Curriculum as Delivery Mechanism Metaphor

The first metaphor, *curriculum as delivery mechanism*, speaks to the perspective that the primary goal of curriculum is to transmit information and knowledge. In the U.S., this perspective has a rich and long tradition. Curriculum as delivery mechanism stems from the technical rational approach to curriculum that has been the predominant curriculum perspective over the last century in the U.S. and was first espoused in the early 1900s (Kliebard, 1975). Early adherents to the technical rational (also termed scientific) approach, such as Bobbitt (1918, 1924) and Charters (1923) describe curriculum development as entailing a highly detailed analysis of disciplinary experts' knowledge and performance, rather than activity from the perspective of the child. Rigorous analysis of expert knowledge and task analysis of expert performance ostensibly are performed to identify the discrete bits of knowledge and skills that, when mastered, constitute competence in a discipline (e.g., the mastery perspective). Of this approach Gravemeijer (2004) states:

> Older design principles take as their point of departure the sophisticated knowledge and strategies of experts to construe learning hierarchies… The result is a series of learning objectives that can make sense from the perspective of the expert, but not necessarily from the perspective of the learner. (p. 106)

The discrete bits of knowledge have the added property of being more easily measured than broader, more complex, and consequently ill-defined knowledge (Eisner, 1967). This property extends the appeal of the technical rational approach to those interested in developing psychometric methods to assess student learning and thus to policy makers who wish to use assessments of student achievement data to gauge teacher and school effectiveness (Datnow & Park, 2009).

This approach appeals to modernist notions of scientific advancement by ostensibly employing disciplinary rigor. Although actual attempts to develop curriculum using this approach have been critiqued as impractical and ultimately subjective (Eisner, 1967; Kliebard, 1975), claims of scientifically-based approaches persisted through the 1900s and are currently evident in the marketing of publisher-developed curriculum programs (defined as those programs developed by large publishers, according to perceived market demand) and neo-liberal educational policies related to assessment and accountability. For example, see the debates around the use of terms such as 'scientifically-based research,' 'evidence-based,' 'high-quality,' or 'rigorous' (Darling-Hammond & Youngs, 2002; No Child Left Behind, 2002; Schoenfeld, 2006; U.S. Department of Education, 2002, 2003). Mainly, the modernist or scientific discourse is used to market an approach or product, while the scientific or rigorous nature of the process is rarely explained or examined in detail.

Curriculum development in the technical rational approach embodies the delivery metaphor, in which knowledge can be detached from an authority or expert (i.e., textbook, teacher) and transmitted to the novice learner (student), what Jackson (1986) calls the mimetic tradition. In the technical rational approach, expertise flows directly from the expert or authority to the learner, allowing those far from classrooms to exert control over content (Datnow & Park, 2009), thus minimizing the role of the teacher. Schoenfeld (2006) describes what he terms traditional U.S. curriculum materials in the following way:

> For most of the 20th century, the dominant perspective on learning in most fields, and specifically in mathematics, was that learning is the accumulation of knowledge; that practice solidifies mastery; and that knowledge is demonstrated by the ability to solve particular (well-studied) classes of problems. (p. 15)

The mastery perspective in this metaphor focuses at the scale of lesson or topic, with mastery expected on one topic before proceeding to the next. Furthermore, the transmission approach inherently entails a deficit view of the learner. The curriculum design is based on explaining and modeling concepts and procedures, which presumes that the learner has minimal understanding of the subject matter or intuitive understandings on which to base instruction. The treatment of language in curriculum materials from the delivery metaphor mirrors the treatment of mathematics content. There is typically an emphasis on early formalization and precision, with little validation of less formal or everyday terminology. In general, terms are defined and explained before students have had opportunities to explore the content.

The delivery approach is so pervasive that there is typically a minimal effort to explain the learning model beyond appeal to a mastery perspective. That is, there is little overt description of an instructional philosophy or theory of learning in the curriculum materials, especially publisher-developed programs. Furthermore, authorship of the materials is often anonymous, with only a listing of the experts consulted during the development process. Distinctions between curriculum programs developed through this approach usually entail the scope and sequence of content, the aesthetics of the materials, and the ancillary materials that are emphasized by publishers to market the materials.

Dissatisfaction with materials developed from this perspective has been longstanding, widespread, and multifaceted, with critiques focusing on the passive nature of student activity (National Council of Teachers of Mathematics, 1989), the coherence and rigor of the materials (Schmidt, McKnight, & Raizen, 1997), unexamined issues of power and identity (c.f. Gutierrez, 2002), and the limited role of the teachers as presenters of content (Confrey, et al., 2008). This dissatisfaction has led to numerous attempts to transform mathematics curriculum, including systematic and well-funded efforts, such as those associated with the New Math era and the programs funded by the National Science Foundation in the 1990s.

Curriculum as Epistemic Device

We conceptualize an alternative metaphor as *curriculum as epistemic device*, in which the primary goal of curriculum is to provoke interactions that generate understanding. In this metaphor, the role of tasks in curriculum materials is to provoke and progressively refine student thinking, individually *and* collectively, as opposed to serving as a delivery mechanism for content. This conceptualization of curriculum design builds from a notion of text as *thinking device* that promotes dialogic interaction (Wertsch & Toma, 1995).

A primary characteristic that shapes task affordances in this metaphor is the potential for heterogeneous approaches that vary in terms of their entry points and sophistication, or what has been called *low-threshold, high ceiling* tasks (Myers, Hudson, & Pausch, 2000). Myers and colleagues described software interfaces in terms of being *low-threshold and high ceiling*, meaning that the software was relatively easy to learn at a basic level but could be used to accomplish complex and difficult problems. This idea can be applied to tasks that are accessible to intuitive approaches while also allowing for the possibility of more abstract or symbolic approaches. Comparing intuitive approaches to more abstract or symbolic approaches creates opportunities for making connections that promote conceptual understanding.

Kapur and Bielaczyc provide insights into the dialogic potential or affordances that result from low-threshold, high ceiling tasks (Kapur, 2008; Kapur & Bielaczyc, 2012). Such tasks afford opportunities for students to initially attempt a problem before encountering challenges that require additional personal and collective resources. Kapur and Bielaczyc refer to the phenomenon of allowing students to reach the limit of their current resources and understanding before seeking assistance as *productive failure*. Productive failure typically entails the use of informal approaches and invented representations or over-generalized application of previous skills that are eventually contrasted with properties of more productive representations or efficient approaches, which helps students to better understand the conceptual properties of a given representation or approach. Students who were allowed to reach productive failure on complex tasks called on their individual and collective epistemic resources in ways that helped them connect their evolving mathematical understandings to more conventional and efficient representations and approaches. Students' *epistemic resources* include their intuitive forms of reasoning, their invented representations, and informal language (Hammer, Elby, Scherr, & Redish, 2005; Kapur & Bielaczyc, 2012).

The discussion above emphasizes the emergent and localized construction of knowledge that is associated with dialogic curriculum and instruction. When tasks promote interactions that generate sense-making and afford opportunities for students to draw on and coordinate their epistemic resources, local and idiosyncratic forms of knowledge are more likely to be emphasized as sense-making resources. This process has been conceptualized as *knowledge building* by Scardamalia and Bereiter (2006). They state that schools should focus on the emergent and collective development of understanding in a knowledge-building community so that student thinking is viewed in terms of its epistemic value – its ability to advance the knowledge of the community. This contrasts with the process of evaluating student thinking with respect to conventional knowledge, as is typically done in classrooms. The emergent and collective development of understanding in a knowledge-building community is facilitated when participants see how their ideas build from one another and how they are positioned with respect to more conventional or expert knowledge. Students' solutions serve as e*pistemic artifacts* (Sterelny, 2005, as cited in Scardamalia and Bereiter) that serve to advance the understanding of mathematics in the classroom community.

In summary, the metaphor of curriculum as epistemic device focuses on the dialogic affordances of tasks that offer the potential for interactions that promote understanding through their accessibility, ambiguity, and connections to big mathematical ideas. These low-threshold high-ceiling tasks allow for students to draw on their epistemic resources in ways that contribute to the collective and emergent development of mathematical understanding. This stands in contrast with the more remote authority manifest in the transmission or delivery metaphor.

In this metaphor, teachers are positioned as orchestrators of mathematical discussions (O'Connor & Michaels, 1996). In order for the dialogic affordances of tasks to be mobilized, teachers need to recognize the heterogeneous approaches and the relations between those approaches in order to support the development of dialogue around those approaches. Furthermore, teachers need to understand how student reasoning develops across instructional sequences, which stands in contrast to the much more local conception of mastery in the delivery metaphor. Similarly, students are positioned as active intellectual contributors with challenging *epistemic roles* (O'Connor & Michaels, 1993, 1996).

The development of curriculum in this metaphor departs from the technical-rational or scientific approach in the delivery metaphor. Gravemeijer (1994) describes curriculum development as integrating elements of research and design, in part by conducting design experiments that inform the development of curriculum materials. These design experiments (Cobb et al., 2003) focus on developing *local instruction theories* (Gravemeijer, 2004) that are situated within particular instructional sequences. The instructional sequences are enacted in classrooms, generating data and insights that are used to revise the sequence. This process involves intensive observations of how student thinking is elicited and refined over the sequence, positioning students as key resources not only in classroom enactments but also as dynamic agents in the design experiment. Another feature of curriculum development is the notion of *progressive formalization* (Bransford, et al., 2000) in which instruction elicits and builds from students' informal or pre-formal thinking, which is then progressively refined toward more formal mathematical representations and terminology. Gravemeijer argues that teachers' ability to recognize and build from student thinking is related to their understanding of how that thinking is situated within a broader instructional sequence.

The curriculum as epistemic device approach is based on interactions that promote sense-making or understanding, which inherently involves heterogeneous voices (Wertsch & Toma, 1995), including those based in everyday or informal language. The instructional sequences provide opportunities for this language to be revisited and revised, and a primary role of the teacher is to facilitate the process of language development. Thus, the view on language development in this metaphor contrasts sharply with the delivery metaphor.

Conclusion

We elaborate two metaphors, in part to draw distinctions between two approaches historically evident in U.S. middle school mathematics curriculum materials but also to develop an analytic lens for looking at new materials and technologies related to the rapid and comprehensive move to digital forms of curriculum resources. In many cases, new digital materials have intensified features that follow the delivery metaphor and accompanying technical rational basis. A few prominent programs, such as Khan Academy, deliver mathematical explanations in new platforms, while others situate traditional content in learning management systems (Author, 2014). Few programs as yet provide the potential to elicit and make public student thinking in ways that utilize those approaches as epistemic devices in classrooms.

Moving forward, it will be important to analyze curriculum programs and enactments of those programs with respect to which metaphor prevails. Given the emphasis on knowledge creation in civic and economic life, it is imperative that curriculum resources and associated instructional systems help teachers recognize and build from student thinking in mathematically productive ways.

GENERALIZING AVERAGE RATE OF CHANGE FROM SINGLE- TO MULTIVARIABLE FUNCTIONS

Allison Dorko
Oregon State University
dorkoa@onid.oregonstate.edu

This paper explores students' ways of thinking about the average rate of change of a multivariable function and how they generalize those ways of thinking from rate of change of single-variable functions. I found that while students thought about the average rate of change of a multivariable function as the change in the independent quantity with respect to the changes in the dependent quantities, they had difficulty determining a process to assign a value to that rate of change. Most tried to represent the average rate of change as a singular expression, generalizing the Δy/Δx expression to create expressions of the form Δz/[Δx and Δy], yet did not appear to have a sense of what they believed they were measuring. This suggests that quantitative reasoning, or lack thereof, was at the heart of the students' generalizations .A pedagogical implication of this research is that students' natural tendency to try to determine a singular expression for the average rate of change of a multivariable function could serve as useful as motivating the need to hold a variable fixed.

Keywords: Advanced Mathematical Thinking; Cognition; Post-Secondary Education

Introduction

While it is clear to experts how multivariable calculus topics are mostly natural extensions of single-variable calculus topics, how students come to see the relationship between ideas like function and rate of change in single- and multivariable calculus is not well understood. Though some recent advances have been made with regard to student thinking about these ideas, these studies are only preliminary (Kabael, 2011; Martinez-Planell & Trigueros, 2013; Trigueros & Martinez-Planell, 2010; Yerushalmy, 1997). Multivariable functions are used extensively in the sciences, engineering, statistics, and higher mathematics. It is imperative that we learn more about student understanding of multivariable functions, as they serve as the foundational tools by which students make sense of and represent relationships between quantities in complicated systems in these fields. I focus in particular on average rate of change in three dimensions for two reasons. First, a coherent image of it is necessary to understand the mathematical construction of instantaneous rate of change. While average rate of change (e.g. average speed) exists in the real world, instantaneous rate of change is a mathematical construction that relies on anticipating the result of taking averages rates of change over infinitesimally small intervals. Second, since multivariable calculus topics like rate of change build on single-variable calculus topics, I think it is important to study students' understanding of the multivariable topic with respect to their understanding of its single-variable counterpart. That is, I focus on how students generalize ideas, which yields insight into both what students understand about a new idea and how they use prior knowledge in the process of making sense of new content. To address these two aims, I sought to answer the following research question: *How do students think about the average rate of change of a multivariable function and how is this generalized from their understanding of the average rate of change of a single-variable function?*

Background Literature

Findings from literature indicate many difficulties that students have understanding rates of change. Thinking about rate of change as a measurement of how fast quantities are changing is foundational to calculus, yet many students have difficulty reasoning about rate in this way (Rasmussen, 2001; Thompson & Silverman, 2008). Thompson (1994) proposed that understanding constant rate of change depends on coordinated understandings of respective accumulations of accruals in relation to total accumulations. The understanding of constant rate of change he described entails quantities having covaried (Saldanha & Thompson, 1998; Thompson, 2011). This is not at all obvious to students. Rather, some students interpret the average rate of change of a single-variable function as the arithmetic mean of some number of instantaneous rates of change (Bezuidenhout, 1998; Dorko & Weber, 2013). Students may also struggle with computing $\Delta y/\Delta x$ to estimate the rate of change of linear and non-linear functions (Orton, 1983). Thompson (1994) and Zandieh (2000) have suggested that these difficulties may be attributed to not conceiving of rate of change as a ratio, but instead thinking of it as the steepness of a function.

To the author's knowledge, there are two studies about students' thinking about slopes and rate of change in three dimensions. McGee and Moore-Russo (2014) found that at the beginning of instruction about slope in three dimensions, students asked to determine the slope between the points (1,2,1) and (3,2,5) computed $m = \Delta y/\Delta x$. Some of these students found it difficult to understand that this formula did not work in three dimensions. Once students accepted that $m = \Delta y/\Delta x$ did not work in three dimensions, they agreed that the "rise" of the slope should be Δz, but were not sure what the "run" was. Weber (2015) also investigated how students conceived of rate of change in three dimensions, and found that students often sought a way to combine the rates of change of two independent quantities into a single rate of change. My work extends these studies' findings by focusing on students' generalizations of rate of change in addition to their conceptions of it.

Theoretical Perspective

My theoretical perspective drew from two sources, both with constructivist underpinnings. First, I used Ellis' (2007) framework for studying generalization. She defines generalization as the influence of prior activity on novel activity, even if the student's action in the new activity is not mathematically correct. It is important to note that by framing my work in terms of Ellis' framework, I implicitly adopt an actor-oriented perspective (Lobato, 2003) for characterizing students' ways of thinking, which sets aside normative notions of correctness and allows us to focus on *how* students make sense of a situation rather than the *outcome* of that sense-making. Ellis' framework characterizes students' generalizing activity in terms of *generalizing actions* and *reflection generalizations*, which we explain later in the methods. Second, I drew from Thompson's (1990) work on quantitative reasoning, which characterizes a specific way of conceiving of situations. Two key ideas from his work that I draw on here are quantity (a measurable attribute of an object), and quantification (the process of assigning a value to that attribute), which help to explain the different meanings for average rate of change that students generalized, and the different ways in which they attempted to calculate average rate of change.

Data Collection and Analysis

I conducted hour-long semi-structured interviews with eleven students currently enrolled in integral calculus at a large university in the Pacific Northwest. While eleven students is not a particularly large sample size, I believe that these results have what Maxwell (1996) calls *face generalizability*, or there is "no obvious reason *not* to believe that the results apply more generally" (p. 97, emphasis original). That is, even a case study of a few students is likely to generate results that apply more generally. Interviews were recorded with LiveScribe technology, which gives a synched record of students' written work and talk. Interviews were subsequently transcribed for use in coding. In this paper, I focus on students' responses to the following two tasks:

[Q1] Let $V(\mathrm{s}) = s^3$ represent the volume of a cube. What is the average rate of change of the volume of the cube if the length of its sides increases by one?

[Q2] Let $A(\mathrm{L,W}) = LW$ represent the area of a rectangle. What is the average rate of change of the area of the rectangle if the length increases by one and the width increases by two?

I chose area and volume as contexts for talking about average rate of change because I hypothesized that they would be novel contexts and hence allow me to observe students in the process of generalizing. If students became stuck, I asked them one or both of the following problems, which we thought would be more familiar:

[QA] What is the average rate of change of $f(x) = x^2$ over the interval [0,5]?

[QB] Suppose you are in a car and you travel from mile 324 to mile 360 in one hour. What is your average speed?

The V(s) and f(x) function tasks (and other similar area and volume tasks not reported on here) allowed me to observe how students thought about the average rate of change of a single-variable function, while the $A(L,W) = LW$ task (and other similar area and volume tasks not reported on here) allowed me to observe how students thought about the average rate of change of a multivariable function. Comparing students' responses from the single-variable to the multivariable tasks allowed me to analyze how students generalized their thinking about average rate of change from one setting to the other.

I used Ellis' (2007) generalization taxonomy as an analytic framework. This taxonomy distinguishes between *generalizing actions*, or students' mental activity as they generalize as inferred through their activity and talk, and *reflection generalizations,* or students' final statements of generalization. In this paper, I focus only on students' generalizing actions (Table 1) because these reveal student thought during the process of understanding a situation, while reflection generalizations are often summary statements of a generalization. Analysis consisted first of reading the transcripts and coding instances of generalization. I then re-read those instances, and coded them based on the categories shown in Table 1. Due to space limitation, I give examples for only the categories that appeared in this study. The examples in Table 1 are from Ellis' (2007b) paper.

Table 1. Ellis' Generalization Taxonomy (adapted from Ellis, 2007a; 2007b) (Ellis, 2007)

Generalizing Actions		
Type I: Relating	1. Relating situations: The formation of an association between two or more problems or situations.	Connecting back: The formation of a connection between a current situation and a previously-encountered situation. (Example: Realizing that "this gear problem is just like the swimming laps problem we did in class!")
		Creating new: The invention of a new situation viewed as similar to an existing situation.
	2. Relating objects: The formation of an association between two or more present objects.	Property: The association of objects by focusing on a property similar to both. (Example: Noticing that two equations in different forms both show a multiplicative relationship between x and y).
		Form: The association of objects by focusing on their similar form. (Example: Noticing that "those two equations both have one thing divided by another")
Type II: Searching	1. Searching for the same relationship: The performance of a repeated action in order to detect a stable relationship between two or more objects.	
	2. Searching for the same procedure: The repeated performance of a procedure in order to test whether it remains valid for all cases.	
	3. Searching for the same pattern: The repeated action to check whether a detected pattern remains stable across all cases.	
	4. Searching for the same solution or result: The performance of a repeated action in order to determine if the outcome of the action is identical every time.	

Type III: Extending	1. Expanding the range of applicability: The application of a phenomenon to a larger range of cases than that from which it originated. (Example: Having found that the difference between successive y-values is constant for $y = \mathrm{m}x$ equations, applying the same rule to $y = \mathrm{m}x + \mathrm{b}$ equations)
	2. Removing particulars: The removal of some contextual details in order to develop a global case.
	3. Operating: The act of operating upon an object in order to generate new cases.
	4. Continuing: The act of repeating an existing pattern in order to generate new cases.

Results

I found that students primarily thought about the average rate of change as a ratio of changes (the measurement process or quantification), which measured some aspect of an object (either the graph or the growing rectangle). The students made sense of the average rate of a multivariable function by connecting back to prior situations; expanding the range of applicability of average rate of change as the ratio of the change in the independent quantity with respect to the change in the dependent quantity; and relating objects based on their form and property. For example, V6 tried to create an expression to represent her understanding of the average rate of change as meaning "how much is the area growing in regards to the changes in the length and the width". V6 struggled with what to put in the denominator of the expression, and concluded that 3 (the sum of ΔL and ΔW) made sense (Figure 1). The crossed-out part in V6's work is $[(L+1) - L] + [(W+2) - W]$, which indicates that she sought to make an expression of the form ΔA/[an expression she believed combined ΔL and ΔW]. After telling the interviewer that having two different variables was confusing her, V6 crossed out her first expression and wrote 3 because "the total change you're adding one to the length and two to the width and so the total change is three". It was unclear whether she recognized that her original denominator simplified to 3, or if she were not paying attention to that expression and instead thinking about a way to combine ΔL and ΔW.

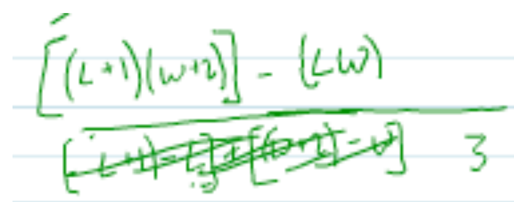

Figure 1: V6's Average Rate of Change of A(L,W)

V10 also constructed an expression of the form ΔA/[an expression she believed combined ΔL and ΔW], choosing to put coordinate pairs in the denominator (Figure 2). She began by writing what she believed to be the expression for the average rate of change of $f(\mathrm{x})$ [see top left of Figure 3] and then tried to construct a version for the average rate of change of $f(\mathrm{L,W})$ [top right of Figure 3], saying "I guess it would just translate over into two variables like that." This statement indicates that she related average rate of change in 2D and average rate of change in 3D as similar situations, and the arrow between the expressions indicates generalization based on the expressions' form (relating objects: form; see Table 1). The lower half of Figure 3 shows V10's attempt to determine an average rate of change for some actual length and width measures (it was unclear why she switched from multiplying the length and width in the crossed-out [(9)(5)] – [(8)(4)] to adding the dimensions in [(9 + 5)] – [(8 + 4)]). It is also unclear why V10 wrote $f'(\mathrm{x}_1)$, $f'(\mathrm{x}_0)$, $f'(L_1,W_1)$, and $f'(L_0,W_0)$, but used $f(L_1,W_1)$ and $f(L_0,W_0)$ in her computation. Other students also thought that average rate of change involved derivative values rather than function values. One student (V11) explained, "I envision derivatives when anything involving change occurs."

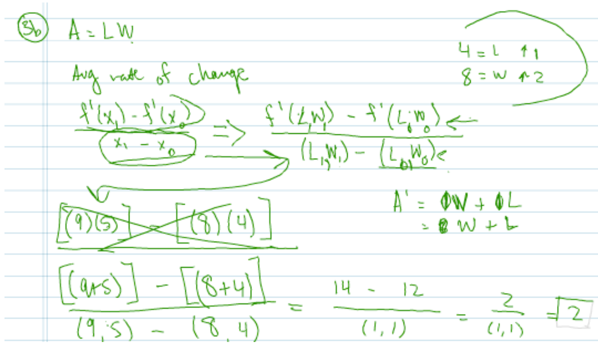

Figure 2: V10's Average Rate of Change for the Area of the Rectangle

While most students identified the average rate of change as meaning the change in area with respect to the change in the length and the width, V10 was the only student who came close to explaining that average rate of change is a *constant* rate. She said

> *V10*: A rate of change would be like at, like at any point it could be a different rate of change, I guess, and then the average rate of change would be more just like the mean rate of change. So like even if they, there might be some different, like some difference, some small difference between every point, you could take the average to try to predict a certain amount to add every time.

I interpret V10's comment about finding 'a certain amount to add every time' as evidence of thinking of average rate of change as a constant rate.

Discussion

Recall that I sought to answer the following question: How do students think about the average rate of change of a multivariable function and how is this generalized from their understanding of the average rate of change of a single-variable function? I found that students think of the average rate of change of a multivariable function as involving changes in three different quantities, and that they attempt to find a single expression to represent it. They generalize the form Δy/Δx to Δz/[a combination of Δx and Δy]. Weber (2015) also found that students' first inclination for the rate of change of a multivariable function is to combine the rates of change of the independent variables.

There is not sufficient evidence to claim that the students think about the average rate of change of a function (multivariable or not) or as a quantification of how variables vary. Indeed, they primarily focused on the structural aspects of calculating the rate of change. Very few students hinted at any notion of many variables varying simultaneously, or that the average rate of change is a constant rate of change. This finding further suggests that rate of change, average or instantaneous, is not about the variation in quantities for students, which led to some of the surprising approaches they used to "find" the average rate of change. In many cases, the students did not have a robust enough image average rate of change as a measure of covarying quantities to support the important conceptual issues one encounters in measuring rate of change in three dimensions.

My finding that students attempted to find the average rate of change of A(L,W) by creating a three-space version of $\Delta y/\Delta x$ is similar to McGee and Russo's (2014) finding that students initially try to find the slope between (x_1, y_1, z_1) and (x_2, y_2, z_2) by computing $m = \Delta y/\Delta x$. A difference is that McGee and Russo's students ignored the z coordinate entirely, while our students created expressions of the form Δz/[some combination of Δx and Δy]. In both cases, however, students tried to leverage their understanding of the 3D scenario by connecting back to their knowledge of slope in 2D. They paid particular attention to the structure of slope as a change in one variable divided by the change in a second variable, and tried to create an expression analogous to $\Delta y/\Delta x$. While this study only reports on the behavior of eleven students, that my finding is similar to what McGee and Moore-Russo (2014) observe supports that the way the students in this study thought and acted with respect to multivariable functions may be representative of students in general.

Students' search for a single expression was largely generalizing by *relating objects* (see Table 1). Generalization by focusing on objects seems to play an important role in students' thinking not only in this setting, but in other cases in which students try to generalize an idea from a familiar $f(x)$ context to the unfamiliar $f(x,y)$ context (e.g., Dorko & Weber, 2014). I hypothesize two reasons for students' attempts to create a single expression. One is that before multivariable calculus most of the concepts students deal with can be represented by a single expression or formula (piecewise defined functions being one exception). I hypothesize that students thus come to expect that there exists one expression for everything. A second reason is that students may not have considered the implications of being in three-space, namely that having two independent variables often necessitates holding one variable constant so that one can talk about the change in the other variable. Supporting this hypothesis, Kabael (2011) found that students' schema for R^3 is critical for their construction of multivariable functions. I think that students' experience in trying to determine what went in the denominator of their expressions could be pedagogically useful as motivating the need to hold a variable fixed. That is, instructors could begin instruction about rates of change of multivariable functions by giving students tasks such as the ones used in this study, letting students discover that it is difficult to talk about two changes at once, and then introduce the idea of talking about a rate of change in a direction. An additional pedagogical implication for precalculus courses and lower-division mathematics is to find other situations in which a single expression is inadequate. This might prevent students from coming to believe that there exists a single equation that describes any given situation.

Regardless of students' difficulty determining what to put in the denominator, it is notable that students tried to compute such an expression in the first place. That is, thinking of the average rate of change as the change in the function values over the changes in the independent variables indicates that multivariable calculus students conceive of average rate of change as a ratio, an understanding that is not always present in single-variable calculus students (Orton, 1983; Thompson, 1994; Zandieh, 2000). In particular, students in this study did not talk about rates of change as "steepness". That students in this study largely generalized their understanding of average rate of change based on the notion of rate-as-ratio reinforces the importance of students developing a robust understanding of slope as a ratio in algebra.

The multiplication principle is a fundamental principle in enumerative combinatorics. It underpins many of the counting formulas students learn, and it provides much-needed justification for why counting works as it does. However, given its importance, the way in which it is presented in textbooks is surprisingly varied. In this paper, we document this variation by presenting a categorization of statement types we found in a textbook analysis. We also highlight mathematical and pedagogical implications of the categorization.

Keywords: Advanced Mathematical Thinking; Curriculum Analysis; Post-Secondary Education

Introduction and Motivation

Consider the following three statements of the multiplication principle[1](MP), seen in Figures 1, 2, and 3. Given that these statements are all meant to describe the same fundamental issue in counting, a number of questions naturally arise. Does Mazur's statement include anything that Roberts and Tesman's does not? Is Bona's set-theoretic statement equivalent to the others? If so, what are pedagogical consequences of such variation? These questions serve as motivation for better understanding how the MP is presented in the current generation of textbooks and what implications such varying formulations might respectively entail. In this paper, we report on a textbook analysis in which we examined statements of the MP, providing a categorization of statement types intended to illuminate mathematical and pedagogical issues related to the MP.

> ***Product Rule:*** *If something can happen in n_1 ways,* ***and*** *no matter how the first thing happens, a second thing can happen in n_2 ways,* ***and*** *no matter how the first two things happen, a third thing can happen in n_1 ways,* ***and*** *..., then all the things together can happen in $n_1 \times n_2 \times n_3 \times \ldots$ ways.*

Figure 1: Roberts & Tesman's (2003) statement of the MP

> ***The Product Principle:*** *In counting k-lists of the form (l_1, l_2, ...,l_k), if*
> 1. *there are c_1 ways to specify element l_1 of the list, and each such specification ultimately leads to a different k-list; and*
> 2. *for every other list element l_i, there are c_i ways to specify that element no matter the specification of the previous elements l_1,...,l_{i-1}, and that each such specification of li ultimately leads to a different k-list,*
>
> *then there are $c_1c_2...c_k$ such lists.*

Figure 2: Mazur's (2009) statement of the MP

> ***Generalized Product Principle:*** *Let $X_1, X_2, \ldots, X_k$ be finite sets. Then the number of k-tuples (x_1, x_2,...,x_k) satisfying $x_i \in X_i$ is $|X_1| \times |X_2| \times \ldots \times |X_k|$.*

Figure 3:Bona's (2007) statement of the MP

TheMP is a fundamental aspect of combinatorial enumeration. It is generally considered to be foundational to many of the major counting formulas students learn and is called by some "The Fundamental Principle of Counting" (e.g., Richmond & Richmond, 2009). Mazur (2009) notes that the MP is "quite flexible and perhaps the most widely used basic rule in combinatorics" (p. 5). Even more, the MP can provide a much-needed source of justification for why many common counting formulas work as they do. For key concepts in other domains (such as limit, derivative, the fundamental theorem of arithmetic, etc.), there tend to be clear, agreed upon, consistent definitions provided in textbooks. However, we have found in our experiencethat textbooks vary widely in how they present the MP. Given the importance and the prevalence of the principle, and given the apparent lack of consistency with which it is presented, we decided to study how the MP is treated in a sample of postsecondary Combinatorics, Discrete Mathematics, and Finite Mathematics textbooks. We answer the following research questions:

1. How is thestatement of the multiplication principle presented in postsecondary Combinatorics, Discrete Mathematics, and Finite Mathematics textbooks?
2. What mathematical issues arise in comparing and contrasting different statements of the multiplication principle?

Literature Review

Counting Problems are Important but are Difficult to Solve

Counting problems foster rich mathematical thinking, and they have a number of important applications. However, correctly solving counting problems is challenging, and there are many studies that report on students' difficulties with counting (e.g., Batanero, Navarro-Pelayo, & Godino, 1997; Eizenberg & Zaslavsky, 2004; Hadar & Hadass, 1981). Brualdi (2004) says, "The solutions of combinatorial problems often require *ad hoc* arguments sometimes coupled with use of general theory. One cannot always fall back onto application of formulas or known results" (p. 3). Within the last couple of decades, a number of researchers have investigated reasons for students' difficulties and have made progress toward better understanding students' combinatorial reasoning and activity (e.g., Eizenberg & Zaslavsky, 2004; English, 1991; 1993; Maher, Powell, & Uptegrove, 2011; Tillema, 2013). In spite of such work, however, student difficulties with counting persist.

There is a growing body of research suggesting that students may benefit from explicitly thinking about the outcomes they are trying to count. Lockwood (2014) has proposed a set-oriented perspective toward counting, which entails viewing the activity of solving counting problems as inherently involving structuring and enumerating a set of outcomes. The work herein contributes to current literature that frames sets of outcomes as an indispensable aspect of students' counting. In addition, previous work (Lockwood, Swinyard, & Caughman, 2015) has demonstrated the importance of the MP in counting, and the lack of a well-developed understanding of the MP appeared to be a significant problem and hurdle for the students. It is important to note that the MP as a principle of counting is different than the operation of multiplication. We have found in our experience that students can easily assume that they completely understand the MP in counting because multiplication is a familiar operation for them. As a result, they use the operation frequently but without careful analysis, and they tend not to realize when simple applications of multiplication are problematic. We are concerned by the lack of attention students give to the MP, and we argue that the MP is worthy of further investigation. While some researchers have discussed multiplication within combinatorial contexts (Tillema, 2013), there have not yet been studies that explicitly target the MP, and more attention must be paid to the role of multiplication *in counting*.

Textbook Analyses as Insight into How Concepts are Presented

According to Thompson, Senk, and Johnson (2012), "Begle (1973) found that the textbook is 'the only variable that on the one hand we can manipulate and on the other hand does affect student learning' (p. 209)" (p. 254). Thompson et al., go on to point out that textbooks "help teachers identify content to be taught, instructional strategies appropriate for a particular age level, and possible assignments to be made for reinforcing classroom activities" (p. 254). In light of this, a number of researchers have examined textbooks in order to get a better sense of how ideas are presented to students (e.g., Mesa, 2004). At the post-secondary level, this has been seen in the domain of linear algebra (Cook & Stewart, 2014; Harel, 1987), trigonometry (Mesa & Goldstein, 2014), and abstract algebra (Capaldi, 2013). We follow such researchers in using textbooks to gain insight into how mathematical ideas are presented. A potential limitation of this study is that we are simply looking at textbooks, and we cannot make claims about how ideas in textbooks are actually taught to students by an instructor or are understood by students. Nonetheless, a textbook analysis provides an efficient snapshot of how experts in the field of combinatorics define and frame a foundational concept like the MP.

Theoretical Perspective

Structural vs. Operational Conceptions

In Sfard's (1991) presentation of the dual nature of mathematical conceptions, she highlights a relationship between structural and operational conceptions. This dual nature is reflected in the idea that mathematical conceptions can, on the one hand, be considered as *objects* (a structural conception), but that those same conceptions might also be able to be thought of as *processes* (an operational conception). It is interesting that, in her original descriptions of these ideas, Sfard mentions an analysis of textbook definitions:

> The careful analysis of textbook definitions will show that treating mathematical notions as if they referred to some abstract *objects* is often not the only possibility. Although this kind of conception, which from now on will be called *structural*, seems to prevail in the modern mathematics, there are accepted mathematical definitions which reveal quite a different approach. (p. 4, emphasis in original)

Sfard goes on to say that "The latter type of description speaks about *processes, algorithms, and actions* rather than being about objects. We shall say therefore, that it reflects an *operational conception* of a notion" (p. 4, emphasis in original). Sfard (1991) also emphasizes the complementary relationship between the structural and operational conceptions, noting that, "the ability of seeing a function or a number both as a process and as an object is indispensable for a deep understanding of mathematics, whatever the definition of 'understanding' is" (p. 5). This suggests that there could be benefits to having both structural and operational notions of a concept like the MP, something we address in our results and discussion.

Methods

In order to create a broad list of textbooks that were used in postsecondary Finite Mathematics, Discrete Mathematics, and Combinatorics courses, we compiled a list of universities in the union the top 25 ranked universities, the top 25 ranked graduate mathematics programs, the top 10 ranked liberal arts colleges, and the universities with the 10 largest undergraduate populations (National Universities Rankings, n.d., Math, n.d., and National Liberal Arts Colleges Rankings, n.d., respectively). This represented 52 schools in 26 states. We then identified and added to the list the largest university in the remaining 24 states. In total, we surveyed 76 universities representing all 50 states and including some of the top universities in the country.[2]

For each of these 76 universities, we identified courses from the university catalogs and found titles of the required texts from the department's website, the university bookstore, or online course pages. We found textbooks from 70 of these universities. In total, we found three textbooks from one university, two textbooks from 22 universities, and one textbook from 47 universities. We thus identified textbooks for a total of 94 courses at these 70 universities. Multiple universities used many of the textbooks, and so this search yielded a total of 32 textbooks. We also examined relevant textbooks within our own personal and university libraries, and this added 32 textbooks not yet on the list. Therefore, in total we had a set of 64 textbooks, which both provides a sense of how students are being exposed to the MP and also gives a relatively comprehensive picture of ways in which the MP is presented in textbooks. Our analysis and results are based on all 64 of these textbooks. Six textbooks did not include a statement of the MP, and some textbooks included multiple statements, and thus we analyzed a total of 73 statements of the MP in these 64 texts.

Analyzing the Textbooks. Once the list of textbooks was compiled, we digitally scanned the sections of each text that introduced the multiplication principle, including any worked examples and *narratives* (the text surrounding the principle, see Thompson, et al., 2012) that accompanied the statement itself. The authors each independently examined the narrative portion of the texts, including the statements of the MP and any worked examples, recording phenomena and developing categories for what we observed. This is in line with Strauss and Corbin's (1998) constant comparative method of qualitative analysis, where our data consist of the textbook sections. Following the creation of codes, for the sake of reliability, each author analyzed the entire set of texts separately, and we then met and discussed all of the codes until consensus was reached. We also addressed our second research question by more deeply examining mathematical properties of the statements via carefully reviewing and discussing the statements.

Results

Due to space, we share only two aspects of our findings. In this section, we first provide a categorization of statements of the MP (which resulted from investigating the extent to which statements themselves reflect structural versus operational conceptions) and report on the frequencies of statement types. Then, we demonstrate the value of this categorization by highlighting a mathematical implication that emerged from an articulation of the statement types.

Structural versus Operational Conceptions Reflected in the Overall Statements of the MP

Drawing heavily on Sfard (1991), we found that the statements of the MP could be categorizedinto three types: *structural statements*, *operational statements*, and *bridge statements*. Broadly, these three statement types differ in terms of what they state the MP is counting. Structural statements characterize the MP as counting objects (without specifying a process to construct those objects), while operational statements characterize the MP as counting ways to complete a process (without specifying the outcomes of that process). Bridge statements provide a link between the two – they frame the MP as counting objects, but they also specify the counting process that would generate the objects. Thus, in order to code the statements, we looked to see how the statement frames what the MP is counting. Table 2 provides the codes, what we took to be criteria for a statement to receive that code, and an example of a textbook whose statement reflects that code.

Table 2: Criteria for Statement Types

Code	Criteria
Structural	The statement characterizes the MP as involving counting objects (such as lists or *k*-tuples)
Operational	The statement characterized the MP as determining the number of ways of completing a counting process
Bridge	The statement simultaneously characterizes the MP as counting objects and specifies a process by which those objects are counted

Structural Statements. To be coded as a structural statement, a statement had to describe counting a set of objects, without any mention of a process that would generate that set. For example, notice that Bona's structural statement (Figure 3) has characterized the MP as a statement about *k*-

tuples (ordered sequences of length k), which are objects with an inherent structure. The MP describes the total number of k-tuples from k sets, and it is simply expressed by product of cardinalities of k sets. There is no connection made between those k-tuples and a process that would generate them; the statement is simply presented set-theoretically.

Operational Statements. In contrast to Bona's structural statements, the operational statements frame the MP not as counting structural outcomes, but rather as counting ways of completing a process (and a process is clearly articulated in the statement). Roberts and Tesman (2003) provide a statement (Figure 1) that we coded as *operational*, describing the MP in terms performing a task with t successive operations, and the MP provides the number of ways of completing a task. Notice that the nature of what is being counted – the result of the MP is not the number of objects, but rather it is the number of ways of completing a process. Note these two types of statements naturally reflect the duality between structural and operational conceptions that Sfard (1991) proposes. We also note that some textbooks provided both structural and operational in their narratives.

Bridge Statements. A statement like Mazur (Figure 2) on the one hand reflects a structural framing of the MP (the objects being counted are k-lists), but the statement also explicitly describes an operation for how to construct those objects. Such statements, which we call bridge statements, simultaneously both count objects and describe a process by which to count or construct those objects. In Mazur's case, the k-listshe describes are the same object as Bona's (2007) k-tuples. However, unlike Bona, notice that Mazur (Figure 2) describes an operational process that explains how to generate the objects (k-lists) that are being counted – specifically, he describes, "there are c_1 ways to specify element l_1 of the list." The presence of this explicit connection between the structural and operational framings of the statement led us to code this statement by Mazur as a bridge statement.

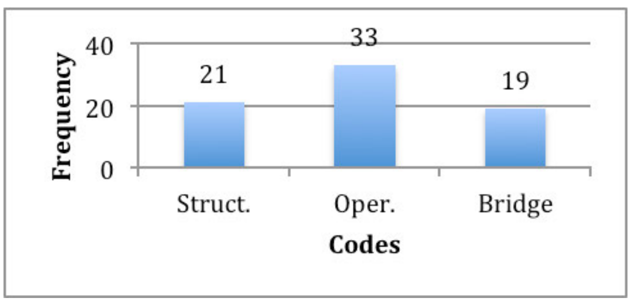

Table 3: Frequencies of structural, operational, and bridge statements (n = 73)

Frequencies. For coding statements at this level, the unit of analysis was a statement of the MP. For any given formulation of a statement, the codes of *structural, operational*, and *bridge* are mutually exclusive, so a statement was coded with exactly one of these codes. Because some textbooks had multiple statements (while some did not include statements), we coded a total of 73 statements across the 64 textbooks. Table 3 shows the respective frequencies of structural, operational, and bridge statements, using the total number of statements as the total frequency.

From Table 3, we observe that operational statements were the most frequent, comprising 45% of the total statements, but each type of statement was represented. These findings convey the variation among statements, supporting the notion that this fundamental counting idea is not presented consistently across textbooks. Through our analysis we also found wide variation in the language used among statements and the representations that accompanied statements, although we do not share those findings here due to space.

Mathematical Implications of Different Statement Types

In this section we address one mathematical implication of different statement types, making a case for what we might gain from a categorization of statement types. As we have noted, the majority of the statements in textbooks are operational, framing the MP in terms of counting the number of ways of completing counting processes that have some number of successive stages. A significant issue with these statements is that they make no claim about whether that total number of ways to complete the process are in a one-to-one correspondence with the desirable set of outcomes, and in fact they make no explicit connection to the overall outcomes of the procedure at all. Given our prior focus on sets of outcomes and their importance (e.g., Lockwood, 2013; 2014), the lack of explicit attention to outcomes is concerning.

For example, Roberts and Tesman's (2003) statement (Figure 1) is strictly operational, and we see that the MP yields the number of ways for "all the things together" to happen, but the statement says nothing about the total number of outcomes. We contrast this with Tucker's bridge statement (Figure 4), which describes a process by which to generate outcomes, not the number of ways to complete the process. In fact, Tucker goes so far as to state that, as a condition of implementing the MP, the "distinct composite outcomes must all be distinct."

> ***The Multiplication Principle:*** *Suppose a procedure can be broken down into m successive (ordered) stages, with r_1 different outcomes in the first stage, r_2 different outcomes in the second stage, …, and r_m different outcomes in the mth stage. If the number of outcomes at each stage is independent of the choices in the previous stages, and if the composite outcomes are all distinct, then the total procedure has* $r_1 \times r_2 \times \ldots \times r_m$ *different composite outcomes.*

Figure 4 – Tucker's (2002) statement of the MP

In many simple problems, using a strictly operational statement type is not problematic, and any differences between the operational and bridge statements may seem immaterial. For instance, consider the question "*Suppose we flip a coin 10 times in a row. How many possible ways are there to do this?*" Here, we can solve the problem by thinking of ten successive, ordered stages, and each stage has two different possibilities (heads or tails). For both statements, the product that yields the total number of ways for "all the things to happen together" (Roberts and Tesman) is the same as the number of the total "different composite outcomes of the procedure" (Tucker). This "Coin Flips" problem is one in which both types of statements can be applied and yield the correct answer to the counting problem. The number of ways to complete the procedure is in a one-to-one correspondence with the number of desirable outcomes.

However, not all counting problems can be solved in such a straightforward manner. To detail our discussion of this issue, we turn to a "Words" problem presented by Tucker (2002, p. 172): *How many ways are there to form a 3-letter word using the letters a, b, c, d, e, and f, if the word must contain e and repetition of letters is allowed?* In applying an operational statement, we note that the first "thing" that will happen is to decide where to put the *e* that must be in the password, and there are 3 choices for this (the first, second, or third position of our word). The second "thing" is to choose a letter for the leftmost available position, and there are 6 choices, because repetition of letters is allowed. Then, the third thing to do is to choose a letter for the last remaining position, and again there are 6 choices. By an operational statement of the MP, then there are 3*6*6 = 108 ways of completing the process. This is, in fact, true, and there is no claim being made about what this means in terms of distinguishable desirable outcomes.

However, a key aspect of counting is that there is a relationship between a counting process and outcomes associated with that process (Lockwood, 2013). In this "Words" problem, it is true that there are 108 possible ways to complete the three-stage counting process. However, the outcomes of that process are not all distinct: notice that many of the outcomes – those involving 2 or 3 *e*s – would appear more than once in the list of 108 ways to complete the process. Our counting process generated some of the same outcomes more than once. If we simply wanted to count possible ways to complete a procedure, this would not be an issue. However, counting involves specifying the cardinality of the set of outcomes – determining exactly how many of something satisfies certain constraints. Therefore, the fact that in using an operational statement, we are counting ways to complete the procedure, and not actually determining the number of distinct outcomes, is problematic. By only counting ways of completing a counting process, without tying that to outcomes, there is a danger of overcounting when the ways of completing that process are not in one-to-one correspondence with the desirable set of outcomes.

Discussion and Conclusion

By drawing on Sfard's (1991) work in identifying and describing structural, operational, and bridge statements of the MP, we have demonstrated the different ways that the MP may be presented. Operational statements frame the MP as counting the *number of ways* to complete some process, procedure, or sequence of tasks. To us, this reflects viewing the act of counting as involving completing counting processes, but not necessarily about determining the total size of a set of outcomes. Lockwood (2014) has previously demonstrated the value of what is called a *set-oriented perspective*, which frames counting as being about determining the cardinality of a set of outcomes. This stands in contrast to how many of the operational statements of the MP situate the activity of counting. We feel that our findings suggest that, in fact, counting is not always framed as inherently involving counting sets of things, and structural and bridge statements might more naturally align with a set-oriented perspective.

Finally, a major pedagogical implication of our study is that the MP is much more nuanced than instructors and students give it credit for. Given its foundational place in counting, we need to help students focus more on understanding the details of the MP. Because there are clearly a variety of ways to present and talk about the MP, we feel that teachers of counting need to be very explicit with students about what exactly the MP is saying. Instructors could offer multiple statements of the principle and have a clear discussion of what a given statement in terms of ways of completing a counting process versus determining number of distinct outcomes of that process, as we discussed. In addition, instructors should very clearly explain how overcounting can occur in counting situations that involve multiplication. Regardless of which type of statement a student (or an instructor) prefers or which statement their particular book uses, students must be faced with the potential to overcount, and it may be up to the instructor to share this, especially if the book does not address it explicitly.

Endnotes

[1]We follow a number of authors by referring to the principle as the "multiplication principle" throughout the paper, even though the textbooks we surveyed had many different names for it.

[2]There are two ways in which we limited our search. We did not include universities outside of the United States to limit the scope and because we did not feel equipped to linguistically analyze textbooks in other languages. We also did not examine probability textbooks, again to limit the scope of the study, primarily because we suspect that reasoning about multiplication in probability contexts may fundamentally differ from strictly combinatorial contexts.

EXAMINING K-12 PROSPECTIVE TEACHERS' CURRICULAR NOTICING

Lorraine M. Males	Darrell Earnest	Leslie Dietiker	Julie M. Amador
University of Nebraska-Lincoln	University of Massachusetts, Amherst	Boston University	University of Idaho
lmales@unl.edu	dearnest@educ.umass.edu	dietiker@bu.edu	jamador@uidaho.edu

This paper explores the construct of curricular noticing, defined as the act of teachers making sense of the complexity of content and pedagogical opportunities in written or digital curricular materials (Dietiker, Amador, Earnest, Males, & Stohlmann, 2014), and reports the results of four exploratory studies aimed to examine the Curricular Noticing framework. Taken together, these studies capture work done with 62 PSTs in elementary and secondary mathematics methods courses at four universities. Findings illuminate what PSTs attend to in curriculum materials and how they interpret and respond to these materials. Irrespective of level (i.e., elementary, secondary) and materials, PSTs can learn to notice aspects of curriculum materials in order to make decisions about what to do and how to do it, and activities within methods courses can facilitate this development.

Keywords: Curriculum; Teacher Education-Preservice; Teacher Knowledge; Instructional Activities and Practices

Curriculum materials are integral to mathematics instruction. In fact, more than 80% of K- 12 teachers use a textbook or curricular program for mathematics instruction (Banilower, Smith, Weiss, Malzahn, Campbell, & Weis, 2013), though such materials greatly vary in design and philosophy. According to Brown and Edelson (2003), curriculum materials have the most direct influence on what teachers actually plan for and enact in their classrooms and, although research does describe what teachers do with materials, we do not necessarily know the process of how teachers make decisions about what to do and how to do it (Stein, Remillard, & Smith, 2007), and we know even less about how prospective teachers make sense of curriculum materials or use them when enacting instruction.

In this paper, we consider how to make such work explicit through curricular noticing. We define curricular noticing as the process through which teachers make sense of the complexity of content and pedagogical opportunities in written or digital curricular materials. In the following sections we briefly present what researchers have learned thus far about teachers' interactions with curriculum materials, describe our framework and how this contributes to this literature, and present a snapshot of this framework in use by describing four individual studies. We conclude with implications.

Teachers' Use of Curriculum Materials

Research on teachers' use of curriculum materials has presented us with a foundation for describing what teachers do with materials. In the midst of planning and enacting instruction, teachers engage in a variety of activities with curriculum. Remillard (2005) describes the teacher-curriculum relationship as a dynamic transaction in which teachers "participate with" the materials. The socio-cultural conception of this relationship emphasizes the fact that both the teacher and the curriculum influences what and how curriculum materials are used. Using this conception, researchers have outlined ways in which teachers participate with curriculum. This includes the activities teachers engage in such as "reading, evaluating, and adapting" (Drake & Sherin, 2009) and what Brown (2009) describes as "offloading, adapting, and improvising." This research has provided us with a sense of what teachers do with curriculum materials, but we still know little about the process of how teachers make decisions about what to do. To understand how teachers make these decisions we turn to describe the Curricular Noticing Framework.

Theoretical Framing of Curricular Noticing for Mathematics Teaching

Curricular noticing (CN) draws upon the extensive work in professional noticing of children's mathematical thinking (PNCMT), a core instructional activity that is integral to ambitious teaching (Philipp, 2014). PNCMT describes a three-part process of making decisions based on student thinking: *attending to*, *interpreting*, and *responding* to children's mathematical thinking (Jacobs, Lamb, & Philipp, 2010). This process illuminates the phases of work involved in how teachers may leverage children's mathematical thinking. Unless teachers can recognize the complexity of students' mathematical thinking (which includes the diverse strategies and rationales of student ideas), they cannot use this information to inform their decisions.

We argue that this noticing framework may be productively applied to yet another dimension of classroom instruction, the use of curriculum materials. Unlike PNCMT, which focuses on student thinking, CN focuses on curriculum materials. Like PNCMT, we draw upon constructs that illuminate aspects of the work of teaching with curriculum materials: attending, interpreting, and responding. We define each of these aspects in the context of curriculum below.

Attending. Looking at, reading, and recognizing aspects of curricular materials

Interpreting. Making sense of that to which the teacher attended

Responding. Making curricular decisions based on the interpretation (e.g., generating a lesson plan, a visualization, or enactment)

Figure 1 further depicts some of the activities in which teachers might engage in each of the phases of CN.

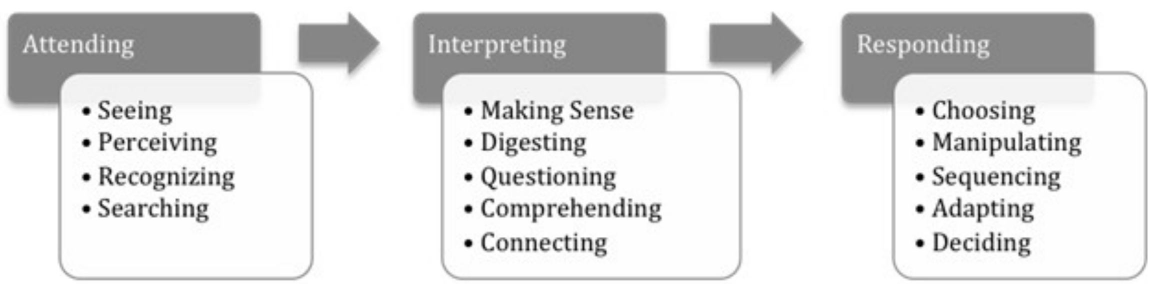

Figure 1. Activities embedded within each of the dimensions of Curricular Noticing.

CN and PNCMT have important commonalities, two of which we highlight here related to (1) the role of tasks and (2) supporting PSTs. First, both CN and PNCMT treat task selection as a necessary and critical component of ambitious teaching. While there have been varied empirical techniques in research on PNCMT, much of this underscores the role of teachers' attending to the mathematics of the present task and interpreting how students interact with the mathematics of that task, and in some cases how to then strategically respond with a new problem, task, or lesson. We see tasks as a critical component of CN as well. Second, both constructs allow the field to consider methods to support PSTs. Cultivating PNCMT practices has been identified as a mechanism to provide PSTs with opportunities to understand student-centered teaching and develop the pedagogical content knowledge necessary for effective and high-leverage instruction (Hill, Ball, & Schilling, 2008; Jacobs et al., 2010). Similarly, we see CN as inextricably linked to these efforts to support PSTs. As teachers make decisions in order to support children's mathematical thinking, curricular materials – specifically teachers' interaction and understanding of the complexity and opportunities reflected in such materials – influence their decisions. In practice, teachers participate or collaborate with curricular materials (Remillard, 2005). Noticing, therefore, is related to both the teacher-student dimension and teacher-curriculum dimension of instructional practices.

We see the CN framework providing a lens for examining not only what teachers do with curriculum materials, but how they do it. Specifically, how may we describe the mechanisms that determine how teachers make particular decisions in their practice? For example, we know some teachers adapt curriculum materials (Brown, 2009; Drake & Sherin, 2011); at the same time, we do not yet know how teachers come to such decisions to adapt. The CN framework allows us describe how teachers make the decision to adapt by considering how teachers' attention and interpretation may lead to such adaptations. We see these actions instead highlighting, more specifically, how teachers are interacting with the text when engaging in the reading and evaluating process, which in turn impacts the responses they make. As described below in our work with PSTs, we argue the phases of CN provide a useful framework for empowering teachers' decision-making, as each phase can be an explicit object of inquiry and development and productive engagement in the phases can help teachers make more informed decisions about how to use their curriculum materials.

Four Studies Aimed at Examining PSTs' Curricular Noticing

Here we present the methods and findings from four independent and exploratory studies, each of which examined CN. The first two studies focused on mathematical tasks and what PSTs can *attend* to in the tasks in order to grapple with identifying affordances and constraints based on the characteristics of these tasks. The second two studies focus on PSTs' *attention to* and *interpretation of* multiple sets of curriculum materials in order to make decisions (or, *respond*) about adoption and lesson planning. Each methods course supported PSTs in inquiry-oriented and student centered mathematics instruction. Studies explored the character of the three phases of noticing, and how these manifest in the context of curricular materials.

Study 1: Noticing Curricular Task Design Features

In Study 1 the task design features to which secondary mathematics PSTs attend to was explored. PSTs (n = 8) in two groups were given one of two versions of the same challenging optimization task, with each version reflecting common presentations in textbooks. One version was open-strategy, prompting students to make a prediction, work together as a group to find a solution, and justify that the result was indeed the optimal solution. The other version was closed-strategy, prompting students to test two possible solutions and use the results of those tests to choose new possible values to test. After each group worked together for 10 minutes on their version of the task, the whole class discussed what mathematical challenges they encountered and what strategies they had used. When the different versions were revealed, they had another five minutes with their group to read through the other version and consider the differences it would have had on their experience solving the tasks.

The comparison of tasks afforded reflections on the interpretation of task design. The whole class held a discussion about what differences they noticed between the two versions of the task. While the mathematical goal of the task (solving for an optimal value) and the context (locating a stereo on a cabinet) were the same, the way the task prompted students to engage resulted in different experiences. Overall, five themes of task design were noticed and mentioned: (1) students pointed out the way in which the design enables or prevents students from following "gut reactions," affecting how the students may engage with the mathematical content of the task. The open-strategy prompt enabled these gut reactions to be followed-up while the given-strategy version encouraged abandonment of potentially fruitful reactions. A teacher with the closed-strategy task commented: "Something interesting was when we were first starting the task, I felt like my gut reaction was to write an equation and graph it to find a minimum, but we were like, 'that's not what we were supposed to do.'" (2) The PSTs pointed to what they called the "heart of the problem," which was taken as the core mathematical point of the task. Fundamentally, the two versions provided different glimpses of what mathematical ideas were in play. Several prospective teachers were disturbed how the design of the task could "obscure" important mathematical ideas. (3) The PSTs explained how the purpose of their work depended on the version they used. The groups that started with the open-strategy task reported testing a point to see what it would tell them, while the closed-strategy group limited to a purpose of following directions. (4) The PSTs noticed the degree to which the task held students accountable for the mathematics. For example, one task explicitly asked “how can you be sure you found the best answer?” while the other just asked for the answer. (5) Several PSTs noted the design constrains what mathematical ideas there is to talk about. They noted that when a strategy is given, the group works in parallel and limited discussion to the verification of answers or how to perform a procedure. They also noted that the opportunity for discussion as a whole class was greatly enhanced when multiple strategies were supported. Findings indicate that such a comparison of tasks afforded interpretations of task design. Next steps will explore how to leverage such interpretations to support teacher decision-making.

Study 2: Noticing Mathematical and Pedagogical Opportunities in Curricular Tasks

The focus of Study 2 was on elementary PSTs’ noticing in the context of fractions, an area of mathematics that is notoriously hard-to-learn and hard-to-teach (Lamon, 1996; Saxe, et al., 2005). In order to empower a teacher to make productive choices in implementing a fractions task, that teacher needs to know something about mathematical properties embedded in—and often hidden in—traditional task design. For example, consider an area model for ¼. The canonical representation features a rectangle or circle divided into four equal sections with one of the four equal parts shaded. Such routine design may obscure two important properties in determining fractional quantities: the role of equal parts and the role of defining the unit (or whole). Study 2 explored how to support PSTs’ *interpretations* of such mathematical properties in routine tasks through the use of nonroutine tasks in the methods course. A premise was that sustained discussion involving a nonroutine task may thereby support teachers’ noticing of—in particular, interpreting—a routine task in terms of core mathematical properties that typically remain hidden.

PSTs (n = 18) were administered a pretest one month prior to and a posttest one month after intervention, each featuring routine and nonroutine fractions representations. In the intervention, all PSTs were asked to identify mathematical properties of two tasks with area models. Task A featured a routine, equally partitioned model with 1/6 shaded. Task B featured a nonroutine, unequally partitioned model with ⅛ shaded. In class, PSTs were asked to analyze each task and anticipate student responses. Results of activities using both routine and nonroutine tasks indicated the vast majority of PSTs did not originally identify *equal parts* or *defining the unit* as mathematical properties of the routine task, yet the majority did so with the nonroutine task.

While a pre-test showed PSTs did not identify equal parts or defining the whole as important mathematical components, a pre-post comparison confirmed PSTs interpreted both routine and nonroutine routine tasks according to these mathematical ideas after intervention. Results of this exploratory study suggest that nonroutine tasks may support PSTs’ interpretations of important underlying mathematical properties of tasks they are likely to encounter in curricular materials.

Study 3: Using a Tool to Examine PSTs Attention to and Interpretation of Curriculum Materials

Within the context of the second of two secondary mathematics methods course, Study 3 examined how PSTs (n=17) evaluated content related to quadratics in three different textbooks. In the first few weeks of a 15-week semester, PSTs were asked to examine the teachers’ guides from Algebra I textbooks in three curricular series: Prentice Hall (PH), The CME Project (CME), and The College Preparatory Mathematics Program (CPM). PSTs were asked first to determine what was similar and different between the three sets of curriculum materials and then to determine which text, if given the option, they would choose to use in their classroom and why. Each PST turned in a written response to these questions. For the next eight weeks PSTs used the CCSSM Curriculum

Analysis Tool (CCCAT, Bush, 2011) to analyze the materials with respect to 1) content, 2) practices, and 3) equity, special needs, and technology. The tool required PSTs to use a rubric to rate each text and to provide qualitative descriptions. Following this analysis, PSTs responded to the same questions from the beginning of the semester. Each pre- and post-tool response was read multiple times to generate initial codes. Each response was then read again and codes were assigned to these responses.

The post-tool responses indicated that, if given the chance, 76% would choose to adopt CPM (compared to 72% before using the CCCAT), 6% would choose CME (no change), and 18% would choose PH (compared to 22%). One important note is that students engaged in this assignment in the second methods course and in the first methods course had engaged in cursory examinations of curriculum materials (without attention to particular content) and also taught from reform-oriented materials in a micro-teaching setting. It is likely that these previous experiences impacted students' choices of materials.

Although there was not much of a difference regarding which text PSTs chose to adopt after engaging with the CCCAT, there was a shift in the reasoning used by PSTs when discussing their choice. In their pre-tool responses, PSTs' responses were quite general in nature and included the general approach of the materials, whether the materials had good or bad teacher resources, the tools included in the materials such as calculator and manipulatives, and the clarity of layout for students. After using the CCCAT, their evaluations were more detailed and they described different aspects of the materials. On average, PSTs wrote 32% more (as measured by number of sentences) in their post-tool response and included more examples from the materials (mostly to illustrate features that they liked). Six out of the 10 most frequent reasons were explicitly aligned to aspects that PSTs were asked to use when evaluating texts using the CCCAT. PSTs made reference to the CCSS Mathematical Practices and the balance between procedural and conceptual opportunities and when referring to the teacher resources described in detail the supports for assessment, differentiated instruction and working with ELL students.

They also commented more on the ways in which technology was integrated, meaning whether it seemed to be an integral part of the text rather than just naming what tools were used in the text. All of these aspects were explicitly addressed by the CCCAT. In addition, however, PSTs also discussed aspects that were not an explicit object of analysis in the CCCAT. PSTs discussed the types of participation structures that were emphasized in the materials, whether detailed lesson plans or suggestions were provided to teachers, the cognitive demand or richness of the tasks, the flexibility (or often lack of flexibility) of the text and the level of planning needed in order to be successful in using the textbook. Although potentially helpful in being able to apply the CCCAT, these aspects were not explicitly addressed, meaning that PSTs were not asked to attend to these aspects in the same ways they were the others. Results indicate that the CCCAT may have aided in shifting what curricular features PSTs attended to and how they then interpreted those features.

Study 4: Responding with Curricular Materials

This study focused on understanding how elementary PSTs made decisions about intended lesson plans as they interacted with multiple curricular resources to further understand the reasons behind their instructional decisions. In this process, close attention was given to what (i.e., the content) the PSTs *attended* to, how they attended to this content (e.g., the degree to which they selected to include in the content in their lesson design), and how they *interpreted* this content with respect to teaching the intended learning outcomes. Finally, there was a focus on how the PSTs *responded* to the selected curricular components to create a plan for teaching with an emphasis on PSTs' decision-making process.

PSTs (n=19) were provided with Grade 6 teacher materials for a lesson on the division of fractions from four curricular programs. PSTs were tasked with using components of any of the resources to write out a detailed lesson plan that would address the following standard: “Apply and extend previous understanding of multiplication and division to divide fractions by fractions” (CCSSM, 2010, p. 42). PSTs were required to provide rationale for their decisions regarding including or excluding particular curricular resources. Following the design of their lesson plan, PSTs were prompted to respond to questions about their use of the resources, motivation for using particular materials, reasons for not including particular materials, and an overall rationale for their decision-making with respect to curricular materials. Often, the PSTs cited their own experiences, belief, and knowledge for their rationale.

Findings indicated that the PSTs noticed curricular components that aligned with their personal conceptualizations about effective mathematics teaching. PSTs considered problems with authentic contexts and problems that involved students through some tangible manipulative to be exemplary components that aligned with effective pedagogical practices. In addition, PSTs based their selections on preconceived notions of what a lesson on the division of fractions should include. For many, they considered how they personally learned the division of fractions and then searched through the materials until they found something closely aligned with their preconceived method of how a lesson on this topic would be taught. In this case, the Curricular Noticing Framework afforded opportunities for understanding how PSTs conceptualized division of fractions after reading multiple curricular resources. Following this, the decisions the PSTs made about how they would respond, or teach the lesson, became transparent. Consequently, past prior experience with the specific content influenced their decision-making process. In contrast, many PSTs documented that the mathematics content was advanced and they had to grapple with the concept of division of fractions before they were able to consider how they would plan a lesson on the topic for sixth grade students.

Implications

Use of the CN Framework identifies the conceptual work involved in translating curricular materials to classroom practice. Our studies offered glimpses of the character of the phases of curricular noticing. We reflect here on both the individual studies described above and what looking across the set of studies as a whole helps us understand about CN.

First, in Study 1, the analysis of different versions of the same mathematical task enabled PSTs to recognize design features of mathematical tasks and connect them to the potential affordances and constraints of teaching with the tasks. PSTs developed a potential lens to critique the tasks of their mathematical curriculum materials. That is, by attending to one aspect of a mathematical task (e.g., how students are held accountable for reasoning), teachers can scrutinize that dimension of the task design (i.e., define how and to what degree students are accountable for mathematical reasoning) and can decide to adapt their task to enhance this quality (i.e., add “Explain how you know” to a task statement).

Second, involving the use of routine and nonroutine problems to support noticing of mathematical and pedagogical opportunities, Study 2 indicated that PSTs may benefit from task exploration that problematizes the big mathematical ideas (in this case involving fractions) embedded in the routine tasks they are likely to encounter in curricular materials. Furthermore, exploration of such tasks may highlight (Goodwin, 1994) the mathematical aspects that are indeed critical to notice in order to choose tasks that anticipate and respond to student thinking.

Third, in Study 3, there was a shift in the reasoning used by PSTs when discussing their choice. This shift suggests that the tool supported PSTs in being able to attend to and interpret curricular features in order to articulate reasons for curriculum evaluations.

Finally, Study 4 indicated that PSTs noticed opportunities that aligned with their concepts about effective mathematics teaching. Many PSTs had some idea of what the target lesson should include and then wrote a lesson plan irrespective of the relation to materials. Findings suggest that PSTs may benefit from further instruction on how to use curricular materials.

These studies are not without limitations. First, the studies were humble in scope, both in terms of working with a single mathematics methods course and without consideration the multiple dimensions involved with CN. As a result, we do not yet fully understand how to support each element of noticing - attending to, interpreting, responding- for PSTs. Second, the contexts for each of the methods courses is varied in terms of level (i.e., elementary, secondary), number of PSTs, and grain-size of materials (i.e., tasks, lessons, units), thereby limiting our capacity to compare across studies.

Despite these limitations, however, the four studies offer a glimpse into the work involved in CN and identify an exciting and important arena in the work of teaching. As mentioned, we do not and cannot know the materials to which PSTs will have access once they have jobs. Yet, we can be confident that most will have some form of curricular materials. Our goal is to understand how to enable PSTs to become strategic and productive users of curricular materials regardless of what those materials are, thereby supporting them to make informed curricular decisions as they teach their students. The first two studies show that by focusing on aspects of tasks that PSTs learned to attend to the mathematics and pedagogical opportunities afforded by or constrained by the tasks. The second two studies indicated that providing PSTs with different curriculum materials and focusing either on lessons or units not only provided PSTs with the opportunity to attend to various mathematical and pedagogical opportunities within the materials, but also required them to interpret the materials in order to respond in some way to a particular question (i.e., What materials would you adopt?) or take a particular action (i.e., plan a lesson).

Taken together these studies indicate that, irrespective of level (i.e., elementary, secondary) and materials, that PSTs can learn to notice aspects of curriculum materials in order to make decisions about what to do and how to do it and that activities within methods courses can facilitate this development. In future research, we hope to further reveal how our framework may be strategically implemented in methods coursework or professional development to support teacher decision-making.

Acknowledgments

We would like to acknowledge the STaR Fellowship Program (NSF Grant #0922410) for bringing us together to pursue this research.

This paper investigates how the selected three East Asian countries—Japan, Korea, and Taiwan—introduce and develop ideas related to fractions and fraction addition and subtraction compared to the Common Core State Standards of Mathematics and EngageNY. Looking at curricular approaches used across countries can provide a better picture of what is of importance in instruction aimed at developing students' mathematical proficiency. Understanding how the aforementioned three Eastern Asian materials treat fractions will offer both mathematics teachers and teacher educators some concrete images of the visions of the Common Core State Standards of Mathematics and specific ideas on teaching and learning of fractions.

Keywords**:** Curriculum Analysis; Elementary School Education; Number Concepts and Operations

Introduction

Teaching and learning of fractions in middle grades remain a major challenge for many teachers and students. Developing deep understanding of fractions, which has been identified as a foundation for algebra (Math commission), is a major focus of the Common Core State Standards: Mathematics (CCSSM, Common Core State Standards Initiatives, 2010). The authors of the CCSSM examined the mathematics standards from the high-achieving countries including Asian countries because one finding from the previous cross-national studies is that, in general, United States students do not perform as well as the Asian students in mathematics especially Hong Kong, Japan, Korea, Singapore, and Chinese Taipei (Taiwan) (Mullis, et al., 2008).

The observed performance differences among students in different countries might be attributed to variations in mathematical curricula (Reys, Reys, & Chavez, 2004). A growing body of research has begun to investigate the content of mathematics textbooks as a possible factor for the achievement gaps as reflected in the large international assessments such as Trends in International Mathematics and Science Study (TIMSS) and the Programme for International Student Assessment (PISA). As Kilpatrick, Swafford and Findell (2001) pointed out, "what is actually taught in classrooms is strongly influenced by the available textbooks" (p. 36).

The purpose of this study is to examine how curriculum materials from the selected three East Asian countries—Japan, Korea, and Taiwan--introduce and develop ideas related to fractions and fraction addition and subtraction compared to the recommendations from the CCSSM. In this study, we seeks to understand intended students' learning opportunities in three Asian countries by analyzing how textbooks from these three countries develop a mathematics topic known to be challenging to school children. In particular, we compare and contrast the treatment of fraction concepts and fraction addition and subtractions in the three Asian textbooks compared to that in *EngageNY*. *EngageNY* is curriculum modules and resources in preK-12 developed by New York State Education Department to support teachers implement key aspects of the CCSSM (https://www.engageny.org/). The research questions that guide this study are: 1) What are the similarities and differences of the intended learning progressions of fraction concepts development among the three Asian curricula and those recommended by CCSSM? and 2) What are the similarities and differences in the development of fraction addition and subtraction fluency among the three Asian curricula and those presented in *EngageNY*?

Cross-national comparative studies in the teaching and learning of mathematics provide unique opportunities to understand the current state of students' learning and to explore how students' learning can be improved (Stigler & Hiebert, 1999; Son & Senk, 2010).

Theoretical Background

Teaching and learning fractions has traditionally been problematic. Prior research identified one of the predominant factors contributing to the complexities of teaching and learning fractions lies in the fact that fractions comprise a multifaceted construct (Lamon, 2007). Kieran(1976)articulated that fractions consist of five subconstructs — part-whole, measure, quotient, operator, and ratio. Behr, Lesh, Post and Silver (1983) further developed Kieren's ideas and proposed a theoretical model linking the different interpretations of fractions to the basic operations of fractions as shown in Figure 1.

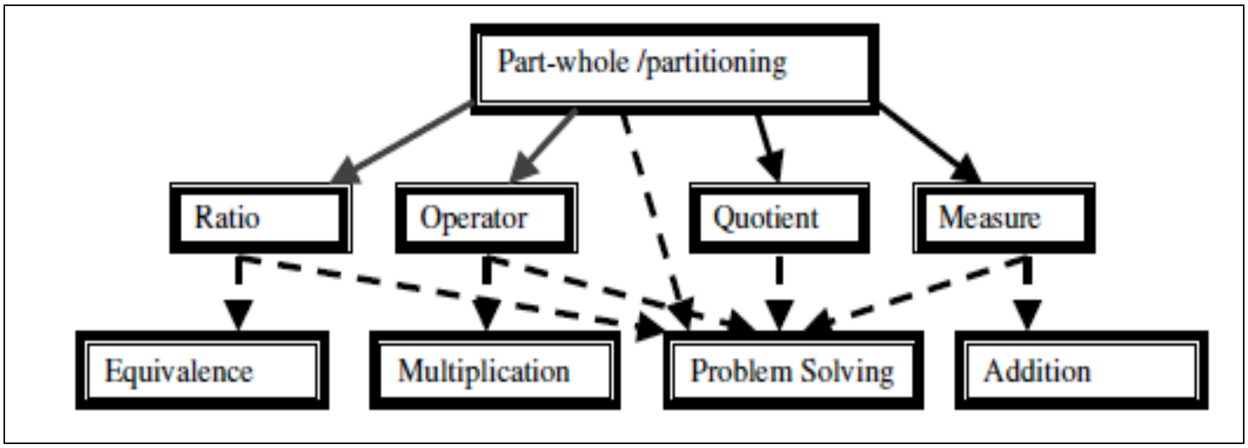

Figure 1. Five subconstructs of fractions and their relationships (Behr, et al., 1983)

According to Behr, et al., the part-whole subconstruct of rational numbers is fundamental for developing understanding of the four subordinate constructs of fractions. Moreover, the operator and measure subconstructs are helpful for developing understanding of the multiplication and addition of fractions, respectively. Although there is a consensus that fraction instruction that focuses solely on the part-whole subconstruct is limiting, there are many unanswered questions about how to incorporate these subconstructs in a mathematics curriculum (Lamon, 2007).

Research on Fractions and Fraction Addition and Subtraction

As mentioned before, over the last three decades researchers and scholars have identified several factors contributing to students' difficulties in learning fractions. The NCTM (2000) provides the following instructional guidelines in developing deep understanding of fractions: (1) begin with a simple contextual task and (2) have students explore each of the operations using a variety of representations and models. We took account of them in our analytical framework. In particular, as word problems serve as a way to contextualize mathematical operations (Carpenter et al., 1999), this study investigated how the meanings of fraction addition and subtraction are addressed and developed through the word problems in each curriculum. The Cognitively Guided Instruction framework (CGI) and CCSSM's problem types, which categorizes addition and subtraction word problems based on the semantic structure of problems shown in Table 1, was utilized for the analysis.

Table 1: Four problem types for addition and subtraction (from Carpenter, et al., 1992)

Problem Type	Unknown Factors		
Join (Add to)	**(Result Unknown)** Connie had 5 marbles. Juan gave her 8 more marbles. How many marbles does Connie have altogether?	**(Change Unknown)** Connie had 5 marbles. How many marbles does she need to have 13 marbles altogether?	**(Start Unknown)** Connie had some marbles. Juan gave her 5 more. Now she has 13 marbles. How many marbles did Connie have to start with?
Separate (Take from)	**(Result Unknown)** Connie had 13 marbles. She gave 5 to Juan. How many marbles does Connie have left?	**(Change Unknown)** Connie had 13 marbles. She gave some to Juan. Now she has 5 marbles left. How many marbles did Connie give to Juan?	**(Start Unknown)** Connie had some marbles. She gave 5 to Juan. Now she has 8 marbles left. How many marbles did Connie have to start with?
Part-Part-Whole (puttogether/take apart)	**(Whole Unknown)** Connie has 5 red marbles and 8 blue marbles. How many marbles does she have altogether?		**(Part Unknown)** Connie has 13 marbles: 5 are red, and the rest are blue. How many blue marbles does Connie have?
Compare	**(Difference Unknown)** Connie has 13 marbles. Juan has 5 marbles. How many more marbles does Connie have than Juan?	**(Bigger Unknown)** Juan has 5 marbles. Connie has 8 more than Juan. How many marbles does Connie have?	**(Small Unknown)** Connie has 13 marbles. She has 5 more marbles than Juan. How many marbles does Juan have?

Method

The primary data source of this study includes the national curriculum guidelines and selected textbook from the three Asian countries. CCSSM and fraction modules from *EngageNY* were analyzed. This study applied the content analysis method to analyze the problems presented in the mathematics textbooks (Confrey & Stohl, 2004). The data analysis of this study went through several iterations with respect to the following aspects:

- Examine the overall curricular flow on fractions – what topics are introduced in which grade
- Analyze in details how textbooks develop the concept of fractions, paying specific attention on fraction subconstructs
- Analyze in details how textbooks develop addition/subtraction of fractions:
- Word problem types, e.g., add to, take from, put together/take apart, compare.
- Types of representations

Note that the textbook series from each country were analyzed in their respective languages by the three authors who are native speakers of the respective languages. Because problem contexts and fraction subconstructs are not always visually verifiable, we needed to calibrate our coding of these two factors. We used the English translation of the Japanese series (Fujii & Iitaka, 2012) and analyzed them independently. We then compared our analysis, and whenever there was a discrepancy in our analyses, we discussed the particular instance until a consensus was reached.

Summary of Findings

Overall Curricular Flow on Fractions

Table 2 shows the overall curricular flow on fractions across the three Asian countries as well as the CCSSM. All Asian curricula shared similar overall flows with some embedded variations. Japanese curriculum introduces the initial concept of fractions in grade two with a brief introduction of the concepts of 1/2 and 1/4. In third grade, the focus is on the continued development of fraction concepts along with the introduction of the addition and subtraction of fractions with the same denominator. Fraction concepts are further extended in grade four to the improper fractions and mixed fractions. The quotient meaning of fractions is introduced in Grade 4 in the Korean and the Taiwanese curriculum, while the idea is introduced in Grade 5 in the Japanese curriculum.

In the Japanese and the Korean curricula, simple cases of equivalent fractions are discussed in Grade 4 even though the formula for creating equivalent fractions is not discussed until Grade 5, while the Taiwanese curriculum addresses this topic in Grade 4. All three curricula took time develop fraction addition and subtraction over three grades: first with proper fractions with the same denominators, then with improper fractions or mixed numbers with the same denominators. Fraction addition and subtraction with unlike denominators follows the discussion of equivalent fractions in the fifth grade curricula. In all three curricula, multiplication of fractions are also discussed in multiple grades. Both the Japanese and the Korean curricula formally discuss multiplication of fractions by whole numbers in Grade 5 and multiplication by fractions in Grade 6. The Taiwanese curriculum follows the same sequence but one grade level earlier. The Japanese and the Korean curricula follow the similar sequence with division while the Taiwanese curriculum discuss division of fractions only in Grade 6.

Table 2:Curricula Flow on Fractions in curriculum in three countries

	Japan	Korea	Taiwan	CCSSM
Fractions as equal shares	2	3	3	1/2/3
Fraction as number	3/4	¾	3/4	3/4
Comparison	3/4/5	3/4/5	3/4	3/4
Equivalent fractions	4/5	4/5	4	3/4
Fractions as quotients	5	4	4	5
Addition/subtraction	3/4/5	3/4/5	3/4/5	4/5
Multiplication	5/6	3/5	4/5	4/5
Division	5/6	5/6	6	5/6

The overall flow in the three Asian curricula is fairly similar to the overall flow in the CCSSM. In the CCSSM, simple fraction ideas are introduced in Grades 1 and 2 through equal partitioning of geometric shape like circles and rectangles. This approach is similar to the Japanese curriculum in Grade 2. The formal introduction of fraction as numbers occurs at Grade 3 for all curricula and CCSSM. However, while the three Asian curricula discuss addition and subtraction soon after they start the formal instruction of fractions in Grade 3, the CCSSM delays the discussion of addition and subtraction until Grade 4. Although the timing of addition/subtraction instruction is different, the three Asian curricula and the CCSSM all rely heavily on the measure subconstruct of fractions, that is, fractions are collections of unit fractions. While multiplication of fractions in the CCSSM follows the same sequence as the three Asian curricula, that is, multiplication of fractions by whole numbers first, then multiplication by fractions, the way division of fractions is developed in the CCSSM is different. Unlike the Asian curricula which first discusses the division of fractions by whole numbers then division by fractions, the CCSSM discusses division of unit fractions by whole numbers and whole numbers by unit fractions in Grade 5 before discussing division of fractions in general in Grade 6.

The Development of Fraction Subconstructs and Contexts/Models Used

Table 3 summarizes which of the five subconstructs offractions are present in different grade levels of themathematics curricula from the three Asian countries and from *EngageNY*.It is clear from this table that there are variations in the ways different fraction subconstructs are used in the three Asian curricula. However, one commonality is that the foundational role the part-whole subconstruct appears to play in the three curricula. Moreover, the part-whole and the measure subconstructs are the two primary subconstructs undergirding the initial instruction of fractions, including addition and subtraction of fractions, in the three curricula. This approach is similar to the way the *EngageNY* (and the CCSSM) introduces fractions, starting with the partitioning of wholes in Grades 1 and 2, and then in Grade 3, developing the understanding of non-unit fractions as collections of unit fractions. Students in *EngageNY* are then expected to use that knowledge to think about fraction equivalence, ordering, and addition and subtraction of fractions in Grades 4 and 5.

Table 3: Fraction subconstructs that appeared in the Asian curricula and in EngageNY

Grades	Japanese	Korean	Taiwanese	EngageNY (US)
2	**Part-whole**			**Part-whole**
3	Part-whole **Measure**	**Part-whole** **Measure** **Operator**	**Part-whole** **Measure**	Part-whole **Measure**
4	Part-Whole Measure	Part-whole Measure **Quotient**	Part-whole Measure **Quotient**	Part-Whole Measure **Operator**
5	Part-Whole **Quotient** Measure	Part-whole Measure Quotient Operator	Part-whole Measure Quotient **Operator**	Part-Whole Measure **Quotient** Operator
6	Part-Whole **Operator** **Ratio**	Part-whole Measure Operator **Ratio**	Part-Whole Measure Quotient **Ratio**	Part-Whole Measure Operator **Ratio**

Note: A sub-construct that is newly addressed in each grade is bolded in Table 3.

While all five subconstructs of fractions are present in each curriculum, there exist different emphases on the operator and ratiosubconstructsamong the four curricula. The Japanese curriculum emphasizes a unitary view of fractions thus putting more emphasis on the measure subcontstruct than the othersubconstructs. The primary representation is linear (either tape or number line) (see example below).

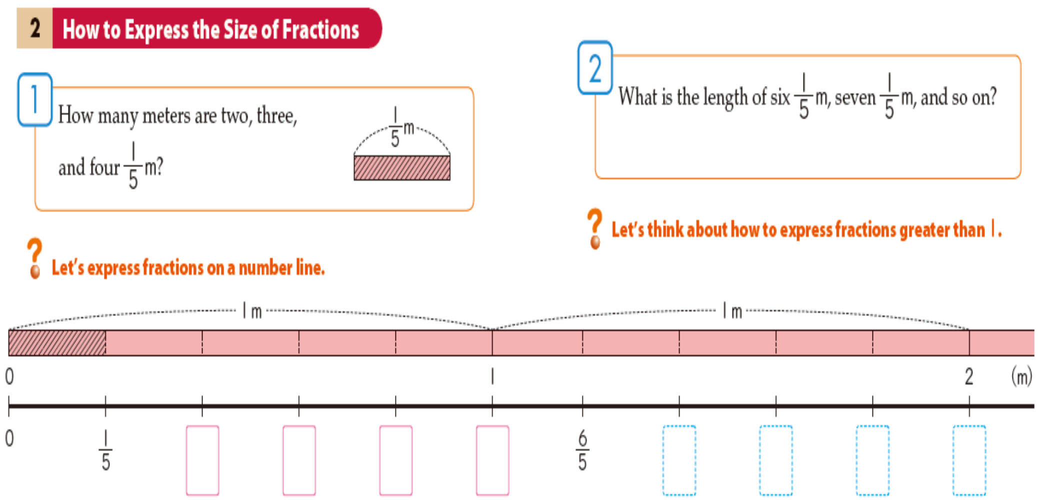

Figure 2. Typical representations used in the Japanese textbooks

One unique feature of Korean curriculum is to introduce operator construct much earlier than Japanese and Korean curricula. Below is an example from the 3rd Grade Korean textbook asking students to find what is ¾ of 8. A fraction as operator typically implies partitioning followed by iterating: for example, 3/4 as operator (3/4 of 8) implies first partitioning the object into four equal parts and then making three copies of (iterating) one of those parts as shown below. In addition, the Korean curriculum addresses the meaning of fractions as operator first in grade 3 and then in grade 5 and 6 as multiplication of fractions is introduced and developed. Furthermore, the ratio subconstruct is used to promote the concept of equivalence and, subsequently, the process of finding equivalent fractions. Thus the Korean curriculum appears to intentionally introduce students to the variety of subconstructs sooner than the other two curricula.

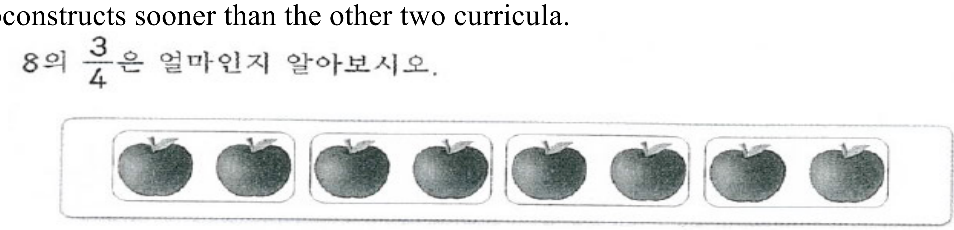

Figure 3. An example problem introducing operator construct in the Korean curriculum

How are addition and subtraction of fractions introduced and developed?

Table 4 describes the types of word problems presented in the mathematics curricula from the four countries. We found that all three Asian curricula included relatively small number of word problems as they discussed addition and subtraction of fractions. Moreover, the problem types found are generally simpler types such as Join/Separate-Result-Unknown and Part-Part-Whole-Whole-Unknown. However, *EngageNY* and Taiwanese textbooks include other types of word problems such as Separate-Initial\Change-Unknown and Part-Part-Whole Part Unknown, which emphasize the relationship between fraction addition and subtraction. Note that the Compare-Smaller-Unknown type was only found in the *EngageNY*

In addition, we found that a significant percentage of pure computation exercises of fraction additions and subtractions with different denominators are included in each curriculum with the following number and percentage: Korean 76 (76%), Japan 29 (74%), Taiwan 24 (75%), and EngageNY (66%).

Table 4:Types of addition and subtraction word problems in four curricula

Join Result Unknown *JKTUS*	Join Change Unknown *TUS*	Join Initial Unknown
Separate Result Unknown *JKTUS*	Separate Change Unknown *TUS*	Separate Initial Unknown *TUS*
Part-Part-Whole Whole Unknown *JKTUS*	Part-Part-Whole Part Unknown *TUS*	
Compare Difference Unknown *JKT US*	Compare Smaller Unknown US	Compare Larger Unknown *T*

Note: J stands for Japanese textbooks with K for the Korean texts, T for the Taiwanese texts, and US for *EngageNY*.

While discussing addition and subtraction, all three curricula incorporated various models including linear, area, and discrete. Below is an example from the 3rd Grade Taiwanese textbook using linear model. The question asked how much would left if Wei-Ting had a 7/10 meter rope and used 3/10 meters for her art project. The students are encouraged to think "7/10 meter is 7 units of 1/10 meter, used 3 units of 1/10 meter. So left will 4 units of 1/10 meter, which is…."

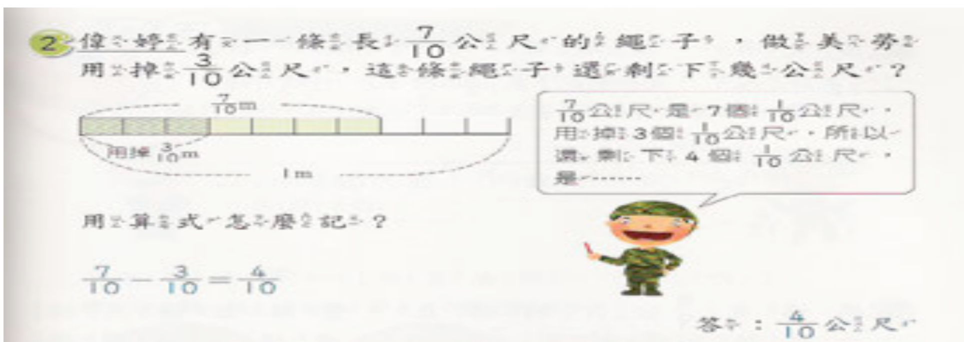

Figure 4. Typical representations used in the Taiwanese textbooks

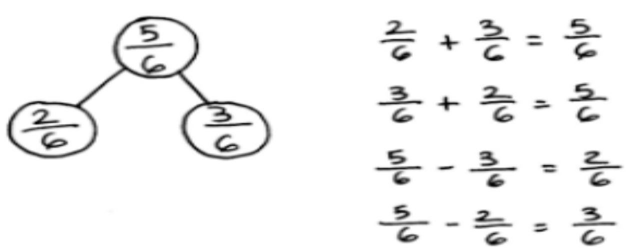
Similar to the three Asian textbooks, modules from EngageNY incorporated various models. The most frequently model is a tape diagram, followed by a number line and area model. One unique model (or an approach) used in EngageNY is using a number bond to find the sum or the difference as shown below.



Discussion

The findings of this study showed more similarities than differences among the three Eastern Asian curricula in terms of overall flow, approach, and grade level expectations. Moreover, as far as the early discussion of basic fraction concepts, there is a significant alignment between the three Asian curricula and the CCSSM. However, some of the differences may have significant implications. For example, we noted that how the Korean curriculum incorporates all five fraction subconstructs from early grades while the Japanese curriculum takes a much more deliberate pace to introduce the subconstructs beyond part-whole and measure. Further research in the way students in these countries understand fractions may tell us how their learning may be impacted by the curricular decision. Research has long reported that many students and even teachers have difficulty understanding fractions (Ball, 1990; Behr et al. 1992; Ma, 1999).An increased understanding how fractions and fraction addition and subtraction are introduced and developed in other countries provides us with a tool to critically reflect on our current practices and that can help us to improve the quality of both curriculum materials and fraction instruction.

Researchers and policy writers have advocated for the importance of curricular coherence. The purpose of this study is to move beyond surface-level features of coherence by attending to the mathematics embedded within problems and investigating how key mathematical concepts are developed across sequences of problems into mathematical storylines.

Keywords: Curriculum; Curriculum Analysis; Learning Trajectories; Middle School Education

Introduction

The importance of coherence in mathematics curriculum policy has been well documented in the literature. For example, in 2000, the *Principles and Standards for School Mathematics* (National Council of Teachers of Mathematics [NCTM], 2000) emphasized that curriculum is "more than a collection of activities: it must be coherent, focused on important mathematics, and well articulated across the grades" (p. 14). In the development of the Common Core State Standards (The National Governors Association Center for Best Practices and The Council of Chief State School Officers, 2010), attending to coherence was key in the development of standards through "research-based learning progressions detailing what is known today about how students' mathematical knowledge, skill, and understanding develop over time" (p. 4). According to Trafton, Reys, and Wasman (2001), "If students are to think mathematically and use mathematics as a tool for solving problems, coherence [in curriculum materials] is crucial, and establishing connections among the big ideas of mathematics fosters coherence" (p. 260).

The purpose of this study is to understand how mathematical understanding embedded in problems is connected and how each problem contributes to the coherence of a mathematical storyline. This is important to mathematics educators because it can inform (a) how teachers understand the development of long-term mathematical goals as supported by the daily lessons, (b) how student thinking and learning is targeted and how that thinking and learning might unfold within and across mathematics units, and (c) the mathematical, pedagogical, and assessment decisions teachers make when planning or enacting lessons that respond to students' mathematical conceptions. This study addresses the major PME-NA 2015 conference theme.

Theoretical Framework and Related Research

To make explicit the mathematical storylines embedded within curriculum materials, we use the *Arc of Learning* framework to describe the implicit learning progressions in the sequence of mathematics problems (Phillips, Gilbertson, Grant, & Stewart, 2014). According to the National Research Council (2007), learning progressions are defined as "descriptions of the successively more sophisticated ways of thinking about a topic that can follow one another as children learn about and investigate a topic" (p. 214). Encompassing learning progressions, the Arc of Learning framework and its phases embody Freudenthal's view that "students should be given the opportunity to reinvent mathematics by organizing or mathematizing either real world situations or mathematical relationships and processes that have substance for them" (Cobb, 2008, p. 105). This is a central tenet in the Realistic Mathematics Education (RME) instructional theory, where mathematics is interpreted as a human activity. From this perspective, realistic "refers more to the intention that students should be offered problem situations which they can imagine" (Van den Heuvel-Panhuizen, 2003, p. 10). From this perspective, contextual problems are defined as situations that are experientially real to the student, which can include pure mathematical problems (Gravemeijer & Doorman, 1999). In RME, "context problems are intended for supporting a reinvention process that enables students to come to grips with formal mathematics" (Gravemeijer & Doorman, 1999).

In our work, the Arc of Learning framework expands on the work in RME and consists of five phases or stages, moving from informal to formal mathematics. These phases describe a process for students to develop their mathematical understandings as they explore problems over time. In the *Introduction (Setting the Scene)* phase, students explore problems that reveal mathematical theme and where the problems informally highlight the key mathematical concepts. The problems also provide an opportunity to assess what students bring to the lesson in terms of the goals of the unit. In the *Exploration(Mucking About)* phase, students explore problems that establish a platform for developing key aspects of concepts and strategies. Students consider and explore a context that students can use to build, connect, and retrieve mathematical understandings. In the *Analysis(Going Deeper)* phase, students explore problems often with a variety of contextual situations and examine nuances in key aspects of the core mathematical ideas. Students make connections between concepts and representations. In the *Synthesis* (*Looking Across*) phase, students explore problems and consolidate and refine their emerging mathematical understanding(s) into a coherent structure. They recognize core ideas across multiple contextual or problem situations. Students begin to generalize their mathematical ideas and strategies. In the *Abstraction (Going Beyond)* phase, students explore problems in which they make judgments about which representations, operations, rules, or relationships are useful across various contexts. Students look back on prior learning to generalize, extend, and abstract the underlying mathematical structure. The tasks provide opportunities for assessing student understandings at a more general level.

Methodology

Since little is known regarding how to deeply characterize coherence for particular topics in curriculum materials, the purpose of this study is to examine the mathematics embedded within sequences of problems and to make explicit the mathematical storyline of curriculum materials. The research question that guides our study investigates how the key mathematical concepts and methods (i.e., unit/chapter objectives)in middle school curriculum materials were developed within sequences of problems. For each curriculum, Grade 7 units or chapters that shared similar big mathematical ideas in probability, proportionality, and linearity are selected. The unit of observation is the mathematical unit/chapter of the curriculum materials. Homework tasks are not examined in this study. Four middle school CCSS-oriented curriculum programs chosen for the study are *Connected Mathematics*, *Mathematics in Context*, *College Preparatory Mathematics*, and *Big Ideas MATH*. This represents a range of materials of middle school programs including commercially developed and NSF-funded materials.

In our analysis, we use the Arc of Learning framework to code each mathematics problem or lesson activity located within the selected units/chapters. The researchers, using the phase description of the Arc of Learning described earlier, code each mathematics problem or lesson activity located in the student text. Codes include the Arc of Learning phases of Introduction, Exploration, Analysis, Synthesis, or Abstraction. Coding is based on information from the student text and accompanying teacher's guide notes that pertain only to the unit of analysis. Independent codes conducted by the researchers are aggregated together to form final code(s) decisions for each mathematics problem. If agreement in codes is not immediate, the research group discusses the accompanying evidence for the code and determine final consensus.

Findings

The analysis of the research study is currently ongoing. Findings of the study will report on the overall development of the mathematical ideas embedded across a sequence of problems for each curriculum unit. For example, Table 1 presents preliminary findings that describe the development of understanding similarity from the *Stretching and Shrinking* unit of *Connected Mathematics 3*. Figure 1 shows how each problem contributes to the development of similarity.

Table 1: The development of understanding similarity for *Stretching and Shrinking*

Introduction (Setting the Scene)	Emergence of initial ideas for the meaning of similarity, including informal ideas from everyday life Emergence of initial ideas of mathematical similarity and tools for creating similar shapes. Some beginning ideas of similarity such as angle, lengths, and area relationships may emerge Assessment of students' understanding of ratio and rates as in "for every" and corresponding angles, and sides
Exploration (Mucking About)	Continue building a working definition for similarity using contexts Emergence of more details of similar and non-similar shapes (e.g., what stays the same, what changes) with attention to measurements using tools such as angle rules, rules, and lengths on a grid Begin a formal description of similar and non-similar shapes using features of side lengths, angle measures, perimeters, or areas
Analysis (Going Deeper)	Refinement of similarity definition regarding lengths and angle relations between similar and non-similar shapes Scale factor and its relationship to side lengths are refined Scale factor and its relationship to areas is strengthened The ratio of two lengths within a shape is equivalent to the ratio of the corresponding lengths in a similar shape
Synthesis (Looking Across)	Build on prior knowledge, experiences, and dispositions of learning from earlier problems to determine scale factors and ratios of adjacent side lengths. Find missing measurements of different situations Discuss similarity in which direct measurement is difficult and collect data. Discuss accuracy of that approximate data
Abstraction (Going Beyond)	Generalize understandings of similar shapes and strategies beyond contextual situations

Implications and Future Work

Unpacking the mathematical storylines over sequence of problems as arcs of learning provide teachers, teacher educators, mathematics education researchers,curriculum developers and administrators effective tools to characterize deeply grounded and connected learning. Attention to mathematical storylines is important because the development of ideas over time istypically not transparent (Davis and Krajcik, 2005; Remillard & Bryans, 2004). This work suggests that the Arc of Learning can be a potentially useful tool as it provides (a) an overall and detailed view of development of mathematical ideas will become more transparent and (b) support in describing student learning goals both at a lesson level at a unit level. Such a curriculumawareness will provide a knowledge space and support mechanism to make curricular decisions thatare more deliberate with their actions (Remillard, 2000). Future research is needed that explores how the Arc of Learning can be utilized in teacher planning and enactment, as a context for developing teacher knowledge in professional learning situations, and to impact student learning.

TEACHING STRATEGIES AND THEIR ASSOCIATED LEARNING OPPORTUNITIES

Nicholas Fortune
North Carolina State University
ncfortun@ncsu.edu

Derek Williams
North Carolina State University
dawilli6@ncsu.edu

This study compared the effects of two teaching strategies on learning opportunities and learning outcomes for students enrolled in different sections of a community college precalculus course taught by the same instructor. Features from Chval, Chavez, Reys, and Tarr (2009) were used to guide the instructional strategies used in one section while lectures were used in the other section. Results show that reform-based teaching methods can provide richer learning opportunities if exploration is supplemented with high-level tasks (Stein, Grover, & Henningsen, 1996). We determined that all students benefit from experience with all types of tasks, but focus should be given to high-level tasks.

Keywords: Curriculum; Post-Secondary Education

There exists a plethora of research centered on curriculum evaluation at the K-12 level (National Research Council [NRC], 2004; Tarr, et al., 2008). However, curriculum research at the postsecondary level is few and far between. This paper is a comparative study that analyzes two sections of precalculus at a Southeastern community college being taught by the same instructor. One section was taught using lecture-based methods and the other section using reform-based methods. The purpose of this study is to delve into how learning opportunities are impacted by inherent differences between teaching methods at the postsecondary level, and to provide a foundation for curriculum enactment research in that setting.

Framework

The premise of our study hinges upon the fact that teaching methods used in each group are in fact different. Accordingly, a crucial component for this study is *presentation fidelity* (Holstein & Keene, 2013). Presentation fidelity describes the level of faithfulness that a teacher maintains to the pedagogical approach suggested by developers of curricular materials. For the present report, we modify this definition and use presentation fidelity as a means to measure how strict the teacher follows the teaching methods prescribed for each group. Features of standards-based instruction (Chval, Chavez, Reys, & Tarr, 2009) guided the reform-based methods. The lecture-based methods are based on an unpublished set of expectations of a college lecture created by the community college where the study took place.

The purpose of this study is to examine how learning opportunities are impacted by inherent differences between teaching methods at the postsecondary level. Therefore, once we laid the foundation for the two different teaching methods we needed to choose a framework to analyze learning opportunities. We chose the mathematical tasks framework (Stein, Grover, & Henningsen, 1996) to code learning opportunities. The authors identify four types of mathematical tasks within two levels of cognitive demand, high and low. Tasks involving *memorization* (MEM) of mathematical facts and completing *procedures without connections* (PNC) to deeper concepts are considered to be low-level. On the other hand, tasks that include completing *procedures with connections* (PWC) to deeper concepts or *doing mathematics* (DM) are high-level. This framework has been used by its developers to assess the learning opportunities afforded to students based on the level of mathematical tasks in which they engage.

In the present study we aim to address two research questions: 1) what effects do reform- and lecture-based teaching have on students' performance?, and 2) how do learning opportunities differ based on teaching method when the teacher and course are the same?

Methods

This quasi-experimental comparative study examines two sections of precalculus at a large community college in Southeastern United States. This study took place at the beginning of the fourth unit of instruction, approximately 75 percent of the way through the semester. Students were studying rational functions at the time. For students within this course, emphasis is placed on intercepts, asymptotes, and points of discontinuity. All observations were video recorded.

Participants

Each section was taught using a different teaching method, which we used to make distinctions between the two groups. One section was taught using lecture-based teaching methods (LG, *N=24*), primarily consisting of lecture and whole class discussion. The second section was taught using reform-based teaching methods (RG, *N=29*), where students worked in small groups using discovery and inquiry to investigate topics. The same instructor, who is one of the authors, taught each section.

To compare the two groups we considered several factors. First, we considered the average test scores on three unit assessments that took place prior to the study. These three scores were consistent between the two groups (*p-values=0.15; 0.50; 0.93*). Second, we found the proportion of students in each group who needed to take remedial mathematics courses prior to enrolling in the course (RG: 13 of 29; LG: 14 of 24; *p-value = 0.33*). Thus, we concluded the groups were academically comparable.

Materials

Students in RG were given a handout that included exploration tasks, and used pre-constructed GeoGebra files during each class. These files utilized sliders that were dynamically linked to functions, tables, and graphs being explored. In RG, students were encouraged to take their own notes based on conjectures they made as they explored. On the other hand, students of LG were not given the handout but instead the teacher wrote many notes on the board that students could transcribe while the whole class discussed mathematical concepts involved.

Data Collection and Analysis

Lesson plans for each group were developed to comply with the pre-selected teaching methods. Following each class, we met to discuss how faithful the teacher was to the method designated for that group. To assess the level of presentation fidelity achieved during each class we created a qualitative scale consisting of four levels: almost always, frequently, rarely, and never.

To respond to our first research focus, we evaluated student scores on a post-assessment. To do so, a two-sample *t*-test was used to determine if there was a significant difference of average score between the two groups. To address our second research question, we analyzed video recordings of instructional time and considered students' engagement with the types of tasks.Further, on the post-assessment we categorized each question as, MEM, PNC, PWC, or DM so that an item-by-item analysis could be connected to learning opportunities. Additionally, some questions on the post-assessment required that students provide explanations, coded as either full (F), partial (P), or no explanation (N), which were used to enhance our discussion on learning opportunities.

Results

When determining presentation fidelity, we coded the teacher at 'almost always' for all criteria for each class in both groups, thus the two sections were in fact unique.

Post-assessment

The post-assessment was given in the class following the three classes that were videotaped. Items 2, 4, 6, 7, 8c, and 8d were items that contained an explanation component. We independently coded post-assessments for correctness and explanation, and then discussed. There was a maximum score of 14; results between the two groups were not significantly different (RG: 7.59 [3.08]; LG:

8.21 [3.02]; *p-value = 0.28*). Therefore based on overall scores of the post-assessment we conclude that teaching method did not have an effect on student performance. However, an item-by-item analysis follows.

In table 1 we report on the mean (and standard deviation) disaggregated by item within each group (only items that were significantly different are reported). Items reported in table 1 were scored with a 0 (incorrect) or 1 (correct). Next to each item number is the type of task (Stein et al., 1996) coded for that specific item. Table 2 describes the proportion of questions answered with full (F), partial (P), or no explanation (N) on the post-assessment.

Table 1: Post-assessment scores disaggregated by item

	Question – Type			
Group	2 – MEM*	6 – MEM***	7 – DM*	8c – PWC***
RG	0.45 (0.51)	0.31(0.47)	0.28 (0.45)	0.69 (0.47)
LG	0.71 (0.45)	0.67 (0.48)	0.08 (0.28)	0.33 (0.48)

Table 2: Proportions of F, P and N for each item by group

	Question – Type											
	2 – MEM			6 – MEM			7 – DM			8c – PWC		
Group	F	P	N	F***	P***	N	F***	P***	N**	F***	P	N***
RG	0.38	0.34	0.28	0.17	0.59	0.24	0.31	0.00	0.69	0.66	0.07	0.27
LG	0.58	0.17	0.25	0.58	0.04	0.38	0.04	0.54	0.42	0.21	0.08	0.71

*$p < 0.10$; **$p < 0.05$; ***$p < 0.01$

Learning Opportunities

Items 2 and 6 were coded as MEM, and in both cases LG did significantly better than RG. Items 7 and 8c were coded as DM and PWC items, respectively. In both cases RG did significantly better. It is clear from these results that because LG was instructed on “rules” of rational functions and engaged primarily in low-level tasks (PNC) throughout the classes they did stronger on items of comparable caliber. Likewise, RG engaged primarily in high-level tasks (DM) throughout the classes and therefore, did stronger on DM or PWC items.

Reform-based. Students were doing mathematics almost exclusively because all classes were student-lead and exploration-based. Small groups explored with the software and modified their conjectures about when holes occur versus vertical asymptotes. Similar activity transpired in groups during each class throughout the study; hence, students of RG were *doing mathematics.*

Students periodically engaged in PWC, the secondary type of task, because of their use of multiple representations to engage with rational functions (Stein et al., 1996). It is worth noting that there was no occasion where we coded tasks as PNC or MEM in RG. We therefore were able to conclude the most common types of tasks for the unit in RG were high-level, primarily DM tasks.

Lecture-based. Alternatively, all lecture-based classes were unique in their structure and the types of tasks in which students actually engaged. The teacher began class one by defining rational functions and outlining procedures to follow to gather information about characteristics of rational functions. These procedures were algorithmic and were focused on the correct answer instead of deepening mathematical understanding; hence deserving a code of PNC (Stein et al., 1996). This style was prominent in class one. However, since students engaged with technology to view graphical and algebraic representations, the secondary level of tasks was coded as PWC. Class three had a comparable lesson to class one so it was coded similarly. It should be noted that some tasks were coded as MEMin class three because students were asked to provide information based on “rules” learned in one of the previous classes (e.g., students’ hearing and subsequently memorizing phrases such as “vertical asymptotes trump holes”).

Class two was slightly different. The primary task was still PNC yet the secondary task was coded as MEM and the tertiary task was coded as DM. Students were instructed on rules to determine if a discontinuity was a hole or a vertical asymptote (MEM); however, students were also given an introductory task where they were given certain criteria and asked to create a rational function to meet those criteria (DM). Consequently, even though all four types of tasks appeared in LG every class, we concluded low-level tasks, primarily PNC were the most common types of tasks.

Discussion

In this section we provide an elaboration on the results presented in the previous section. To begin, there was no significant difference in mean scores on the post-assessment between the two groups. This is consistent with the students' prior unit assessments, so it is not very surprising, and indicates that a reform-based teaching method did not have an effect (at least in this case) on community college students' performance. However, when an item-by-item analysis of the post-assessment was conducted we see that there were many significant differences between the two groups. We will focus this section on those differences and then suggest areas for future research.

Recall that the most common level of tasks in which students engaged in the two groups was low-level in LG and high-level in RG. Students in RG did not experience low-level tasks during any of their classes. On the other hand, students in LG were able to experience all four types of tasks during every class. Students in LG outperformed RG students on memorization tasks, such as item 6. This implies that all students benefited from both low- and high-level tasks, but low-level tasks should not be prevalent during instructional time. Students in RG did significantly better than students in LG on item 8c in terms of both performance and explanation. In RG the teacher and the group never specifically went through finding y-intercepts of rational functions, indicating that students in RG were able to realize that y-intercepts cannot exist when there is a vertical asymptote of $x=0$. On the other hand, LG students were not able to explain that there was no y-intercept for the given function. These results further justify that all students should be exposed to all types of tasks, but high-level tasks should prevail during instruction. This answers our second research question.

In conclusion, curriculum research at the postsecondary level is lacking in the literature. Our findings can act as a basis for future research endeavors. However, some limitations of our study are we only studied one teacher working with 53 students and our assessment may not have been reliable. Nevertheless, during our investigation of the effects on learning opportunities, we see that reform-based teaching methods can provide students with richer learning opportunities if student exploration is supplemented with high-level tasks. However, all students benefit from experience with all types of tasks, but focus should be given to tasks that require doing mathematics and procedures with connections.

In order to evaluate a curriculum, it must be known how students are using it. However, the opportunities for use afforded to students by curriculum are changing with technology. The purpose of this study was to discover how undergraduate students in applied calculus use the written curriculum in their course which included an online homework system. The study drew on three data sources: (a) online survey, (b) observations, and (c) interviews. Students' survey responses indicated that, while not many students referenced the textbook, those that did preferred to use textbooks for finding worked problems, finding formula or definitions, and doing homework problems. The observations and interviews revealed that students responded to negative feedback by checking computations and for formatting errors.

Keywords: Curriculum; Post-Secondary Education; Technology

Use of Curriculum

Researchers across disciplines have recognized the importance of curricular use. Lee, McNeill, Douglas, Koro-Ljungberg, and Therriault (2013) studied undergraduate engineering students' use of textbooks during problem solving, and Peng (2009) studied accounting students required to use an online homework system. In mathematics education research, Williams and Clark (2012) looked at student actions broadly, including "what resources they used such as tutors, textbooks, online notes, and study groups" (p. 184), also considering the use of an online homework system and textbooks. The only resource which received significant use was the online homework, and that only for the completion of homework; students did not read the online textbook.

Over the last two decades, many mathematics departments implemented online homework systems as part of their curricula (Hirsch & Weibel, 2003). Beginning in the 1990s, colleges and universities posited that online homework system in mathematics classes enhanced students' learning in their first-year courses (Kehoe, 2010; Hauk & Segalla, 2005; Zerr, 2007). In these studies learning was measured by students' self-reporting on surveys and performance on standardized assessments. Studies on the effectiveness of online homework determined either that there is no significant difference in standardized-assessment performance between online homework system and traditional paper homework (e.g., Hauk & Segalla, 2005), or that the use of online homework system has a small positive effect on performance compared to traditional paper homework (e.g., Burch & Kuo, 2010). Until we know how students are using the online homework systems, we cannot be certain how the features support student performance or learning.

Methods

In order to build on this research, we investigated the question: How do undergraduate students in an applied calculus course at a large Midwestern university use the written curriculum in their course?We define the *written curriculum* as the collection of instructional materials endorsed by the course coordinator to be used by students. It may include textbooks, documents, and online homework systems. By *use of curriculum* we mean any action involving the written curriculum with the intention of accomplishing a goal (e.g., using the textbook to find a similar problem on which to model a solution or using the online homework system to satisfy a course requirement).

Setting

This study took place in an applied calculus course at a large Midwestern university. The syllabus listed the textbook and described the required online homework system (WebAssign). This particular instance of WebAssign allowed students three tries before deducting points for each question, required answers to be in one of a few acceptable formats, and included resources called Read It and Watch It for some problems in which students could reference a relevant section of the textbook or watch a short instructional video, respectively.

Procedure

When recruiting participants, we randomly selected instructors and then recruited in each of the two sections they taught. In this way all the students taking the applied calculus course were potential participants. Students were invited to volunteer to complete the online survey and participate in the observation and interview portion of the project. Thirty-five students completed the online survey and eight students were additionally observed and interviewed. Participants will be referred to by gender-preserving pseudonyms.

Survey

The survey was designed and distributed using Qualtrics software. Responses served as a baseline for descriptions of students' access to and use of curriculum. Questions were designed to explore three different curricular materials: online homework systems, textbook (electronic or printed), and exams from a previous semester. For each of these materials, questions focused on exploring students' use and/or goals for use.

Observation/Interview

Observations of the students using the written curriculum and an interview of those students provided the main sources of data. We observed eight participants working on their homework assignment or studying for an exam for 30 minutes. Immediately after finishing the observation, each student was interviewed for up to 30 minutes. We implemented a guided interview (Patton, 2002). There were some questions which were created before the interview and others were informed by the observation.

Findings

Use of Textbooks

Of the 35 participants who responded to our survey, 34 (97%) had access to the textbook with either a physical copy, digital copy, or both. Of these 34, only 15 (44%) participants reported referencing the textbook at least once per week (see Table 1). No participants reported referencing the textbook more than 5-6 times per week.

Of the eight participants we observed and interviewed, three had only a physical copy of the textbook, two had only the e-book, two had access to both, and one had no access to the textbook at all. Two of the participants who did have access never used it (from Brendan: "It's been sitting in my room collecting dust"), and the remaining participants reported rarely using it. Brendan initially tried to use the textbook to find similar problems to those on the homework, but found, "It never corresponded with the problems I was having." Another participant reported that, "When we were told we had to get it, I thought we would be assigned problems out of it, but we're not."

Table 1: Students' Frequency of Use of Textbooks

Frequency	Responses	Percentage (out of 34 students)
0 times	19	56%
1-2 times	10	29%
3-4 times	4	12%
5-6 times	1	3%
7 or more times	0	0%

Use of Online Homework System

Each of the 35 participants reported having access to WebAssign. Most students reported using WebAssign for working on current homework (97%). A majority of students use WebAssign for looking ahead to future homework assignments (68%). Students also reported consulting WebAssign when studying for exams (65%), learning new material (94%), and studying for quizzes (88%). Kristen reported that when using WebAssign to study for exams, she would "try to think of problems I had difficulty with and maybe go back through them." Cathy reported: "Just before the exam I will do the WebAssign again, go through all of them."

We also asked students to rank the strategies they were likely to employ when WebAssign marked an answer incorrect. Students reported being most likely to look for mistakes in their work, closely followed by trying the same answer in a different format. Students were much less likely to reference their textbooks or give up.Of the eight participants we interviewed, seven reported checking their own computations, four reported seeking the advice of peers (be it through personal communication or WebAssign's online forum) or seeking the help of their instructor. Two reported consulting extracurricular online resources (e.g., Khan Academy) before resorting to the textbook.

Use of Previous Exams

Another curricular resource available to students was the exams used during the previous semester the course was offered. Perhaps not surprisingly, 82% of the participants in our study reported using these previous exams primarily to study for exams, with no other reason being reported by more than 18% of participants. Each of the eight participants we interviewed reported using the previous exams only to study for midterms and the final exam. Manny reported using the previous exams to gauge how many of each type there would be. Ben reported that he wanted to "see what kind of questions would come up on the exam." Brendan wanted to use the previous exams to gauge the difficulty of upcoming exam problems and how many of each type would be used, but felt that they did not do this sufficiently well.

We observed Brendan when he was using the previous exams to study for the final exam. He would highlight questions he wanted to review again later. Manny reported that he would take the practice exam under exam-like settings: "I keep a clock with me, I remove everything out, I just keep calculator, I do have a pencil with eraser." After working through the entire exam, he would check the answers. Esther also reported taking the practice exam "like I was taking the exam." Ben and Cathy would treat the previous exam as a set of sample problems and checked the answers after each question.

Discussion and Conclusion

Once a major pillar of written curriculum, our study shows that the textbook no longer holds a place of privilege (cf. Lee et al., 2013). Less than half of the participants surveyed reported accessing the textbook weekly. With few exceptions, the class met three times a week and there were six homework assignments due per week. Thus, for most students, neither lectures nor homework consistently prompted use of the textbook, a finding consistent with Williams and Clark (2012).

Nevertheless, it may be that the textbook was used irregularly by the majority of students; the lone participant interviewed without it revealed that there were a few times he wished he had purchased it.

The lack of textbook use may be partially attributable to its integration into this particular course. The interviews uncovered a student who tried to use the textbook, but found it unhelpful. In another interview, a student attributed the lack of use to the fact that problems were not assigned directly from the book. In fact, none of the assessments for the course were directly related to the textbook. Those students who were using the textbook were using it merely as a reference for worked examples, formulas, and definitions, rather than as a way to learn material, a finding consistent with those by Lee et al. (2010), Williams and Clark (2012), and Lithner (2003).

We conclude that course coordinators should look for more connections between parts of curriculum, including the features of the online homework system and use of the textbook. In this study we found that students did not use the textbook often, and, if they did use it, it was to look for worked examples, formulas, or definitions. The most prominent motivating factor seemed to be the bonus points they get for completing assignments early. Also troubling, students' expressed a persistent concern about being able to correctly format of the online homework answers. If students do not trust the feedback from the online homework systems, its value as a learning tool, that is, its status as curriculum must be critically examined.

EXAMINING TEACHERS' CONCEPTUALIZATIONS OF CURRICULAR MATERIALS IN THE PLANNING PROCESS WITH DISCOURSE ANALYSIS

Zenon Borys
University of Rochester
zborys@warner.rochester.edu

Keywords: Curriculum; Middle School Education

It has long been established that there is a difference between written curriculum and enacted curriculum. Teachers play an intermediary role between written curriculum and enacted. This suggests curriculum developers' intentions do not directly determining what occurs in the classroom and therefore what students learn (Tarr, et al., 2008). This poster is focused on one aspect of how written curriculum is turned into enacted curriculum, teachers' planning process.

This study is a part of a larger NSF funded study (grants DRL-746573 and DRL-1222359) that utilized discourse analysis in the tradition of Gee (2014) by analyzing contextual/situated meaning to examine the relationship between teachers' conceptualization of curriculum during the planning process and features of the curriculum resources used. The primary data source included interview data from 14 middle school teachers from the same state. Teachers participated in a staged lesson plan (SLP), a semi-structured interview where teachers were provided with materials from a curriculum that was philosophically different from the curriculum they currently enact and asked to plan a hypothetical lesson. For example teachers who used a traditional curriculum were given reform-based materials to plan from and vice-versa.

Analysis of data included open coding of interview transcripts and provided resource materials. Remillard's (2005) work was used as a framework to categorize how teachers conceptualized curricula. The framework was based on ways researchers have conceptualized mathematics curricula, namely as a resource to be: followed with fidelity/subverted, drawn from as one of multiple resources, treated as a text subject to interpretation, or utilized as a tool whose use is determined dialogically between the materials, teacher, and students.

Findings included that when deciding how to use "new" curricular materials three features served as catalyst points for teachers' decision making. The curricular features included teachers' interpretation of how activities in the lesson related back to the stated goal/standard, physical layout of the materials including sequencing, and teachers' anticipated student reactions to the materials/instructional activities. Analysis also indicated that the most difficult decisions for teachers focused on relating the standard/objective of the lesson to the lesson activities. The confusion teachers evidenced was attributed to differences in curricular materials. Most notably, reform-based materials provided discussions in teacher resources that tied objectives and guiding questions to the problem contexts students engaged with, whereas traditional resources did not. The lack of connections between objectives and activities made envisioning how materials could be used in the classroom more difficult and confusing for teachers.

CONTRASTING MATHEMATICAL PLOTS: A STUDY OF "IDENTICAL" MATHEMATICS LESSONS

Aaron Brakoniecki	Elyssa Miller	Andrew Richman	Leslie Dietiker
Boston University	Boston University	Boston University	Boston University
brak@bu.edu	erm74@bu.edu	asrich@bu.edu	dietiker@bu.edu

Keywords: Curriculum; Curriculum Analysis, Instructional Activities and Practice, High School Education

Efforts to analyze the enactment of curricular materials have largely used tasks as their unit of curricular analysis (e.g., Henningsen & Stein, 1997). While the quality of tasks is clearly central to student learning, this level of analysis ignores the role that the sequencing of tasks plays in the way that students experience the lesson. Examining the sequence of tasks enables the examiner to see how the posing and resolution of questions over time shapes the experience of the learner. Interpreting a math lesson as a story (Dietiker, 2013) allows for this type of analysis. This poster uses Author's mathematical story framework to address the research question: When enacted lessons based on the same written materials are interpreted as mathematical stories, what are the variations in how the content unfolds and how do these variations potentially impact students' mathematical experiences? For this study, student mathematical experiences can include emotional responses to the story, opportunities for continued investigations, the closure of explorations, engagement with new content, etc.

As part of a larger, ongoing study, this poster presents contrasting case studies of two different enactments of content that are based on the same textbook lesson. Two teachers were recorded teaching a lesson on using substitution to solve systems of linear equations from the same curriculum materials (blinded here, as an author of the materials is also an author on this proposal). These were veteran teachers with three or more years of experience teaching with the selected textbook and were chosen to represent a range of geographic and demographic sites. The recorded videos and interviews with the teachers were analyzed by the research team for the mathematical plot of the lesson (Dietiker, 2013). The questions found in these enactments, though often similar in form, emerged in different orders and are addressed in different ways. This poster presents an analysis that helps us understand and describe how the unfolding of content may result in different mathematical experiences for the students.

Note: An author of this poster receives research funding from College Preparatory Mathematics (CPM), which is developing products related to research described in this poster. This author also receives book royalties from CPM for the textbooks used in the study. The terms of this arrangement have been reviewed and approved by Boston University in accordance with its conflict of interest policies.

Keywords: Algebra and Algebraic Thinking; Curriculum Analysis; Instructional Activities

The Common Core State Standards of Mathematics (CCSS) highlight the importance of gaining a conceptual understanding of key ideas by students (CCSS0, 2010, Key Shifts in Mathematics). One key idea in the CCSS for secondary mathematics is the knowledge of solving quadratic equations. The New York State Education Department (NYSED) developed EngageNY, which is a collection of curriculum modules and resources in PreK-12 aligned with the CCSS, to support teachers implementing key aspects of the CCSS. What is not known, however, is how well the EngageNY modules address the key shifts in Mathematics stated by the Common Core Initiative. In this study, we seek to answer the following research question: How many and what types of problems in solving quadratic equations are presented in the Algebra 1 and Algebra II modules on EngageNY.
The analysis in this paper compiled information on: the number of lessons (horizontal analysis) and location of lessons (vertical analysis) in the Algebra I and Algebra II modules on EngageNY that involved the knowledge of solving quadratic equations. Individual lesson content, cognitive demand and response type of each task relating to the solving of quadratic equations were also compiled. Individual lesson tasks were coded using the framework drawn from Stein, Grover and Henningsen (1996) and Son and Senk (2010). Of the five Algebra I modules on EngageNY, three modules contained lessons involving the solving of quadratic equations for a total of 14 lessons and 141 tasks. Of the four Algebra II modules on EngageNY, only 1 module contained lessons involving the knowledge of solving quadratic equations for a total of eight lessons and 70 tasks. With regard to lesson context, 110 of the lessons were purely mathematical (78%) while only 31 were coded as real-world examples (22%) for Algebra I. In Algebra II, 67 of the tasks were purely mathematical (96%). In terms of the cognitive demand of mathematical tasks, we found that 26 of the tasks were coded as memorization (18%) and 79 were coded as procedure without connections (56%) for Algebra I. Thirty-three of the tasks were coded as procedure with connections (23%), while only 3 were coded as doing mathematics (2%). For Algebra II, none of the tasks were coded as memorization and 47 were coded as procedure without connections (67%). Response type was another area of weakness for the tasks in the EngageNY Algebra I modules. One hundred twenty one tasks required students to give an answer only (86%) while only 20 tasks required an explanation (14%) for Algebra I. In Algebra II, 59 of the tasks required an answer only (84%) and 11 tasks required an explanation (16%). Although New York State has touted the EngageNY modules as having a level of difficulty equal to the Common Core expectations, our study shows that the intended curriculum of the CCSS is not being fully met by the module lessons provided on EngageNY for solving quadratic equations.

RIGOR, RELEVANCE, AND RELATIONSHIPS: PRESERVICE TEACHERS' PREPARATION ON PROJECT BASED LEARNING

Jean Sangmin Lee
University of Indianapolis
jslee@uindy.edu

Keywords: Curriculum; Instructional Activities and Practices; Teacher Education-Preservice

Several national initiatives have sought to reform mathematics teaching to prioritize critical thinking and reasoning in order to address concerns about the mathematical underachievement of US students (NMAP, 2008). One inquiry-based instructional approach that has become increasingly popular is PBL. Unlike units in which a project is used as a culminating experience, PBL poses a realistic situation at the beginning of a unit and uses the need to create a deliverable product to drive the course content through an extended inquiry process. Students who learn in PBL environments learn rigorous mathematics, address relevant problems or topics, and build relationships with one another. The question that motivates this study is: *What are the successes and challenges PSTs encounter as they design and implement math PBL units?*

Theoretical Framework

The framework used to evaluate the rigor and relevance of PBL units is the Six A's: Authenticity, Academic Rigor, Applied Learning, Active Exploration, Adult Connections, and Assessment Practices (Markham, Larmer, & Ravitz, 2003). This framework guided the analysis of the units and how they were implemented.

Methods & Data Sources

This exploratory study involved ten math PSTs in an accelerated, teacher residency program, earning a Masters of Arts in Teaching and a teaching licensure in 12 months. This study employed axial coding techniques (Strauss & Corbin, 1990). Data sources included before- and after-implementation reflections, student-generated artifacts, and original and revised unit plans.

Results

PBL is an innovative instructional method designed to provide an authentic purpose for students to learn and engage with mathematics. However, implementing PBL instruction is no easy feat. The implementation of project based instruction in mathematics classrooms requires a shift from more traditional teaching practices to create classroom cultures that focus on flexible and robust understandings of math. This departure from conventional modes of teaching involves more than just a change in teachers' knowledge; it requires teachers (and students) to reconceptualize what it means to teach and learn, and that they create new and different opportunities for learning in and out of classrooms.

INVESTIGATING ALGEBRA PROGRAMS: INDIANA AS A CASE STUDY

Brooke Max
Purdue University
foster90@purdue.edu

Lane Bloome
Purdue University
lbloome@purdue.edu

Keywords: Algebra and Algebraic Thinking; Assessment and Evaluation; High School Education; Middle School Education

The *Common Core State Standards for Mathematics* (National Governors Association Center for Best Practices & Council of Chief State School Officers [NGA & CCSSO], 2010) and separate individual state standards position algebra as a critical component of the secondary curriculum. The issue of access to algebra has also garnered much attention, as it is a gatekeeper for future success in mathematics and post-secondary schooling (Adelman, 1999), as well as access to it having been identified as a civil right (Moses, Kamii, Swap, & Howard, 1989).

The current accountability culture (e.g., No Child Left Behind, 2001) and attempted national coherence of Algebra I standards (e.g., NGA & CCSSO, 2010) present persistent challenges in mathematics education. It is important to investigate policy changes made in response to the high-stakes accountability measures within this culture as well as the state of curricular flux in this course that is required by numerous states for graduation.

Our driving question is: "What policies shape Algebra I programs at the state level?" To answer this, we consider Indiana as a case study, investigating: How do schools determine when students take and who is teaching Algebra I? Who has influence in making these decisions? To answer our research questions, we gained a broad picture of programs across the state through surveying the 292 public non-charter school districts in Indiana, asking quantitative and qualitative questions. The survey was emailed to the superintendent of each district, who then answered or distributed the survey to someone with a stronger knowledge base of the Algebra I program structures.

With a response rate over 40%, our survey suggests school personnel are ready and willing to participate in a discussion on algebra policy. On average, 57% of respondents' Algebra I students were 9th graders, with 8th graders making up 22% of respondents' Algebra I students, as expected. The most common criteria that influence when students take Algebra I were found to be age/grade level (79% of respondents), grades in previous math classes (75%), current math teacher recommendations (68%), and test scores (60%). Our survey revealed that roughly half of high school mathematics teachers and roughly one third of middle school teachers in Indiana teach Algebra I, with respondents indicating the most powerful voices in deciding who teaches Algebra I as being administrators (95% of respondents), department head (64%), and individual teachers (59%). These survey results are being used to construct interview protocols aimed at discovering the individual features of representative Algebra I programs.

This study seeks to add to the current conversation about Algebra I across the state and nation by reporting trends and patterns found throughout an entire state. We posit that being familiar with the policies that are in place will aid in understanding Algebra I programs across different schools, districts, and states.

REFRAMING PARENTS' CONCERNS OF MATH CURRICULUM CHANGE

Lynn M. McGarvey
University of Alberta
lynn.mcgarvey@ualberta.ca

P. Janelle McFeetors
University of Alberta
janelle.mcfeetors@ualberta.ca

Keywords: Elementary School Education; Curriculum

My son in Grade 5 still doesn't know the answer to 6 x 8. Why aren't kids today memorizing their times tables?

As mathematics educators, we've been asked this question dozens of times. Put on the defensive, we try to justify current strategy-based approaches and explain the importance of sense-making over memorizing supported by research (e.g., Boaler, 2002; Thompson, et al., 2013). Unfortunately, our efforts often inflame parents further. Despite 80 years of research that consistently demonstrates the detrimental effects of memorization and rule-based approaches to mathematics learning, the tug-of-war between "new math" and "back to the basics" continues to be waged. In Canada, efforts to communicate advantages of current curriculum reforms to parents have largely failed. This failure leads to conflicting pedagogical agendas at school and at home or simply the disengagement of parents in supporting their children's learning.

The reported research was framed by the questions: What are parents' experiences with and perceptions of curriculum change? What is the nature of their concerns? With our long term goal to identify fruitful ways to communicate reform to parents and help them re-engage in their children's learning, the aim of the study was to establish theoretically and methodologically parents' experiences in their own histories of learning mathematics, their perceptions of current approaches, and concerns or conflicts between their past experiences and current perceptions.

Phenomenography (Marton & Booth, 1997) provided a theoretical grounding and methodological approach, where researchers develop a framework of related categories empirically to illustrate the range of participants' perceptions of their experiences. Located in a large Canadian city and in rural communities, 96 parents across socioeconomic levels volunteered to participate. Qualitative data included 12 focus group sessions and follow up interviews with 36 of the parents, selected for the diversity and intensity of their perspectives. Categories of collective experience were generated and further substantiated through rich description of data exceprts.

The results reveal two categories of collective concerns held by parents and educators: (1) the opportunity for students to reach expected learning goals, such as mastering computational skills, developing problem solving ability, and becoming functionally numerate citizens; and (2) ensuring adequate supports are in place so that learning goals are accessible and attainable, such as teaching expertise matched to learning expectations and clear, sequential resources accessible to teachers and parents.

Our findings allow us to lay aside the rhetoric of oppositional stances in approaches to learning mathematics to identify and describe commonalities. Doing so helps us establish effective avenues of communication with educational stakeholders and empower parents to re-engage in supporting their children's learning of mathematics.

Extensive research (e.g., Silver & Su, 2010) has attended to the affordances of professional learning experiences in which teachers collaboratively examine artifacts of students' mathematical work to develop mathematical and pedagogical knowledge and to reflect on classroom practice. Less attention has been placed on the student practice of examining student work and how this impacts their mathematical understanding and reasoning (Rittle-Johnson & Star, 2011). The purpose of this study is to focus on the use of student work as a context for student learning. This is relevant to the PME-NA conference audience as student work can provide students with potentially different opportunities to examine varied mathematical conceptions by focusing on the reasoning, strategies, methods, and understandings of others.

Our research study is framed by *student*, *teacher*, and *curriculum* generated student work. First, many teachers collect and use work generated by students to develop mathematical ideas. Second, the teacher anticipates a strategy that highlights an important insight or misconception. If students do not produce this strategy themselves, the teacher implants the strategy in the class discussion. Third, student work may be embedded in mathematics curriculum materials. Our research is guided by the question: What are the intended purposes of the student work embedded within the written curriculum materials for learning mathematics?

To address this goal, we analyzed three middle school mathematics curricula: *Connected Mathematics*, *College Preparatory Mathematics*, and *Big Ideas*. The unit of analysis is each mathematics problem containing embedded student work. Curriculum-embedded student work includes references within the student text to how a person thought about a mathematical context or problem and requires that students analyze, evaluate, generalize, critique, and/or reflect on another's mathematical thinking. Analysis of the student work focuses on the existence, nature (e.g., location, frequency, problem type such as error analysis), and intended purpose.

Results of this study explicate existing curriculum-embedded opportunities for students to engage in the analysis, evaluation, generalization, critique, and/or reflection on another's mathematical thinking. This work has implications for classroom practice because it serves as a mechanism to ensure students have access to opportunities for learning key concepts and strategies. Future work includes examining how teachers use curriculum-embedded student work and its impact on student learning outcomes. In addition, future research includes examining the impact of curriculum-embedded student work on teacher pedagogical content knowledge.

Keywords: Assessment and Evaluation; Middle School Education; Teacher Knowledge

Assessment and evaluation remain an enduring challenge in mathematics education. Paralleling the advent of standards-based curricula that advocates for reform-based mathematics instruction, formative assessment challenges conventional notions of assessments as paper-and-pencil tests used to measure student achievement at the end of instruction. Black and Wiliam (1998) used the term, assessment, to refer to "all those activities undertaken by teachers – and by their students in assessing themselves – that provide information to be used as feedback to modify teaching and learning activities. Such assessments becomes formative when the evidence is actually used to adapt the teaching to meet students' needs" (p. 140). In this study, formative assessment is characterized as an ongoing process that occurs before, during, and after instruction by which teachers anticipate student strategies and solutions, gather and analyze evidence of student learning, and adapt their teaching to meet students' needs and to help students develop their own reflective habits of mind.

To provide attention to the complexities of daily formative assessment that occurs in mathematics classrooms, a group of curriculum developers, teachers, and mathematics education researchers have created a framework for formative assessment. The following research question guided our study: What is a framework that describes formative assessment opportunities and related teacher practices during planning, teaching, and reflecting?

Based on the research literature and best practices, a framework was developed that includes suggested questions, examples, and strategies for formative assessment practices. The resulting framework is organized around two dimensions. One dimension captures key practices of anticipating student strategies and solutions, gathering and analyzing evidence, and adapting teaching. The other dimension is the Launch–Explore–Summarize instructional model. For example, the teacher's role in the Launch is to assess students' prior knowledge and its relationship to the challenge of the problem. This contrasts with the teacher's role in the Explore where she attends to the needs of individual or groups of students as they work on the problem. Building on the Launch and Explore, the teacher orchestrates discussions during the Summarize phase to develop students' understandings as they relate to the mathematical goals of the lesson.

The framework suggests that formative assessment is an integral part of daily teaching practice and can be used as a lens to broaden teachers' interpretations of formative assessment. Future research studies may use this framework to investigate, characterize, and report on teachers' formative assessment practices. In addition, professional learning experiences can be designed using the framework to make the ongoing daily practice of formative assessment more accessible to mathematics teachers so that they can improve their classroom instruction.

TURKISH 8TH GRADERS' MATHEMATICS SUCCESS ON TIMSS IN RELATION TO NATIONAL HIGH SCHOOL PLACEMENT TESTS

Musa Sadak
Indiana University
msadak@indiana.edu

Keywords: Assessment and Evaluation

This study examined the mathematics items in two national assessments conducted in Turkey, namely the OKS 2007 (Assessment of Secondary Educational Institutions) and the SBS 2011 (Secondary Education Placement Test), in terms of content and cognitive domains. The main focus was to interpret the gains in Turkish 8th graders' mathematics scores on TIMSS between 2007 and 2011 in terms of the OKS 2007 and SBS 2011 assessments.

The data for this study was derived from the Turkish 8th graders' mathematics scores in TIMSS 2007 and 2011 (Martin, Fullis, & Foy, 2008; Mullis, Martin, Foy, & Arora, 2012) and the mathematics questions in OKS 2007 and SBS 2011 assessments. For this study, the questions in OKS 2007 and SBS 2011 assessments were categorized into one of four content domains (numbers, algebra, data & chance, and geometry) and one of three cognitive domains (knowing, applying, and reasoning) according to the TIMSS 2011 framework.

Although Turkish 8th graders' overall average mathematics score increased from 432 to 452 from 2007 to 2011 in TIMSS assessment, there was no significant difference between given years in numbers content (Mullis et al., 2012). On the other hand, performance improved on the other content domains, especially geometry (Mullis et al., 2012) where the score increased 43 points (Mullis et al., 2012).

One of the likely reasons for the lack of improvement on the numbers domain of TIMSS is that the percentage of content items in number decreased from 39% to 20% between OKS 2007 and SBS 2011. Along with this decrease, there is evidence that teachers decreased emphasis in the area. In contrast, the percentage of geometry items increased from 35% in 2007 to 50% in 2011. Thus the change in focus of the Turkish assessments in relation to TIMSS, where the emphasis on each of the content domains was constant, is likely a major reason for the increase in geometry performance relative to number.

With respect to the cognitive domains in the assessments, it was found that there was an increase in the percentage of items in the knowing domain (28% to 55%) and a decrease in the percentage of items in the other two domains between the OKS 2007 and SBS 2011. Relative to PISA, TIMSS is more of a factual and knowing-based assessment (Kloosterman, Roach, & Pérez, in press) and thus emphasis on the knowing domain in the Turkish assessments could also have impacted the strong gains of Turkish students on TIMSS.

Background and Research Questions

Through studies conducted in the latter half of the twentieth century across many different languages and cultural norms, the semantic structure of word problems has been found to influence problem difficulty for young children, and word problems have been organized into taxonomies based on semantic structure and difficulty (Fuson, 1992; Verschaffel, Greer, & DeCorte, 2007). In the current era, the Common Core State Standards for Mathematics (CCSSI, 2010) explicitly incorporate the full range of word problems found in the established taxonomies.

This change in the standards presents an interesting opportunity to explore questions of whether there is a fundamental way that children think about word problem types that makes some problem types inherently more difficult than others, or whether the differences in difficulty are manufactured by relative amounts of exposure and opportunities to learn.

Using data generated from interviews and written assessments involving more than 2,000 students during the 2013–2014 school year, our investigation is driven by the following two research questions:

- With respect to the semantic structure of word problems, do the textbooks used in classrooms of students in our sample afford different opportunities to learn than the textbooks used in classrooms of students in the samples of students in the 1970s and 1980s?
- Do the previously identified patterns in relative problem difficulty based upon the semantic structure of word problems continue to be valid for first grade students?

We consider this study to be an important preliminary investigation into a larger question concerning the influence of semantic structure and opportunities to learn on the relative difficulty of word problems for young learners of mathematics.

Introduction and Method

In this study, we engaged middle grades mathematics teachers in a comparative study of national and quasi-national standards documents, the CCSSM and the National Council of Teachers of Mathematics *Principles and Standards for School Mathematics* (PSSM). Findings indicate tensions exist between what teachers' desire in standards documents and what standards authors provide. Nine middle grades teachers who were part of an existing professional development community that focused on increasing mathematical knowledge for teaching, participated in a focus group that reviewed and compared the PSSM and CCSSM. The focus group was conducted near the end of the academic year in which CCSSM was adopted by the state. The teachers were randomly divided into two focus groups, and were presented with three blinded sets of parallel excerpts from each standards document that represented similar content and foci. The excerpts included a topic from the algebra and geometry content standards, and the Problem Solving Process Standard from PSSM and the Standard for Mathematical Practice (SMP)Make Sense of Problems and Persevere in Solving Them from CCSSM. During the focus groups, the teachers were asked to compare the relative clarity and usefulness of the blinded excerpts. The discussions were video recorded and transcribed for inductive analysis. Open coding (Ryan & Bernard, 2000) was used to identify themes. All discrepancies in coding were discussed until consensus was reached. The data were then analyzed for similarities and differences (Charmaz, 2006) using a constant comparative method.

Findings and Implications

Based on teacher responses, the following findings were organized by three broad themes: 1) *formatting*, 2) *implementation of standards*, and 3) *characteristics of ideal standards.* The documents examined by the teachers in this study represent the intended curriculum; however, teachers' indicated expectations of support that are traditionally found in a written curriculum (Reys & Reys, 2010). The ideas expressed by teachers in these groups suggest that practitioner consensus regarding features of standards has yet to be conceived which manifests as tension between desired characteristics that, at times, appear in conflict with one another.

This study examined how (1) visual representations including illustrations and diagrams and (2) personalization to students' out-of-school interests, affects 7th grade students' performance on and perceptions of math story problems. Considerable research shows that learners benefit from visual representations, and effectively using visual representations is one way in which to improve problem solving. Research also suggests that even shallow attempts to personalize problem contexts to student interests in areas like sports or shopping can promote learning and interest. In prior research we found no effect for personalization or decorative illustrations for 7th graders solving percent problems, but diagrams with mathematical information were associated with higher performance. Here, we seek to replicate the results for a new content area and examine student perceptions of easiness and interestingness for the problems they solve.

Participants were 179 7th grade students attending a suburban middle school; they solved a worksheet containing 8 story problems on which diagrams, illustrations, or personalization were manipulated. Students were significantly more likely to get a problem correct if it had a diagram alone than if it had no visuals (*Odds* = 1.66, $p = 0.014$). Students were not more likely to get a problem correct if it contained an illustration ($p = 0.225$) or a diagram with an illustration ($p = 0.378$) compared to no visuals, and students were not more likely to correctly solve personalized problems than non-personalized problems ($p = 0.526$). In the models predicting students' ratings of easiness (1-5 scale), problems with a diagram alone were rated as significantly easier compared to: no visuals ($B = 0.17$, $SE = 0.07$, $p = 0.013$), illustration alone ($B = 0.19$, $SE = 0.07$, $p = 0.006$), and a diagram with an illustration ($B = 0.20$, $SE = 0.07$, $p = 0.006$). Problems with an illustration were rated as significantly harder than problems without an illustration ($B = 0.11$, $SE = 0.05$, $p = 0.029$). Personalization was not related to easiness ($p = 0.53$). In the models predicting students' ratings of interestingness (1-5 scale), problems with a diagram alone were rated significantly less interesting compared to: no visuals ($B = -0.16$, $SE = 0.07$, $p = 0.017$), illustration alone ($B = -0.20$, $SE = 0.07$, $p = 0.002$), and a diagram with an illustration ($B = -0.27$, $SE = 0.07$, p < .001). Personalized problems were significantly more interesting than non-personalized problems ($B = 0.46$, $SE = 0.05$, $p < .001$).

In both this study and our prior study, performance was highest on problems that had personalization, a diagram, and no illustration. The combination of personalization and diagrams may be ideal to promote engagement while scaffolding performance for struggling learners. We found that diagrams improved performance and made problems seem easier but students found them boring. Personalization did not affect performance or easiness, but made problems more interesting. Illustrations did not impact performance, but students felt they made problems harder. This study provides guidance to inform curriculum design in math education.

DEVELOPING EFFECTIVE CURRICULUM MATERIALS FOR PROFESSIONAL DEVELOPMENT

Zhaoyun Wang
University of Toronto

Keywords: Teacher Education-Inservice; Curriculum

This study examined the effectiveness of the curriculum materials for a series of grade 8 mathematics teacher workshops. In recent decades, educational researchers have tried to find effective ways to improve teachers' professional knowledge (Desimone, 2009). Educational "field has acknowledged a need for more empirically valid methods of studying professional development" (p. 181). The development of computer information communication technology (ICT) provides an informal and integral tool for teaching and learning.

The objectives of the materials were to integrate technology, mathematics content, pedagogical content knowledge and teaching resources in a collaborative environment of learning. The core features in this grade 8 mathematics program concentrate on Ten Dimensions (McDougall, 2004) for teachers' professional development. The Ten Dimensions are: (1) program scope and planning, (2) meeting individual needs, (3) learning environment, (4) student tasks, (5) constructing knowledge, (6) communicating with parents, (7) manipulatives and technology, (8) students' mathematical communication, (9) assessment, and (10) teacher's attitude towards and comfort with mathematics. The research questions are: (1) how do curriculum materials meet the needs of participants? And (2) how do workshops in mathematics content, use of technology and pedagogical strategies affect teacher's attitudes and beliefs about mathematics teaching?

The participants were 29 middle school teachers and 8 principals from an urban school district. The teachers took part in four full day workshops and were provided teaching materials through a two-way website. The participants selected five dimensions as core objectives for the workshops. The curricula materials and delivery for this teacher program identified a few key factors: teachers' needs based on former research, their feedback after each workshop, curriculum content selection, style of content delivery, and when and how to distribute workshops. The participants were interviewed individually and completed two surveys at the beginning and end of project in the academic year. This survey is a Likert-like six scale with 20 questions (McDougall, 2004). A paired T-test was employed to test significance for each of 20 questions to see the effects. Finally, the quantitative results were confirmed by the qualitative study.

The results showed that the tailored curriculum material designed by focusing on the Ten Dimensions framework is an effective approach for in-service teacher programs. The participants increased their knowledge in their targeted objectives of this program. The participants changed their beliefs about their scope and planning skills, their ability to design interesting students' tasks, their ability to communicate with parents and peer teachers, and the effective use of manipulatives and technology in classes. The participants were satisfied with the materials of mathematics content, use of technology for teaching and communication, and assessment activities conducted in the program. The findings of this program for design of curriculum content can be used in the similar educational contexts.

When to introduce negative integers to children is an important issue in school mathematics; delaying their introduction can lead to lasting misconceptions such as one cannot subtract a larger whole number from a smaller. Yet understanding negatives involves a complex extension of whole-number knowledge. It is not known whether this extension is only possible after whole-number concepts are learned or whether simultaneous acquisition of positive and negative integer concepts is possible. This study used an established whole-number intervention (playing linear board games), extended to include negatives, with kindergartners and first graders. Performance placing integers on empty number lines provided evidence of students' understanding of integer concepts.

Keywords: Number Concepts and Operations; Cognition; Elementary School Education

Purpose of Study

One of the enduring challenges students face when learning number concepts is determining how to revise and build on their whole number understanding to include new numbers. In particular, incorporating negative integers into their number system is challenging, and many students will continue to assert that you cannot subtract a larger number from a smaller one, even if they can solve other problems with negative integers (Murray, 1985). At a basic level, when learning about negative integers, students must extend their backward counting sequence to below zero, using the positive number names with the word "negative" before them. Likewise, they must reinterpret the meaning of the minus sign to mean "negative" when attached to a numeral and referring to the numbers less than zero (Vlassis, 2004).

When given the opportunity to explore negative numbers, even first graders were able to talk about their values (Bofferding, 2014) and use them in arithmetic problems (Behrend & Mohs, 2005/2006). Other researchers have identified kindergarteners who were able reason about negative numbers (e.g., Bishop et al., 2010). However, questions still remain about the extent of knowledge possible for young students, whether typical kindergarteners can learn about negative numbers, and what types of activities might support their understanding. We explore these issues in this paper.

Theoretical Framework

According to Case's (1996) theory of Central Conceptual Structure for Number, before the age of four, children have two cognitive structures for number. The first allows them to count a set of objects, and the second allows them to make visual comparisons of sets of objects. However, they cannot use counting to help determine which set has more or less; these cognitive structures remain separate. Around the beginning of kindergarten, children begin to coordinate the two structures and can reason that adding one object to a set corresponds to moving up one number in the counting sequence. They also learn to map the numerals to quantities and number words. By first grade, these structures are often fully integrated if students have had supportive numerical experiences (Griffin, Case, & Capodilupo, 1995). This integration is referred to as a mental number line. As mentioned previously, to extend their mental number line to include negative integers, students must accept that there are numbers less than zero and learn the new notation (i.e., the importance of the negative sign), number names, how they are ordered, and their values.

One experience that helps students develop their whole-number mental number line is playing linear board games (Ramani & Siegler, 2008). On a simple board game labeled with squares from 1

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

to 10, preschoolers counted on as they moved toward the finish. The experience of seeing and saying the number sequence helped the children progress in their ability to identify the numerals and determine which number is bigger. Further, they outperformed a control group on a series of number line estimation tasks, which were the main measures of interest. When given a number line marked with 0 and 10 and asked to mark where numbers 1-9 go, the students who played the game were more likely to space the numbers evenly. Therefore, a linear model more completely explained their plots (based on R^2 values) and slope values of their lines were nearer to one. The results indicated that playing the board game helped the children develop a mental number line for whole numbers (Ramani & Siegler, 2008).

Unlike with whole numbers, where students have experiences both counting and working with sets of objects, children cannot work with negative sets of objects (unless we artificially impose a negative value onto objects). Therefore, playing a similar linear board game that includes negative integers may be a helpful way to give children experiences with the order and values of negative numbers. On the one hand, this extension might only make sense to children after they have developed a whole-number mental number line (in first grade). On the other hand, they may be able to learn about negatives while they are simultaneously developing the whole-number mental number line (in kindergarten). Based on these possibilities, we explore the following research question: To what extent can playing a linear board game including negative integers help kindergarteners and first graders develop a linear representation of the integers?

Methods

This study took place over two years. In the first year, we worked with first graders, and in the second year, we replicated the study with kindergarteners.

Setting and Participants

The participants came from an elementary school located in a low-income area in the Midwest with a large proportion of English Language Learners. In the first year, we conducted the study during the first three months of the school year with 50 first graders (26 female; 24 male); however due to two students moving and one not completing the tests, we only present complete data from 47 students. In the second year, we conducted the study during the first three weeks of the school year with 45 kindergarteners (27 female; 18 male).

General Design

Each year, the study involved an experimental design, which included a pretest, stratified random assignment to control or experimental ("game") group, intervention, posttest, and follow-up. We only present data from the pre- and posttest portions of the study. The design and materials replicated those used by Siegler and Ramani (2009) but included some modifications and additions to include a focus on negative integers. For the intervention, each participant worked with a researcher (professor or one of two graduate students) for three, 15-minute sessions. One of the graduate research assistants worked with four kindergarten students who benefitted from Spanish translation. During the first year there were 22 first graders in the game group and 25 first graders in the control group with complete data. During the second year, there were 23 kindergarteners in the game group and 22 kindergarteners in the control group.

Pre-test and Post-test Measures

The pretest and posttest were identical and conducted as individual interviews with the students; we did not provide specific feedback on their performance. Across the sections of the test, the problems used positive integers as well as negative integers with tasks involving counting, ordering integers, determining which integer was closer to or further from 10, and solving addition and subtraction problems involving positive and negative values (for further descriptions see Bofferding & Hoffman, 2014). We describe the two main measures of interest here.

First, on the integer identification task, we presented numerals on isolated pages in random order and asked students to identify integers from -10 to 10. Second, in the final section of the test, students were asked to place integers on number lines. Students completed a packet involving positive integers followed by one involving negative integers. Each page of the packet contained an empty number line 25.5cm long with two integers marked. On the first page of both packets, students were asked to put a pen mark where 0 would go, given the locations of -5 and 5. For the positive packet, the remaining pages contained empty number lines marked with 0 and 10. The placement of zero in the middle, i.e., leaving space for the negative numbers to the left, was an important feature. Students were asked to make a mark where a given integer should go a total of 18 times (1 through 9 in random order, twice). The researchers gave instructions such as, "If here is 0 [point to the middle] and here is 10 [point to the right], then make a mark on this line [motions to whole 25.5 cm line] where 6 should go." The negative number packet worked similarly, only with -10 marked on the left and 0 marked in the middle. Students were told to place the negative integers -1 through -9 on the respective pages.

Control Group

For their three sessions, the control group students rotated through three types of activities with the researcher. The first activity involved counting a collection of 1-10 items and counting backward as far as they could. No feedback was given on correctness. On the second activity, students put a set of six integer cards in order from least to greatest. For example, one set they ordered included the following integers: 2, 1, 0, -5, 10, and -8. After the students ordered the set, they were asked to show the least and the greatest. No feedback was given on the ordering or the identification of the cards. The last activity in the sequence was a game of memory where the goal was to match integers. Corrective feedback was given if students attempted to collect an incorrect match, but they were not told the names of the numbers.

Treatment (Game) Group

During each 15-minute intervention session, the experimental group played a board game against the researcher using a board labeled with the integers -10 to 10 (see Figure 1).

										START											
-10	-9	-8	-7	-6	-5	-4	-3	-2	-1	0	1	2	3	4	5	6	7	8	9	10	FINISH

Figure 1: An illustration of the linear, numbered game board.

Players started by placing their tokens at zero, and the first player drew a card from a card deck. In the first version, all but one of the cards was labeled with a 1, 2, or 3. The remaining card contained the text, "All players go back to -10." When this card was drawn, the student had to count backward while moving the tokens back to -10. The researcher always stacked the deck so that this card would come up in the first few turns of the game, ensuring players would advance from -10 to 10 in each round. Players drew a 1, 2, or 3, moved their tokens that number of spaces, and named the numbers on the spaces they passed through. For example, if a player on -7 drew a "2," then she would move her token to -6 and say "negative six," then move her piece to -5 and say "negative five." The game ended when a player crossed 10.

During the third session, the card sending players back to -10 was replaced with a stack of cards marked with -2 or -4. Players began the game by drawing from this stack and counting backwards as they moved to -10. Once a player reached -10, on her next turn she would begin drawing with the deck containing positive numbers. From this point, play continued as normal, with the game ending once a player crossed over 10.Students played an average of 4 games in 15 minutes, and the researchers gave feedback (if needed) to correct the name of the integer that students landed on or correct the number of spaces they moved their game piece. Students had to repeat the correct name or counting sequence before the game play continued.

Analysis

Measurement

All items from the assessments were marked as correct/incorrect, except those in the number line estimation tasks. For the latter, we measured how far away from zero the student made a mark on the empty number line (to the nearest half-millimeter). We also gave the magnitude a sign, positive or negative (because zero was in the center of the line). While students were instructed to make a single, vertical line segment as their mark, some made several segments (by moving the pen rapidly up and down) or drew the numeral instead of a line segment. When measuring in these cases, we took the average of the left and right-most marks.

After one researcher completed the initial measurements for a set (e.g., measured one student's placements of positive numbers on the pretest), another researcher randomly checked five measurements. If there was disagreement on even one measurement, the second researcher checked all the measurements for that set. Lastly, a third researcher took measurements to resolve all disagreements.

Coding

To interpret the measurements, we created a four-tiered coding system. When dealing with only whole numbers as Siegler and Ramani (2009) did, it was sufficient to use two quantitative measures. The R^2 values measured the degree to which the placements were linear, and the slope of the regression line measured whether increases in the numbers to be placed resulted in a proper increase in the placements. When negatives were introduced, a complication was added. Students not only had to space the numbers evenly (high R^2value) and with equal spacing (slope near one), but they also had to know on which part of the number line to make the placements. As an example, consider a student who counted from the left (at -10) when marking positive numbers. The R^2 and slope could be exactly one, but the student would have major errors as 1 would end up at -9, 2 at -8, 3 at -7, and so on. To capture errors such as this, we added a third quantitative measure: numbers placed on the wrong side of zero. For students to show great understanding in their placements, they needed to have high R^2 values, a slope near one, and few numbers on the wrong side of zero.

To make this systematic, we created codes for four levels of understanding. A student with Level 3 understanding had an R^2value ≥ 0.90, a slope of 1 ± 0.3, and at most one value placed on the wrong side of zero. A student with Level 2 understanding did not show Level 3 understanding and had an R^2value ≥ 0.80, a slope of 1 ± 0.8, and at most two values placed on the wrong side of zero. Level 1 understanding meant not fitting into the higher levels and an R^2value ≥ 0.60, a positive slope, and at most four values placed on the wrong side of zero. Finally, Level 0 understanding was for students who did not fall into any of the higher levels. The cutoffs for these levels evolved after familiarizing ourselves with the data, including looking at scatterplots, regression lines, and using qualitative codes.

Comparing Groups

Our primary hypothesis was that the game groups would make significantly more gains in their ability to place integers on an empty number line. We operationalized this using the level-of-understanding codes described above. Specifically, we hypothesized that the mean increase in level of understanding would be significantly higher for the game group both in kindergarten and in first grade, and both with positives and negatives. We were most cautious in our hope with the kindergarteners' performance with negatives, especially if they lacked the ability to correctly identify negatives. In addition to using inferential statistics to test the above hypotheses, we also sought qualitative patterns in the data to motivate fuller explanations and future research.

Results

Identifying Negative Integers

On the pretest none of the kindergarteners in either groups could identifying any of the negative integers; instead they ignored the negative signs and either identified the positive numeral or said random number names. On the posttest, none of the kindergarteners in the control group were able to identify the negative integers. However, six students (26%) in the game group could correctly identify the majority of them. In first grade, three students (12%) in the control group and four students (18%) in the game group were able to identify negative integers on the pretest. By the posttest, eight students in the control group (32%) and 21 (95%) students in the game group did so.

Number Line Estimation

Overall, the kindergarteners showed low levels of proficiency at placing integers on an empty number line. Despite the fact that six students in the game group had success identifying negative integers on the posttest, none of the students showed Level 2 or 3 understanding according to our coding system (see Table 1). Similarly, there was limited success with positives in the game group; only two students achieved Levels 2 or 3. No students in the control group for kindergarten moved above Level 0 for positives or negatives. While several kindergarteners' R^2 values improved, they often had a tendency of placing the numbers on the wrong side of zero (see Table 2 for an example).

Table 1: Students' Levels of Number Line Estimation on Pre- and Posttest

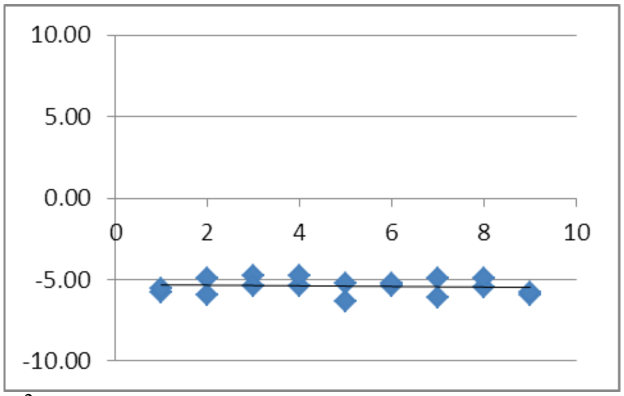
	Kindergarten Control (N=22)		**Kindergarten** Game (N=23)		**1st Grade** Control (N=25)		**1st Grade** Game (N=22)	
Level	Pre	Post	Pre	Post	Pre	Post	Pre	Post
Positive								
3	0	0	2	2	7	6	2	3
2	0	0	0	0	6	4	6	6
1	1	0	1	3	3	2	1	2
0	21	22	20	18	9	13	13	11
Negative								
3	0	0	1	0	4	3	3	7
2	2	0	1	0	6	4	5	6
1	1	0	0	2	2	3	3	1
0	19	22	21	21	13	15	11	8

The first graders performed better than the kindergarteners in every way. There were seven students who achieved Level 3 with negatives on the posttest and six who achieved Level 2. Thus, well over half (59%) showed high levels of proficiency. With the positive integers, nine students achieved Levels 2 or 3 (41%). Even the control group experienced success: ten students achieved Levels 2 or 3 with the positives (40%) and seven with the negatives (28%).

To make the comparison between the groups more rigorous, tests of four a priori hypotheses were conducted using Bonferroni adjusted alpha levels of .0125 per test (.05/4). The four hypotheses consisted of checking for significant differences between the mean change in level of understanding, pretest to posttest, for the positive and negative integers, crossed with the two grade levels. Results

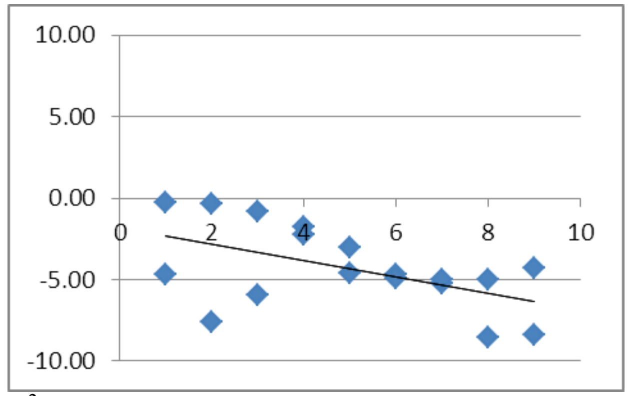
Table 2: A Kindergartener's Number Line Estimation Data (Level 0) on Pre- and Posttest

Student G02, Pretest Positive Values



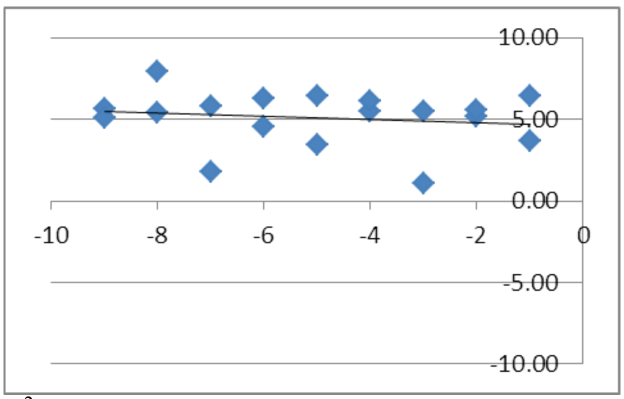
R^2 = .01; Slope = -.02, all with wrong sign

Student G02, Posttest Positive Values



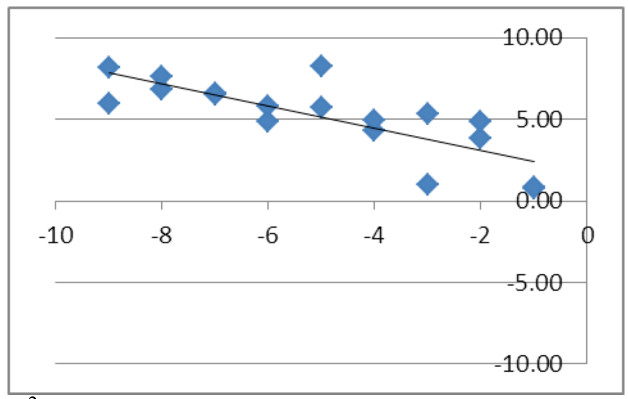
R^2 = .28; Slope = -.50, all with wrong sign

Student G02, Pretest Negative Values



R^2 = .02; Slope = -.10, all with wrong sign

Student G02, Posttest Negative Values



R^2 = .62; Slope = -.68, all with wrong sign

indicated that the mean change in level of understanding was not significantly different with the positives for the kindergarteners between the control group (*M* = -0.05, *SD* = 0.21) and the game group (*M* = 0.09, *SD* = 0.29). Also for the kindergarteners, the mean change was not significantly different with the negatives between the control group (*M* = -0.23, *SD* = 0.61) and the game group (*M* = -0.13, *SD* = 0.46). Likewise, there was no significant difference seen in the first graders with the positives between control (*M* = -0.32, *SD* = 0.95) and game (*M* = 0.18, *SD* = 1.01). However, there was a significant difference seen the mean change with respect to the negatives in first grade between the control (*M* = -0.24, *SD* = 0.72) and the game group (*M* = 0.55, *SD* = 1.18), $t(34) = -2.70$, $p = .011$. Therefore, the intervention, i.e., playing the linear board game significantly impacted participants' ability to place negative integers on an empty number line.

Students who were less successful on the number line estimate task fell into two major groups. One set of students spaced out the numbers along the entire line, ignoring that 0 fell in the middle of the line. Therefore, these students had close to half of their points fall on the wrong side of zero (see Figure 2).

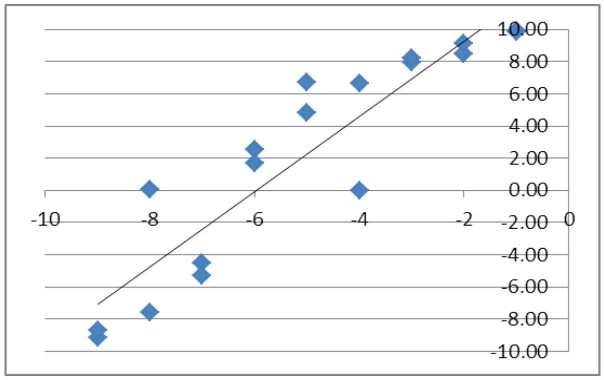


Figure 2: An illustration of data spanning the whole number line when placing -9 to -1.

A second set of students placed numbers in two to three similar locations, regardless of the number shown, as if they split the number line into small and large or small, medium, and large. Therefore, their points formed distinct clusters along the line (see Figure 3). Sometimes, these students started at 0 and counted up to place numbers 1-5 or started at 10 and counted down to place numbers 6-10, which accounted for the clustering.

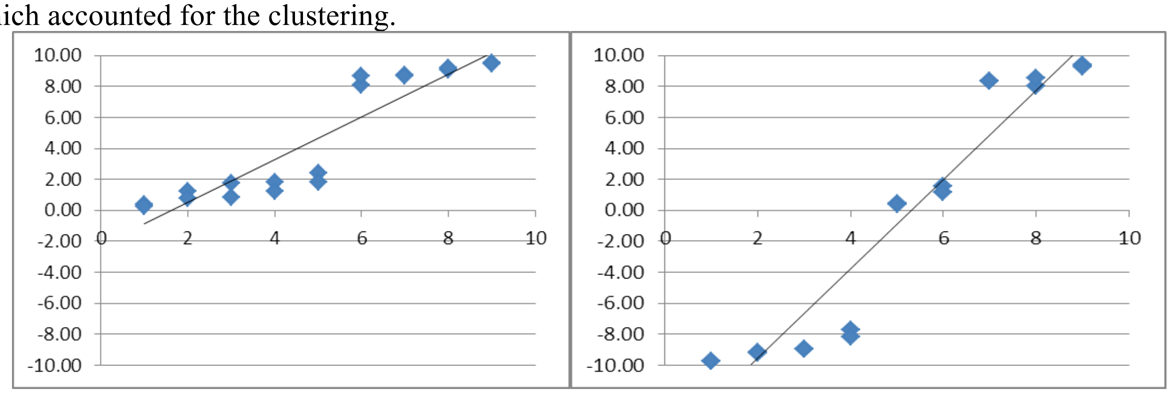

Figure 3: Illustrations of data chunked along the number line when placing 1 to 9.

Conclusions and Implications

Based on the results, we conclude that playing the board game did not help kindergarteners develop a mental number line including negative numbers. Although they started to space out their placement of the integers, they frequently placed numbers on the opposite side of zero. More surprising, they did not improve on placing the positive values on the board as was found in previous studies with preschoolers (Ramani & Siegler, 2008; Siegler & Ramani, 2009). A likely reason for this is that students were given space to mark positive numbers before 0 (as opposed to having zero at the edge of the page). Therefore, they often chose to mark 0 and 1 near the left edge of the paper, to the left of zero, at the beginning of the line. This suggests that as students learn about positive numbers, they need opportunities to see zero in other locations than just at the edge of the paper, and also suggests that Ramani and Siegler's (2008) results may overestimate students' abilities. Because the kindergarteners here learned about positive numbers *and* negative numbers, it is also possible that the kindergarteners had too much to learn compared to children in Ramani and Siegler's study (2008), and the time spent on negatives might have taken away from time needed with positive numbers. Alternatively, providing a longer intervention may lead to a stronger effect for both positive and negative numbers.

On the other hand, the first graders in the game group benefitted from playing the board game. Almost all of the students were able to identify negative numbers on the posttest and a significant number were able to estimate the placement of all integers on the number line fairly well. These results suggest that students are more likely to develop a mental number line that includes negative numbers if they already have a whole number mental number line.

Finally, students' placement of the numbers suggests a few areas to focus on in instruction. Students had an inclination to take up as much space as they were given, spacing out the positive numbers across both negative and positive parts of the number line (and similarly for negative numbers). Further, they often started counting from the very left of the page, rather than attending to the given points. When introducing and using visual aids such as the number line in the classroom, teachers should present numbers in multiple formats (not always starting at the left of the paper) and talk about numbers on either side of key reference points, such as zero. Presenting number lines with different numbers marked and with different scales may help students attend to the relevant features of the number lines and placement of numbers.

Proportional reasoning is key to students' acquisition and application of complex mathematics and science topics. Research is needed regarding how students' progress towards and come to demonstrate key developmental understandings within proportional reasoning. To this end we created and administered assessment items to 297 middle grades students. We categorized student solution processes qualitatively, followed by Rasch analysis to examine item difficulty and strategy use in relation to an anticipated trajectory. Our findings indicate that different strategies manifest themselves in a hierarchical manner, providing initial confirmation of categories based on strategy efficiency and emphasizing the importance of teacher (and researcher) analysis of classroom assessments from a student cognition perspective.

Keywords: Learning Trajectories; Measurement; Number Concepts and Operations

Purpose

Proportional reasoning is a lynchpin for future success in mathematics and science (Lesh, Post, & Behr, 1988). Based on a substantial body of proportional reasoning research (e.g., Lamon, 2005; Lobato, Ellis, & Charles, 2010; Tourniaire & Pulos, 1985), there have been several calls for shifting instruction from the typical focus on the cross-multiplication algorithm to students' meaningful understanding and application of ratio related concepts (e.g., National Governors Association & Chief Council of State School Officers, 2011). However, implementing this shift in instruction is difficult. Schools and teachers need resources to support this change and more information is needed on how students' proportional reasoning develops from less efficient to more efficient strategies.

The overall purpose of our research is to develop measures to assess students' flexibility and efficiency in proportional reasoning situations. Our work revolves around: (a) measuring and identifying qualitatively different categories or aspects of student reasoning, and (b) determining whether these categories manifest themselves along a hierarchical progression. The qualitative and quantitative confirmation of different categories or aspects of students' proportional reasoning along a continuum would contribute to a better awareness of how students' progress towards important understandings and assist in designing classroom instruction, curriculum, assessment, and teacher professional development.

More specifically, the present research uses Simon's (2006) KDUs as a theoretical framework for examining student work samples to identify qualitatively different categories or aspects of proportional reasoning in simple missing value contexts. From there we use the structure of Steinthorsdottir's (2009) hypothetical trajectory to create assessment items which measure students' proportional reasoning and enable us to analyze and categorize the resulting student thinking. Lastly, we use Rasch modeling to determine whether our identified categories for student thinking manifest themselves hierarchically, indicating the potential usefulness of the assessment items and qualitative rubric for teachers and researchers in their analysis of students' thinking.

Theoretical Framework

Simon's (2006) articulation of key developmental understandings (KDUs) provides a framework for analyzing students' flexibility and efficiency in proportional reasoning situations. Simon (2006) describes key developmental understandings by stating,

> …I am not claiming that these understandings exist in the student; rather, specifying understandings is a way that observers (researchers, teachers) can impose a coherent and potentially useful organization on their experience of students' actions (including verbalizations) and make distinctions among students' abilities to engage with particular mathematics (p. 360).

We see KDUs as a potential framework for identifying important categories of students' reasoning when analyzing work samples. The following section articulates a KDU important to students' initial development of proportional reasoning.

Research indicates that students' demonstration of flexible and efficient use of the scalar and functional perspectives in proportional reasoning situations may be a KDU (Lobato, Ellis, and Charles 2010; Lamon 2005). A scalar perspective entails recognizing a ratio as a composed unit that can be scaled up or down by multiplying each quantity in the ratio by a constant factor. For example, given the problem "Callie bought 7 cookies for \$3. How many cookies can Callie buy for \$12?" a student recognizes the original 7 cookies to \$3 ratio can be scaled up by multiplying each quantity in the ratio by 4 to generate the 28 cookies for \$12 ratio (see figure 1a). A functional perspective entails recognizing and using the constant multiplicative relationship between the two quantities within the ratio and applying this relationship to create equivalent ratios. For example, given the similar context "Callie bought 6 cookies for \$2. How many cookies can Callie buy for \$13?" a student recognizes the number of cookies to be purchased is three (6 ÷ 2) times the number of dollars paid. This understanding allows the student to quickly realize Callie can purchase 3 x 13 or 39 cookies (see figure 1b).

Figure 1a: Callie bought 7 cookies for \$3. How many cookies can Callie buy for \$12?

Scalar Perspective

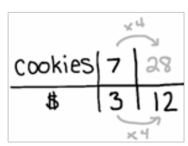

Figure 1b: Callie bought 6 cookies for \$2. How many cookies can Callie buy for \$13?

Functional Perspective

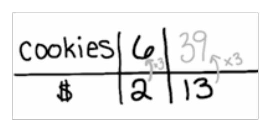

Figure 1. Scalar and functional assessment items and solution perspectives.

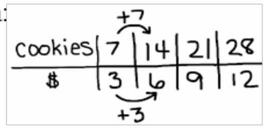
In simple missing value problems, students demonstrate attainment of this initial proportional reasoning KDU by flexibly and efficiently demonstrating knowledge of either the scalar or functional strategies based on the situation or number relationship presented (Steinthorsdottir & Sriraman, 2009). For example, given the situation illustrated in Figure 1a, an efficient and flexible strategy is to scale up by a factor of four. A student who applies the functional multiplier of 2.33 is likely performing a standard procedure without reasoning through the proportional relationships, indicating a possible lack of flexibility in their proportional reasoning.

In addition to examining a students' work for application of the scalar or functional perspective, one must also examine scalar situations for the level of efficiency used in the scaling process (Authors, 2015). For example, in missing value situations with an integral scalar relationship strategies can often be differentiated as additive or multiplicative (see figure 2).

Additive strategies may indicate initial understanding of the scalar relationship but a multiplicative understanding is needed for eventual generalization of the scalar perspective to non-integral relationships. Therefore, student work must also be examined for use of an additive versus multiplicative approach in addition to the scalar and functional perspectives.

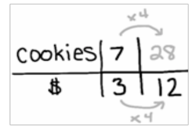
Callie bought 7 cookies for $3. How many cookies can Callie buy for $12?

Figure 2a:



Additive

Figure 2b:



Multiplicative

Figure 2. Additive and multiplicative solution strategies for a scalar problem.

In sum, we observe students' flexible and efficient application of the scalar or functional perspective in simple missing value situations as an initial KDU in a proportional reasoning learning trajectory. In students' application of the scalar perspective, student solution strategies must be examined for an additive versus multiplicative approach to ensure students are able to eventually generalize their strategy to non-integral situations. The next section details a potential developmental trajectory for these ideas, followed by a description of the assessment items designed to capture students' understanding of these concepts.

Steinthorsdottir and Sriraman (2009) articulated a potential progression for students' proportional reasoning. They identified four levels of increasingly sophisticated strategies students used to solve missing value problems. In level one, students incorrectly focus on the difference in quantities either within or between the ratios. In level two, students focus on either additively iterating or multiplicatively scaling the given ratio as a composed unit to reach the missing value in the equivalent ratio (scale-up). Level three involves scaling down a given ratio, and includes two sub-levels, the ability to partition the given ratio as a composed unit to reach the missing value in the equivalent ratio (scale-down) and the ability to combine iteration and partitioning to reach the missing value (scale up and down). Level four involves the flexible use of either the scalar or functional relationship depending upon the ease of calculation with the numbers in the problem.

Based in part on the progression outlined by Steinthorsdottir and Sriraman (2009) and the identified KDUs for scalar and functional perspectives, we developed an assessment with a focus on manipulation of number relationships to examine students' types of reasoning and the level of efficiency in their solution process. For the sake of brevity we focus on presenting three exemplar problems from the assessment and their solution strategy analysis (Table 1).

Table 1: Assessment framework and anticipated solution strategy analysis

Item Construction		Solution Strategy Analysis	
Type of Reasoning	*Integral Number Relationship*	*Less Efficient*	*More Efficient*
1. Scalar	Scale Up	Additive	Multiplicative
2. Scalar	Scale Down	Additive	Multiplicative
3. Functional	Functional	Scale Up and Down	Functional

Methods

Research Questions

1. Can we identify qualitatively different categories of student thinking related to use of an additive or multiplicative solution strategy and/or fluent and flexible use of the scalar or functional relationship depending on the number relationship presented?

2. Do the items manifest themselves as anticipated in relation to a progression from easiest-scale up, moderate-scale down, to functional-hardest?
3. Do the strategy labels and associated scoring codes based on strategy efficiency manifest themselves as anticipated along a continuum? In other words, are less efficient strategies used by less able students and more efficient strategies associated with more able students?

Participants

The respondents represent a convenience sample of 297 students from fourth to ninth grade with the majority of the students coming from 6th and 7th grade (*n*=198).

Measure

As described in Table 1, we constructed a measure based on the Steinthorsdottir progression. We focus on presenting data from three of the assessment items: scale up, scale down, and functional. Table 1 provides the 3 items and the anticipated ‘efficient’ strategy based on the number relationship.

Table 2: Assessment items included in analysis.

Strategy Focus	Context	Anticipated Strategy
Scale Up	Callie bought 5 cookies for \$2. How much will it cost to buy 20 cookies?	Scale Down	Thomas found a cookie deal with 10 large cookies for \$8. How many cookies can he buy for \$2?	Functional	Jason found a cookie deal with 16 cookies for \$8. How many cookies can he buy for \$3?	
Timeline and Setting

In order to focus on initial cognitive understanding rather than procedural knowledge, assessment items were administered in the fall prior to formal proportional reasoning instruction. Older students in our sample should have received instruction around proportional reasoning and we would expect more efficient strategies from these students. However, contact with teachers in our study indicated instruction was based primarily on implementation of cross-multiplication, with little or no emphasis on scalar or functional perspectives.

Results

Qualitative analysis of the outcome space

We analyzed the student strategies for each assessment item. We coded each for an additive or multiplicative solution strategy and/or fluent and flexible use of the scalar or functional relationship. Table 3 provides an overview of the coding framework with example student work for each efficiency level. In addition to the qualitative coding of strategy name, description and example, we identified the following scoring categories with respect to strategy efficiency: 0 = incorrect, 1 = correct but inefficient strategy, and 2 = correct and efficient strategy.

Rasch Analysis

We selected Rasch modeling for our quantitative analysis due to its usefulness in (a) identifying the difficulty level of an item in relation to other items, and (b) evaluating the strategy thresholds of our efficiency-based scoring model (Van Wyke & Andrich, 2006). Assessments created to fit the Rasch model consists of items designed to assess a single (unidimensional) construct. Rasch analysis situates test takers' understanding (person ability) and item difficulty along a common equal interval scale, often with a score range between -4 to 4 with 0 as the mean. Therefore, person ability and item difficulty scores can be interpreted in relation to one another through probabilistic language. In situations involving dichotomous scoring (0=incorrect, 1=correct), when person ability and item difficulty are the same, this indicates a 50% probability that the individual would respond correctly (or incorrectly). When a person ability score is higher (e.g., 1) than the item difficulty (e.g., -1) the person is more likely to solve the problem correctly and vice versa. Figure 3 provides an example of a Rasch

Table 3: Strategy coding framework for assessment items with example student work.

Number Relationship	Number Relationships	Rubric Points	Strategy **Name** and Description	Strategy Example
Scale Up	Cookies | 5 | 20 $ | 2 | ?	1	**Scale Up Additive:** Iterate initial ratio additively or double and continue to double resulting ratios until desired number of given component is reached			2	**Scale Up Multiplicative:** Determine and use scale factor that scales initial ratio to desired number of given component in one step	Scale Down	Cookies | 10 | ? $ | 8 | 2	1	**Scale Down Additive:** Halve initial ratio and continue to halve resulting ratios until desired number of given component is reached			2	**Scale Down Multiplicative:** Determine scale factor that scales initial ratio down to desired number of given component	Functional	Cookies | 16 | ? $ | 8 | 3	1	**Scale Up and Down:** Use a combination of scaling up/down to reach desired number of given component			2	**Functional:** Determine constant of proportionality and apply to the number of given component	
item scale map based on our analysis. Typically Rasch item maps display person ability on the left side of the scale and item ability on the right. However, for ease of interpretation, we focus on item difficulty and are not displaying person ability.

Analysis 1

In the context of our present work, we first used Rasch analysis to examine item difficulty in relation to the number relationships being manipulated across problems. Our initial analysis examined whether the item difficulties manifested themselves as anticipated in relation to our hypothetical progression; easiest-scale up, moderate-scale down, and functional-hardest?

Figure 3a presents the results of Rasch analysis using the Winsteps program with dichotomous item scoring (0=incorrect, 1=correct). The difficulty scores in the box represent the item difficulty (and standard error) and determine an item's placement on the scale. For example in figure 3a, for the scale up item, -2.99 is the point on the continuum where students with an estimated ability below -2.99 are more likely to get the problem incorrect. Students with an estimated ability score above -2.99 are more likely to get the problem correct. If a student had an estimated ability score of 0, it is likely they would correctly solve the functional and scale up item but incorrectly solve the scale down item.

Findings from Analysis 1

The item order from easiest to most difficult was (1) scale up, (2) functional, and (3) scale down. Our empirical data indicated more students were likely to correctly solve the functional item than the scale down item. This was different than we anticipated. However, we recognized potential issues with this analysis. First, there was the issue with the scale down item not resulting in an integer answer (i.e., 2.5 cookies) and it is highly possible this non-integer result influenced the level of item difficulty.

However, perhaps more importantly, there was also an issue with examining the data from a dichotomous or correct/incorrect perspective instead of investigating students' strategy approach given our qualitative scoring rubric. We knew students used different strategies to correctly solve an item. Our dichotomous scoring model did not allow us to take student strategies into account, nor did it allow us to examine whether students had selected a flexible and efficient approach based on the number relationships presented in the problem. For example, on the scale up problem we wanted to determine whether students who were more likely to use an additive strategy (less efficient) versus a multiplicative strategy (more efficient) differed in ability score.

Analysis 2

Analysis 2 evaluated the qualitative rubric and associated scoring model of less and more efficient strategies. Our specific question was, did our strategy labels and associated scoring codes related to strategy efficiency manifest themselves as anticipated along the interval scale? In other words, are less efficient strategies associated with less difficult threshold scores and more efficient strategies associated with more difficult threshold scores. Thresholds are the point on the continuum where adjacent categories (or strategies) are equally probable. For example, the transition point between correct but inefficient (1) and correct and efficient (2) for the scale- up problem is .48 (see table 4). A student with an ability score of 1 would be more likely to use an efficient strategy, while a student with an ability score of 0 would be more likely to use a correct but inefficient strategy. To conduct this analysis we used a partial credit Rasch model in the Winsteps program. The strategy categories were scored as more efficient (2 pts), less efficient (1 pt), and incorrect (0 pts).

Findings for Analysis 2

Table 4 provides the Rasch item statistics for the three items and the associated category thresholds (other assessment items administered on the test are not included for ease of interpretation). The fit statistics indicate the items are 'fitting' the model. Figure 3b presents findings from analysis 1 and 2 in conjunction with each other. For example, the less efficient scale up additive strategy for the scale up item had a difficulty threshold of -3.85, and the more efficient scale up strategy for the same item had a difficultly threshold of 0.48. This indicates that a student with an ability level below -3.85 would likely get the item incorrect. Those students with ability levels between -3.85 and .48 would likely get the item correct, but use an additive strategy. Those students with an ability level above .48 would be more likely to use a multiplicative strategy.

Table 4: Rasch item statistics for proportional reasoning items

	Strategy Category Threshold	Threshold Difficulty	SE	Infit MNSQ	Outfit MNSQ
Scale Up	0-1	-3.85	0.22	1.01	1.00
	1-2	0.48	0.21	1.06	1.12
Scale Down	0-1	-0.38	0.18	0.89	0.80
	1-2	1.54	0.37	1.20	1.07
Functional	0-1	-0.97	0.18	0.98	0.92
	1-2	1.57	0.37	1.07	1.00

The threshold levels for additive versus multiplicative strategies also held true for the scale down item. While still preliminary, these findings support analysis of students' use of additive or multiplicative strategies in classroom and assessment practices to determine their depth of understanding of the scalar perspectives. This will support later work on related topics, such as geometric scaling where students must be flexible and efficient in applying a scalar multiplicative strategy. In addition, threshold levels for the functional item strategy categories supported the progression articulated by Steinthorsdottir and Sriraman (2009).

In conclusion, we recognize a continuum of ordered strategies related to students' ability is not equivalent to a progression of how students' develop understanding of a KDU. However, Rasch analysis has the potential to support our qualitative findings in ways that would assist in identification of hierarchical relationships between strategy approaches. This can provide important information to inform future research. In addition, the fact that the observed strategy thresholds match the scoring rubric indicate the usefulness of the qualitative rubric in analyzing student work through an efficiency perspective.

Lastly, while not a focus on this investigation, comparison of the two scoring models highlights the importance of analyzing students' strategies in the evaluation of students' understanding of a topic. We cannot assume students have demonstrated knowledge of a key development understanding simply because they provide the correct answer. A student could (and did) correctly solve all three assessment items using a scalar additive or scale up and down strategy. However, these strategies do not demonstrate understanding of the scalar and functional perspectives and will not continue to work as number relationships increase in difficulty.

FRANK'S PERCEPTUAL SUBITIZING ACTIVITY RELATIVE TO NUMBER UNDERSTANDING AND ORIENTATION: A TEACHING EXPERIMENT

This proposal explores how the activity of subitizing – quickly apprehending the numerosity of a small set of items – changes with the development of number concepts. We describe how varying the orientations of items in teaching experiment sessions promoted one pre-schooler, Frank, to attend to subgroups of items and change his thinking about conjoining two numbers. The results illustrate how game-play oriented subitizing activities may support growth in number understandings.

Keywords: Number Concepts and Operations; Pre-School Education; Learning Trajectories

Introduction

Subitizing is a quick apprehension of the numerosity of a small set of items (Sarama& Clements, 2009). Sarama and Clements (2009) suggested that subitizing processes transition from a reliance upon orientations to a reliance upon number understandings. MacDonald (2013) conducted four concurrent teaching experiments to investigate how subitizing activity changed in relation to understanding of number and perceived space between items. In this study, we focus on how one student's (Frank) understanding of number changed over time to rely on more conceptual processes.

Literature Review

Subitizing

Sarama and Clements's (2009) argue that children rely on either *perceptual subitizing* or *conceptual subitizing* when subitizing. Perceptual subitizing, an innate ability to discriminate different quantities, emerges in infants as young as three to five months of age and is limited to five items. Conceptual subitizing is grounded in a child's number understanding due to a child's ability to subitize groups and then compose the total number of items (Sarama & Clements, 2009). When children in kindergarten through grade two engaged in *Building Blocks,* a computer learning environment, their subitizing activity became more sophisticated and included conceptual processes (Clements & Sarama, 2007).

Number Understanding

Number understandings will be grounded in theories stemming from number conservation (Piaget, 1941/1965). This is characterized as a child's simultaneous coordination of their *serial* (number follows a sequential order) and *algebraic* (number is composed by smaller subgroups) thinking structures (Piaget, 1968/1970). Number understanding in this study will be centered on the following four areas: (a) counting (Steffe, Cobb, & von Glasersfeld, 1988), (b) composition and decomposition of number (Fuson et al., 1997), (c) links between quantity and number words (Krajewski & Schneider, 2009), and (d) perceived dimensionality (Piaget & Inhelder, 1948/1967).

Counting. Counting is described as a child relying primarily on serial thinking structures, as items are empirically pointed to and coordinated with a sequence of words. (Steffe et al., 1988). Multiple sets of research findings emphasize the importance counting has in children's mathematical development (Chan, Au, & Tang, 2014; Jones et al, 1994; Steffe et al., 1988). Steffe et al.'s (1988) research findings essentially describe how counting promotes children's number development through a coordination of units. Van Nes & van Eerde (2010) found that relationships between spatial reasoning and counting exist, as children's counting changed in relation to block arrangements. Thus, spatial orientations of objects promote children to rely on different types of counting and construct sophisticated number understandings.

Composition and decomposition of number. Fuson et al. (1997) found that children able to construct multi-digit number understandings had more sophisticated grouping techniques. Essentially when children compose and decompose number they progress through six stages of development. Jones, Thornton, and Putts' (1997) also suggest that many aspects of number understanding, including composition and decomposition of number, are foundational for students' development of number. Thus, these findings imply that young children build multi-digit number understandings through effective composition and decomposition of numbers less than ten.

Link between quantity and number words. As number is understood in a more abstract manner, number words are said to link to quantities (quantity-number competencies [QNC]) (Krajewski & Schneider, 2009). Krajewski and Schneider found that kindergarten children's QNC explained about 25% of these children's achievement scores four years later. Implications from this study suggested that future research consider how young children's empirical activity with concrete material promotes children's QNC ability prior to entering kindergarten.

Dimensionality. Topological thinking structures involve a child's attention towards the perceived topology of objects and sets of objects (Piaget, 1968/1970). One aspect of topological thinking structures, *dimensionality,* is described by Piaget and Inhelder (1948/1967) as directly promoting the flexible thinking necessary for children's later conceptualizations of formal Euclidean Geometry. Four areas of development characterize dimensionality: (a) proximity (nearbyness), (b) separation (betweeness), (c) continuity (connecting objects in spatial fields), and (d) enclosure of shape (surrounding) (Piaget & Inhelder, 1948/1967).

Purpose

Parallels between children's construction of number and subitizing activity have been suggested in the research literature (e.g. Freeman, 1912; Sarama & Clements, 2009), but a fine-grained analysis of this relationship is absent from the literature. To understand number, children need to engage with empirical items to group, partition, compose, decompose, and count. Linking number to number words would allow for number to be abstracted. Subitizing activity would essentially promote several of these empirical and mental activities to provide a child a vehicle in which to construct number understandings. The purpose for this study was to investigate how one child's understanding of number changed as he engaged in subitizing activity.

Methodology

Teaching Experiment Methodology

This study uses teaching experiment methodology (Steffe & Ulrich, 2014) and is grounded in the *radical constructivist paradigm* suggesting that mathematics understanding is actively constructed (von Glasersfeld, 1995). A teaching experiment includes a teacher-researcher, a witness for each teaching episode, at least one student, and a way to record student actions and words in each teaching session (Steffe & Ulrich, 2014). In this study, the first author was the teacher-researcher, and the second and third authors alternated as the witness. The teacher-researcher and witnesses initially met prior to the start of the experiment to establish a similar theoretical grounding and establish the functional aspects of each of our roles in this study.

Participants

Fifteen students between the ages of three years, 11 months, and five years, five months were initially recruited to participate in a larger study. The 15 students were enrolled in a preschool located near a university campus located in the southeastern portion of the United States. Four students spoke a second language at home. Eleven students were male and four students were female. Following an initial screening, six of these preschool students were selected to participate in a teaching experiment. The selection was based on their ability or lack of ability to conserve number, count, and subitize two to five items. An in-depth analysis of one student, Frank, is the focus of this study.

Frank. Frank is a male student whose family is from China. He was four years and five months old at the onset of this study. He spoke English, and in his home spoke Mandarin. Frank was interviewed two separate times on June 5th to determine if he was able to conserve number and to determine his counting and subitizing abilities. Throughout the interviews, Frank wanted to have the "correct" answer. This disposition promoted Frank to reflect more often on his activity. Frank engaged in 22 teaching experiment sessions.

Procedures

Interviews. Frank's first two interviews were used to determine (a) whether he conserved number, (b) whether he could keep track of items when counting, and (c) whether he perceptually or conceptually subitized. Frank was found to not be able to conserve number, and used perceptual subitizing. When counting, it seemed as if Frank was able to initially "count on" from 12 items. Knowing that Frank was able to count on and not conserve number seemed atypical, as Steffe et al.'s (1988) findings indicated that "counting on" required a more comprehensive understanding of number.

Teaching experiment session tasks. The teaching experiment was comprised of 22 sessions occurring two days per week no more than 20 minutes each. Tasks were designed to either assess or provoke change in Frank's thinking. Item orientation, reliance upon empirical material, and QNC were considered in the formation of the tasks throughout analysis. Tasks required him to subitize a set of items, draw or use counters to show what he remembered, and use words or actions to justify his response. They were refined prior to the teaching experiment sessions, allowing for orientation, quantity, or color of items to change to test and expand the limits of Frank's thinking. The five following tasks were used: (a) Draw what you saw, (b) Camera game, (c) Concentration, (d) Board games, and (e) Hidden Pictures. Below, we focus on the first two.

Draw what you saw. The teacher asked Frank to subitize a set of dots or counters and then to draw or use counters to show what he "saw" or "remembered." This activity was also followed up with, "How do you know you saw _______?" Frank was given material to draw what he remembered or use counters to represent what he remembered.

Camera game. The camera game was adapted from Clements and Sarama's (2007) activities. Clements and Sarama's (2007) camera game used a computer program, but in this study the activity had a series of camera pictures on a three-ring notebook. Frank was shown quickly an image of the viewfinder of a camera with dots arranged. He was asked how many dots were seen, and then he drew what the picture would look like when it came out of the camera.

Analysis

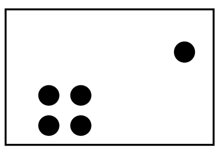
Two forms of analysis, conceptual and retrospective, were used to model and describe Frank's thinking (Steffe & Ulrich, 2014). *Conceptual analysis* regards students' responses between tasks and sessions, and *retrospective analysis* regards changes over a longer period of time. Each session was videotaped with two video cameras. Each session's video footage was reviewed after each session (conceptual analysis) and sections of video footage from the entire study were reviewed six times throughout the study (retrospective analysis).

Results

Conceptual Analysis

Subitizing activity relative to the perceived symmetry of items. Initially, Frank subconsciously relied on symmetry when subitizing, as it seemed the symmetrical orientations of the items afforded Frank the opportunity to build towards four. In Frank's first teaching experiment session he was shown four dots arranged in a square-like orientation. Frank stated that he saw "T…four," but when asked about almost stating two, he responded that he did not remember seeing two. When asked to draw what he remembered, he drew two dots and wrote the numeral two beside them. After seeing the orientation a second time, he stated that he saw four and drew the four dots in the same square-like orientation and wrote the numeral four beside them. His response suggests a subconscious attention to the two by which to build towards four.

Subitizing activity relative to the perceived space between items. In the middle of his fourth teaching experiment session Frank was playing the "Camera Game." He was shown an image with five dots (see Figure 1). The space between the square and the one dot seemed to disrupt Frank's ability to subitize the total group. This is evident when Frank draws four dots and one dot, and then writes the corresponding numerals beside his drawings (see Figure 1). After Frank describes seeing "four and one," he is asked "how many is there altogether?" This question elicits his response of "fourteen." This happened in subsequent sessions when Frank used counters, and it suggests that Frank's QNC was grounded in a procedural understanding for two-digit numbers (Krajewski & Schneider, 2009).



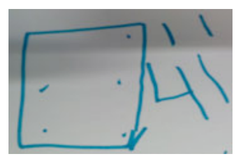


Figure 1: The orientation shown to Frank and the drawing Frank made respectively.

In Frank's earlier sessions, it seemed as if Frank's QNC was primarily procedural. This was evident when he used two-digit numbers to describe what he saw (i.e. "four and one…that makes fourteen"). Space between clustered items played a critical role in Frank's subitizing activity, as it seemed to promote him to attend towards subgroups, but he lacked the ability to compose these two groups of number. Thus, Frank would rely on a procedural QNC by stating a two-digit number. Symmetrical orientations with a regular amount of space between items prompted Frank to build towards the total number of items with one subgroup. This was evident when Frank said, "T…four." This activity does not require Frank to compose groups but to count up after subitizing two, eliciting a serial thinking structure. Thus, it seemed as if he was having difficulty coordinating his serial and algebraic thinking structures.

Changes in Frank's subitizing activity relative to changes in Frank's understanding of number. Throughout the first three sessions, Frank was capable of subitizing four items, but when shown five items, he needed space between clustered groups of two or three to subitize the subgroups of two or three. Frank did not have a conceptual understanding of five at this point because he could not compose the subgroups to name the total group of five. When Frank was shown five items without a space between the clustered items, he either named this as "six," "seven," or rearranged the items to look like the "X" orientation shown on the face of a typical die before describing this total set of items as "five."

Frank continually described two-digit numbers (i.e. fourteen, twenty-three) when attempting to conjoin the two subgroups he subitized, which indicates that his number understanding remained procedural. He may have been taught to name and identify two-digit numbers before understanding

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

single digit numbers. To perturb this notion, we asked Frank to count items and name the total number, or covered up portions of an orientation, incrementally building (+1) from a group of three to the total number of items. This task design utilized Frank's counting and subitizing ability, to perturb what he understood number to entail.

In the early portion of Frank's seventh teaching experiment, Frank is describing "two" and "three" items as "twenty-three." To perturb his thinking, the teacher asked him to count the counters he placed on his mat. He counts out three counters and then counts out two counters. After two more attempts, Frank's counting responses remain the same, so the teacher counted the counters in front of her and had him "parrot" her counting. Immediately following this task, Frank is shown items clustered to represent "two," "one," and "two," (see Figure 2) and Frank describes seeing "two plus one plus two makes five." This is the first time Frank begins to construct five by composing groups of numbers, suggesting a change in how Frank understands five.

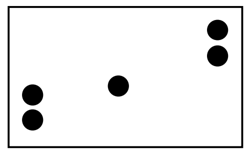

Figure 2: This orientation was shown to Frank in the middle of his seventh session.

Throughout the subsequent sessions, Frank's responses reveal more conceptual understandings of number (i.e. "three and then one is four," "two and two is four," "three and one is what tells me four"). These responses seem to reflect how Frank is perceiving the space between clustered groups of items, as he simply subitizes the total groups of items when no space is evident. Also, it is important to note that each time Frank explains his thinking he needs to rely upon his description of the subgroups to describe the total group. This seems less abstract than if Frank were to state the total group and then reverse his thinking to then describe the subgroups. Thus, it seems as if his number understanding is still developing.

Frank's number understanding in session 17. Prior to session 17, Frank was capable of subitizing four with subgroups "three and one," "two and two," and "one and three," and his QNC was more conceptually grounded with regard to four. However, Frank was not able to describe the total group and then reverse his thinking to describe the subgroups of four. For Frank to describe the total group and then the subgroups would suggest a cognitive reorganization of what Frank knew about four because he would have to compose four and then decompose four. Composing and decomposing a number would require Frank to reflect on his actions and be cognizant of the subgroups he used to compose four.

Additionally, Frank's understanding of five was still limited, and after his seventh session, he was not able to carry his description of five as "two plus one plus two" into subsequent tasks. Often when shown an orientation that promoted "two, two, and one" he would describe seeing four because he saw two and two or state that he saw, "four…five." These responses suggested that Frank was still solidifying what he knew "four" to be and was not able to coordinate the composition of two subgroups to build towards four and then coordinate a third subgroup to build towards five. Thus, we planned to use symmetrical orientations to promote Frank's subitizing of five in session 17.

In the Data Excerpt below, Frank was in his 17th teaching experiment session and his teacher showed him the circular counters in an orientation (see Figure 3), and asked him how many he saw. Frank brought his stuffed mouse to this teaching experiment session, and at times he pretends the mouse is the one responding to the tasks. This task was near the end of the session, and just before this task Frank was shown five counters which he determined were four and one, which then made fourteen. Once Frank counted these five counters, he determined the group was five. So again, Frank was having difficulty with composing five. As Frank described the subgroups which made up the composite groups, it seems evident that symmetry supported this activity, as only one two is mentioned.

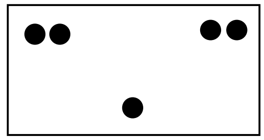

Figure 3: This orientation was shown to Frank near the end of his 17th session.

Data Excerpt.

Teacher: Okay, set mousey aside. Okay, one, two, three. [Teacher-researcher lifts the top piece of cardstock revealing counters arranged so that two counters are on the left-hand portion of the mat, and two counters are on the right-hand portion of the mat. In the middle there is one counter (see Figure 3).]
Frank: Five. [Frank talks in a squeaky "mouse-like" voice.]
Teacher: Five? How did you know that so fast?
Frank: Mousey says that.
Witness: How did mousey know it so fast?
Teacher: Yeah, how did mousey know it that quickly? Do you agree with mousey?
Frank: Yeah.
Teacher: Yeah? Why?
Frank: Because mousey said five [says five again in a squeaky "mouse-like" voice.] But mousey wins.
Teacher: He did win, but why did mousey know it was five? I don't know why that's five.
Frank: But you put it…you put two and down [motions with both his hands to show two on his left hand and right-hand portion on the bottom portion of his mat] and one and up [motions in the middle top portion of his mat.]

This data excerpt illustrates three cognitive changes in how Frank is understanding five. First, the symmetrical aspects of the orientation seemed to scaffold a change in Frank's understanding of five, as he described "two and down and one and up." Second, Frank composed subitized groups to quickly state that he saw five, but then "unpacked" or decomposed five to describe the actions and the groups he saw when subitizing five. This activity is more sophisticated than building up to five, and the symmetrical nature of the orientation seemed to promote this activity. Third, Frank no longer needed to "make" the orientation, but pointed to the imagined areas where the counters are located. This step away from the perceptual material was an important one; it seems as if Frank relied on more abstract actions when subitizing.

Retrospective Analysis

Frank's subitizing activity initially relied on common images or patterns to describe four, and at times, five. Also, Frank's initial QNC was grounded in procedural knowledge related to what he "knew" two-digit numbers "to be" which did not support a conceptual conjoining of number. To press Frank to attend to subgroups, Frank was shown orientations with large amounts of space between small clustered items that Frank was capable of subitizing. To connect what Frank knew about five to his subitizing activity, Frank reflected upon his counting activity and the relationship between subgroups when items were covered up. Frank developed more sophisticated number understandings as a result of subitizing symmetrical orientations. Frank was replacing the visual patterns with actions, as he was able to explain his thinking without having the perceptual material in front of him as evidenced in the Data Excerpt. Frank used prepositional phrases to explain what he saw (i.e. down, up) which suggests he may also be describing his eye movements. Thus, it seemed that Frank developed strategies that promoted changes in his number understanding (i.e. composition, decomposition, QNC). These strategies seemed to result from counting, subitizing, and the orientations (i.e. symmetry and space between items).

Conclusions

The purpose of this teaching experiment was to investigate how a child's understanding of number changed as he engaged in subitizing activity. Item orientation, reliance upon empirical material, and QNC were considered throughout the analysis. The two main findings of the study were related to (a) how Frank composed number and (b) the nuances in his perceptual subitizing activity.

Number Composition and Decomposition

With such a societal push to promote early childhood instruction in mathematics, it is important to understand what is (in) appropriate to teach young children. Entering the teaching experiment, Frank's understanding of conjoining two groups of items was a procedure resulting in a two-digit number word. This understanding of composition changed for situations in which the procedure was linked to a conceptual conjoining of groups to explain five. Though it seems that his procedure for naming two-digit numbers distracted from his construction of five, perhaps developing the procedure helped him attend to subgroups. Future research that focuses on helping children make appropriate connections between procedures and conceptual number understandings would be important for developing early childhood curricula. Findings from this study brought new ideas to light about how subitizing activity can press students to engage in meaningful activities when beginning to understand number.

Nuances in Perceptual Subitizing Activity

Throughout the teaching experiment, Frank's subitizing activity was described as perceptual instead of conceptual because he relied heavily upon perceptual material when discussing subgroups and total groups of items. The identification of sub-stages of perceptual subitizing are useful for further understanding topological, serial, and algebraic thinking prior to number conservation (Piaget, 1941/1965). First, shapes and patterns were initially described when explaining how a number was understood. This reliance upon patterns seemed to provide Frank a template to work from when recreating the orientations. Second, attention to subgroups before describing the total group of items indicated a "building up" of number. Third, near the end of the study, it seemed that Frank could compose items quickly when subitizing and then decompose these groups to explain his thinking. Children making connections between early perceptual activities and conceptual processes gives purpose for particular curriculum choices. Thus, early childhood educators' utilization of findings from this study could inform their pedagogical choices when designing subitizing tasks embedded in game play.

In this paper, we analyze individual semi-clinical interviews conducted with one kindergarten and one first-grade student. We build on prior research to offer evidence, via excerpts from these interviews, that children as young as kindergarten have a powerful, intuitive sense of generality and indeed naturally draw upon it to reason through mathematical scenarios. We identify within these children's utterances four features of generalizing for which educators might attend.

Keywords: Classroom Discourse; Algebra and Algebraic Thinking; Elementary School Education

Introduction, Issues, Theoretical Framework

Hyman Bass credits generality as "one of the most important and powerful characteristics of mathematics" (2003, p. 326); John Mason dubs it mathematics' "heartbeat" (1996, p. 65). Concordant with these voices, both the *Common Core State Standards for Mathematics Initiative* (CCSSI) and the National Council of Teachers of Mathematics' (NCTM) *Principles and Standards for School Mathematics* emphasize generalizing as a key mathematical practice throughout the grades, one that can and should be encouraged early and honed over time (CCSSI, 2010; NCTM, 2000). To truly foster this practice beginning in the early grades, however, educators must first recognize young students' generalizations, a task complicated by the extent to which the language children employ differs from that of adults. The risk of underestimating the robustness of children's understandings or overlooking their insights altogether may be especially pronounced in the domain of mathematics, whose exactness can lend itself to particularly formalized conventions as to how generality should be expressed. For instance, universal qualifiers, be they explicit or implicit — "for all $x \geq 0$, $|x| = x$," "multiples of four are even," or "every integer greater than 1 has a unique prime factorization" — are the standard fare of generalizations in mature mathematical discourse. As students are inducted over time into communities of mathematical discourse, they gradually assimilate these conventions of communication. But there is no reason to believe that children in the earliest grades would have learned these communicative conventions, and there is no simple litmus test for whether children are thinking in generalized terms. These challenges call for further research into the range of ways in which very young children may express generality. By honing our own ability to recognize early inclinations to generalize, we can, in turn, better nurture their development.

Identifying young children's generalizations can be challenging, requiring "the skilled and attentive ear of a teacher who knows how to listen carefully to children" (Kaput, 2000, p. 6). Our goal in this paper is thus twofold: (1) to offer evidence, via excerpts from mathematical interviews with two case students, that children as young as kindergarten have a powerful, intuitive sense of generality and indeed naturally draw upon it to reason through mathematical scenarios, and (2) to identify within these children's utterances several characteristics indicative of generalizing for which educators might, in Kaput's phrase, "listen carefully."

Prior research has yielded numerous examples, largely from teacher documentation or classroom discussions, of young children's generalizing about comparison of quantities (Schifter, Bastable, Russell, Riddle, & Seyferth, 2008a) including non-specified quantities (Dougherty, 2008), commutativity (Schifter, Monk, Russell, & Bastable, 2008b), classes of numbers (Bastable & Schifter, 2008), additive and multiplicative identity properties (Carpenter & Levi, 2000), and use of the equal sign (Carpenter, Franke, & Levi, 2003). As a body, this research demonstrates that it is within the reach of young children to observe mathematical regularities and talk about their discoveries in a variety of ways.

What does it mean, really, to generalize? Rowland (2000), Carraher, Martinez, and Schliemann (2008), and Kaput (2000) each propose perspectives. According to Rowland (2000), generalizations are statements of beliefs about properties of an entire class that have not and indeed cannot be inspected and tested. For Carraher et al. (2008), generalizations involve claims for an infinite number of cases, where "the *scope* of the claim is always larger than the set of individually verified cases" (p. 3, italics in original). Finally, Kaput (2000) highlights that generalizations "deliberately extend … the range of communication beyond the case or cases considered, [to the] patterns, procedures, structures, and the relations across and among them" (p. 6). These three proposals share an emphasis on the generalizer's conviction with respect to an inference that includes many cases simultaneously, a conviction that obtains in the absence of envisioning each of those individual cases.

Mode of Inquiry, Data Sources

In this paper, we analyze individual semi-clinical interviews conducted with one kindergarten and one first-grade student as part of a research project focused on exploring kindergarten through second-grade (K-2) children's understandings of functions. The data are drawn from an eight-week classroom teaching experiment (CTE). Individual interviews with a subset of students in each of the three grades were carried out immediately prior to, halfway through, and at the end of the CTE. The students in the school in which the CTE was conducted are 98.6% minority (non-white), with 89.5% categorized as low SES and 33.9% as ESL.

To facilitate the process of data reduction, a series of steps was taken. First, because the goals of the study were to explore young children's intuitive sense of generality and to provide evidence for what generalizations look like among young students, we focused on the initial interviews (pre-interviews), which took place before any lessons were implemented. By selecting for analysis data collected before the teaching experiment began, we ensured that each child's productions, both verbal and written, would best approximate what might be described as "naturally" present. Second, we focused our selection on kindergarten and first-grade students to explore expressions of generalization among the youngest children in our study.

In our pre-interview protocol, students were first asked how many noses a dog has. They were then asked how many noses there would be altogether among two dogs, three dogs, and so on. We did not doubt that students would answer correctly for all specific cases proposed. Rather, we were interested in students' explanations of how they knew — that is, in how they spoke about their reasoning. Each student was asked at some point in the interview to organize the information in a function table, reason about far values (e.g., the case of one hundred dogs), and reverse the relationship (supply a number of dogs given a number of noses), as well as to respond to a proposed "mismatched" case (e.g., the suggestion of five dogs and six noses).

Students were also asked how they might tell a friend how to know the number of noses for any number of dogs and whether there was a rule for making this determination. They were also invited to generate their own examples rather than simply responding to interviewer-generated values. These questions were intended to create an open-ended space for students to verbalize their understanding of the problem and the functional relationship that governed it.

All interviews were transcribed verbatim from video, and all video and transcripts were reviewed. This review facilitated a progressive selection of the dataset for this paper. Our criterion for selecting the students for this paper's analysis was that they exhibit diverse verbalizations of mathematical ideas. Our aim was not to showcase the most sophisticated thinking in young students, but rather to highlight a range of ways young students' mathematical thinking might find expression. In this way, we selected interviews with Kinetta and Ferdinand, a kindergartener and first-grade student respectively.

In analyzing these interviews for generalizing, we appealed to the common thread among the perspectives on generalizing noted above: conviction in an inference about many simultaneous cases that is independent of envisioning of those individual cases. We reviewed the transcripts line-by-line using the constant comparative method (Glaser & Strauss, 1967). Our research goal was to identify features of this thread within these students' interviews.

Results

Bills (2001) theorizes that qualitative differences in students' language correspond to qualitative differences in their conceptual constructions and that these shifts in language may be markers of progress towards recognizing the generality of procedures. Adopting this premise, we highlight four prevalent features of the two case students' verbal productions that emerged as a result of our analysis. Examples of each of these features will be provided below in Table 1.

- *Definite Articles, Indefinite Quantities*: We observed that when students were asked questions that might easily have been construed as centering on a particular case, they often nonetheless replied with a generalized answer that could accommodate any case. In such instances, the student also indicated that a strict rule would uniquely determine the relevant numerical "output" based on the input, whatever the input might happen to be. We took these instances, referred to here as "definite articles, indefinite quantities," to indicate that the student was spontaneously generalizing, displaying conviction about many simultaneous cases not individually envisioned.
- *Certain Denial*: If a student was prepared to cry foul without hesitation in response to a mismatched (e.g., five dogs and six noses) scenario proposed by the interviewer and to justify and defend his or her position, we took this as an indication of the student's conviction. (These impossible scenarios were akin to Carpenter and Levi's [2000] and Davis' [1964] false number sentences, leveraged as windows into young children's ability to justify generalized properties of whole numbers.) Moreover, if the student justified his or her conviction by giving reasons that appealed to the general logical structure of the problem, as opposed to simply the particular case, we took this as evidence of generalized thinking about cases not individually envisioned. We refer to this feature as "certain denial."
- *Generic Examples*: We adopt this terminology from Balacheff (1988), who lists generic example as the third of four main forms in the cognitive development of proof. Balacheff makes much of the transition from the second form — termed "crucial experiment" — to its successor. While a crucial experiment offers only the outcome of a particular case to support a general conclusion, the case has been chosen deliberately for its perceived particular ability to carry that import.[1] Balacheff maintains that one crosses a "fundamental divide," or undergoes a "radical shift in ... reasoning" in stepping from crucial experiment to generic example, and that in the latter territory, one "establish[es] the *necessary nature of [a] truth* by giving reasons ... by means of operations or transformations on *an object that is not there in its own right, but as a characteristic representative of its class*" (pp. 218-19, emphasis added to correspond to conviction with respect to many simultaneous cases not individually envisioned). Accordingly, in our study, we took students' generic examples to be evidence of

generalizing. Bills (2001) also regards generic examples as steps toward more formal generalizations.

- *Authoritative "You"*: Rowland (1992, 1999, 2000) has paid considerable attention to children's use of the pronoun "you." One use is as a substitute for the more formal "one" and thus as an indicator that a generalized procedure is being described. Rowland notes that this procedural "you" is common even in non-mathematical situations, especially but not only among children — for instance, in explaining how to play a game. He has observed that a shift from "I" to "you" in children's discourse seems to parallel a shift from explaining work done with specific cases towards describing a more generalized procedure. This procedural "you" also appears in excerpts from Schifter et al. (2008a), Bastable and Schifter (2008), and Carpenter and Levi's (2000) research with young children (though these researchers do not highlight it as such in these studies): for instance, "you don't have to pay attention to the 6s," "each time you add a number to a group that can go, you get a group that can't," and "when you put zero with one other number, just one zero with the other number, it equals the other number," respectively. A second use of "you," distinct from the first, is as a pronoun of direct address. Rowland notes that it is considerably less common for students to use "you" in this fashion when speaking to teachers than vice versa, an imbalance he attributes to power relations. Thus we take students' usages of direct-address "you"s to be indicative of their willingness to assume an authoritative position and their usages of procedural "you"s to be indicative of explaining generalized rules or procedures — which in turn we take as indicative of conviction with respect to many simultaneous cases not individually envisioned. We refer to this feature as "authoritative 'you.'"

Owing to space constraints, we give limited excerpts from each case student's interview and highlight these four features within the transcript. We use **boldface** text to foreground particular phrases that, situated in context, exemplify these features. Following the transcripts, we organize these examples in a table (see Table 1) with some discussion.

Excerpt from Initial Interview with Kinetta (Kindergarten)

Interviewer: If there are three dogs?
Kinetta: Three noses.
Interviewer: How do you figure out? How do you know how many noses there are?
Kinetta: You count.
Interviewer: How do you count?
Kinetta: One, two, three.
Interviewer: Mm-hm. And how do you know how to stop — when to stop counting?
Kinetta: When **you** get to **the** number.
Interviewer: So [...] for instance, what if there were ten dogs? How many noses [...]?
Kinetta: Ten.
Interviewer: How do you know that?! I didn't see you count! I didn't see you do any counting.
Kinetta: That's because I counted in my head.
Interviewer: Oh! You went all the way to ten that quickly?
Kinetta: [Nods.]
Interviewer: [...][2] What if there are one million dogs? How many noses are there?
Kinetta: One million.
Interviewer: You did not count that fast. How do you know what number to say?
Kinetta: Because **you** just said **it**.
Interviewer: Oh! What do you mean?

Kinetta: **You** said "one million."
[...]
Interviewer: What if there were twenty-four noses?
Kinetta: Twenty-four dogs.
Interviewer: Was that easy? Yeah? How did you figure that out?
Kinetta: Because **you** just said **it.**
[...]
Interviewer: Can I show you something that some people use? It's called a table. [Draws function table setup.] They do this, and here they put th— how many dogs, and here they'll put how many noses. So for instance, if it's one dog [writes the numeral 1 in the left-hand column of the function table], how many noses?
Kinetta: One.
Interviewer: [Writes the numeral 1 in the right-hand column.] If it's two dogs [writes 2 in the left-hand column]...
Kinetta: Two noses.
Interviewer: And can you put it? Can you show it right there [in the right-hand column]?
Kinetta: [Writes 2 in the right-hand column of the table.] [...]
Interviewer: What if there were three here [in the left-hand column]? How many noses?
Kinetta: [Writes 3s in both columns.]
Interviewer: Oh, great, and what if there were— let's put another number here [in the left-hand column]. Whatever number you want.
Kinetta: **[Writes 100, 100.]**
Interviewer: Oh my goodness! What number is that?
Kinetta: **One hundred.**
[...]
Interviewer: If we put a number here, whatever number here [in the left-hand column], what number do we have to put here [in the right-hand column]?
Kinetta: **The same one.**
[...]
Interviewer: So, you know what someone told me? Someone told me that there were five dogs and there were six noses. What do you think of that?
Kinetta: **[Shakes head no.]** [...]
Interviewer: No? Why not?
Kinetta: **Because it needs to be the same.** [...] Six noses and six dogs. Five noses and five dogs.

Excerpt from Initial Interview with Ferdinand (First Grade)

Interviewer: So, if — what if we put here that there's one dog, okay [writes the numeral 1 in the left-hand column]? How many noses are there gonna be?
Ferdinand: One.
Interviewer: One [writes the numeral 1 in the right-hand column]. What if there are two dogs [writes 2 in the left-hand column]?
Ferdinand: It's two.
Interviewer: Okay, can you show me that?
Ferdinand:[Writes 2 in the right-hand column.]
Interviewer: What if there are three dogs?
Ferdinand: Then three [writes a 3 in each of the two columns].
Interviewer: Do you want to show me some other numbers of dogs?

Ferdinand: We're going like number?[3]
Interviewer: Whatever you want. If you want to do it that way, we can do it that way.
Ferdinand: **I'm gonna do a five [writes 5 in the left-hand column of the table].** [...]
Interviewer: What would you put on the other side? [...]
Ferdinand: Oh, five [writes 5 in the right-hand column]. [...]
Interviewer: How do you know it's five noses?
Ferdinand: 'Cause fiv— it's five 'cause five noses **has to** be the same, **like** — they could play, **if** they didn't have a lot of— **like** they're playing hide and seek **if** they didn't have a lot of people to play—
Interviewer: Mm-hm.
Ferdinand: **So they have to** have five and five.
Interviewer: Mm, okay.
Ferdinand: **Like** teams.[4]
Interviewer: So, so if a friend asked you what number — how you know what number to put here, what would you tell them?

Table 1: Examples of the Four Features

Feature	Key phrases (regarded in context)	Discussion
Definite Articles, Indefinite Pronouns	"When you get to **the** number" (line 8); "Because you just said **it**" (line 19, line 26); "**The same one**" (line 48). "**It** was **the** number that — that you said" (line 82).	Lines 8, 19, 26, and 82: Rather than give answers specific to the particular cases the interviewer has just referenced — of three and five dogs, respectively — as they might reasonably do, both students instead respond in generalized terms even though they have not been "asked" to generalize. Line 48: Kinetta appears to have no trouble responding when posed a question in general terms.
Certain Denial	"**[Shakes head no]** [...] **Because it needs to be the same.** [...] Six noses and six dogs. Five noses and five dogs" (lines 52, 54-55). "You say, 'You **have to** take one more out, 'cause we **have to** have five and five, **'cause** [...] we **have to** play five-five, **'cause**[...]'" (lines 86-88).	Both children appeal to the logical necessity of sameness: it "needs to" or "has to" happen for a reason. Additionally, that Kinetta allows for both possible corrections of the mismatch (five-five and six-six) suggests an understanding that this sameness is not only necessary but also sufficient. She's willing to vary the number of dogs *or* the number of noses, but she insists that those two counts have to match.
Generic Example	"**[Writes 100, 100]** [...] **One hundred**" (lines 42, 44). "**I'm gonna do a five [writes 5 in the left-hand column of the table]**" (line 69); "It's five 'cause five noses **has to** be same, **like** — they could play, **if** they didn't have a lot of— **like** they're playing hide and seek **if** they didn't have a lot of people to play [...] **So they have to** have five and five [...] **Like** teams" (lines 73-75, 77, 79).	While the dogs-and-noses problem centers on an identity function, and thus in some sense masks the "transformations" enacted on objects, we maintain that these examples proposed by Kinetta and Ferdinand are nonetheless "characteristic representative[s] of [their] class," "objects ... not there in [their] own right" (Balacheff, 1988, pp. 218-219). In Kinetta's case, one hundred dogs is fundamentally a case not individually envisioned. While one might precisely visualize one, two, or three dogs, it's reasonable to surmise that it's fairly impossible to hold a quantitatively precise mental image of one hundred dogs. One hundred serves as a representative of the class of theoretically possible, potentially arbitrarily large quantities of dogs. Ferdinand's usage of "if" and "like" (lines 73-75, 79) resonates with Bills' (2001) findings that children often use "if it's like" to introduce generic examples (where adults, Bills posits, might use "for example," "consider for instance," or "suppose"), as well as with the diction that accompanied the use of generic examples in Carpenter and Levi's (2000) study. Furthermore, that Ferdinand says that "five noses **has to** be the same" (line 73) and concludes, "**So they have to** have five and

		five" (line 77) suggests that, as Balacheff describes, what he's arguing about is the "necessary nature of [the] truth."[5]
Authoritative "You"	"When **you** get to the number" (line 8); "Because **you** just said it" (line 19, line 26); "**You** said one million" (line 21). "It was the number that — that **you** said" (line 82).	Line 8: "You" is used impersonally to convey a generalized procedure. Lines 19, 21, 26, 82: "You" is used as a pronoun of direct address.

Ferdinand: "**It** was **the** number that—that **you** said."
Interviewer: Okay. [...]What if you had a friend who said that they counted that [...] with five dogs, there are six noses? [...] Five dogs and six noses [points to these places on function table]. What would you tell your friend?
Ferdinand: You say, "You **have to** take one more out, 'cause we **have to** have five and five, **'cause** [...] we **have to** play five-five, **'cause** if we don't have five-teams, we ha— we have more than five."
Interviewer: Okay.[...] If your friend says that there are ten dogs and he counted twelve noses?
Ferdinand: It'll be — twelve.
Interviewer: Twelve what?
Ferdinand: Dogs.

Significance of the Research

The examples we provide from interviews are far from exhaustive; nonetheless, they build a portion of a catalogue to which educators might look to identify instances in which students as young as kindergarteners are spontaneously generalizing, so that we might better capitalize on opportunities to foster this type of reasoning. Importantly, for our purposes, they contribute to an existence proof that young children do indeed bring natural intuitive powers of generalizing to formal schooling and that, as such, the power of generalizing is "natural, endemic, and ubiquitous" (Mason, 1996, p. 66).

Endnotes

[1]This contrasts with the first of the forms, naïve empiricism, which lacks the deliberate "*this* is my *test* case" element, in that it entails believing a proposition simply because one conceives of *a* case, or a handful of cases, that "works."

[2]Throughout the transcripts, the symbol [...] indicates dialogue removed for irrelevance.

[3]We take Ferdinand to be asking here whether he was expected to increment the number of dogs consecutively.

[4]We take the analogy to be to the necessity that two teams have equal numbers of players.

[5]Kinetta also speaks to the logical necessity of sameness when she says (line 54) "it needs to be the same." However, since this was an instance of her rejecting a proposed "impossible case" as opposed to proposing an example of her own, we have not considered it a generic example.

HOW STUDENTS' INTEGER ARITHMETIC LEARNING DEPENDS ON WHETHER THEY WALK A PATH OR COLLECT CHIPS

Julie Nurnberger-Haag
Kent State University
jnurnber@kent.edu

In light of conceptual metaphor theory, historical mathematicians' and students' difficulty with negative numbers reveals that the collecting objects metaphor may be a cognitive obstacle to those first learning about negative numbers. Moreover, consistency of physical motions with targeted ideas is a factor of cognition. Thus, this pre-post-delayed post study randomly assigned 8 classes of initial learners to a collecting objects integer model (chip model) or a moving-along-a-path metaphor-based model (number line model) to learn integer arithmetic with the four primary operations during an eight-day mini-unit. The study investigated the questions: What do students demonstrate learning with each model and what, if any differences in learning are found between models? Findings did support theory that a motion-aligned model using a moving-along-a-path metaphor would likely support learning better than collecting objects.

Keywords: Number Concepts and Operations; Cognition; Learning Theories

In this paper I share results from a larger study designed to understand the effects of instructional models on students' learning about integers. This study contributes to resolving two enduring challenges in mathematics education: one practical and one theoretical. The first concerns improving the way that classroom-based research can inform teachers' practical decisions about teaching integer arithmetic. The second offers new insights into the theoretical and practical debate about whether and how physical experience supports learning mathematics. The study provides evidence about how students' physical motions or model-movements can support or interfere with mathematics learning.

Prior Research

Integer arithmetic with negative numbers is counterintuitive, yet essential to most mathematics beyond middle school. It has been extensively studied (Gallardo, 2002; Küchermann, 1981; Liebeck, 1990; Linchevski & Williams, 1999; Vlassis, 2008), yet recommendations are contradictory about how to help students adapt their arithmetic concepts to embrace negative numbers (Star & Nurnberger-Haag, 2011). Most integer research has assessed students' learning during or immediately after instruction and focused on addition and subtraction only. Given that students need to understand negative number arithmetic to build on and use in complex ways in formal algebra (Vlassis, 2008), research that investigates a larger set of integer knowledge, including all operations, along with longer-term implications of instructional experiences is crucial.

Küchermann (1981) categorized three types of integer instruction models as (a) cancellation models in which two opposites cancel, (b) number line, or (c) abstract models. Although integer thinking and learning has been extensively studied, investigations of integer learning with particular models, particularly those most accessible in classrooms, have yet to be conducted. In spite of this lack of research about student learning with different models and theoretical critiques of models offered (e.g. Star & Nurnberger-Haag, 2011; Freudenthal, 1973; Vig, Murray, & Star, 2014), multiple integer models are promoted in methods textbooks for prospective teachers as well as school textbooks, particularly cancellation and certain number line models. One study did compare a cancellation model and a number line model (Liebeck, 1990) but it did not involve parallel instruction and post-tests nor did it include a pretest. For educators to make effective instructional decisions, it is important to compare methods (Nunez, 2012) and to understand how different

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

methods might offer similar or different learning opportunities. Consequently, the present study experimentally compared students' initial learning of negative number arithmetic using a cancellation model or a number line model.

Theoretical Perspectives

Documentation of historical mathematicians and of modern students has described cognitive obstacles for negative numbers (e.g., Fischbein, 1987; Pierson, et al., 2014). A reading of these works in terms of conceptual metaphor theory reveals that the *object collection metaphor* may be a cognitive obstacle to those first learning about negative numbers (hereafter called *initial learners)*. The conceptual metaphors identified by Lakoff and Nunez (2000) applicable to integer arithmetic include the *object collection*, *motion along a path*, and *measuring stick* metaphors. Flexible use of more than one metaphor may be necessary for expert understanding of negative numbers (Chiu, 2001). Yet, research of integer arithmetic via conceptual metaphors is in its infancy and has focused on what metaphors people used while thinking (Nurnberger-Haag, 2013; Chiu, 2001; Kilhamn, 2011), rather than the impact of metaphor-based physical motions on initial learning.

Conceptual metaphor theory offers educational researchers valuable insights to identify the ways that different models invite students to conceive of numbers. *Cancellation models* treat numbers as objects (using an object collection metaphor for negative number concepts). In schools, the cancellation model most commonly used is an integer model that uses chips of opposite colors to represent opposite numbers. In research additional models have also been promoted and studied that draw on an object collection metaphor (Nurnberger-Haag, 2013; Kilhamn, 2011). At first glance Küchermann's (1981) characterization of cancellation versus number line models might offer a sufficient framework. Or one might suspect that Fischbein (1987) and Freudenthal's (1973) explanations that thinking of numbers as objects renders use of conceptual metaphor theory moot, because this neatly aligns with the object collection metaphor. Using conceptual metaphor theory to investigate integer arithmetic learning, however, affords considering the differences between the mathematical representations and the ways we think about these representations. For example, *number line models* all use a commonly accepted representation of a number line, but there is not a single number line model. A number line representation can be thought of using a measuring stick metaphor as Descartes did historically (Berlinghoff, & Gouvêa, 2002; Lakoff & Nunez, 2000) in which numbers are found at the end of a positive length in a particular direction. Number line representations can also be thought of with a motion-along-a-path metaphor (Lakoff & Nunez, 2000; Nurnberger-Haag, 2007; Kilhamn, 2011), or as a combination of both of these metaphors to be discussed in later studies. Moreover, considering conceptual metaphor theory aides recognition that the differences of model metaphors might matter because of how these ways of thinking fit with the ways humans think more generally. In other words, conceptual metaphor theory assists with explaining and unifying mathematical thinking to show that and in what ways mathematical thinking is part of the varied abstract thinking humans do (Lakoff & Nunez, 2000).

Lakoff and Nunez treat conceptual metaphor as an object of thought that results from physical experiences, which grounds how we think about abstract ideas. Whereas other research has referred to conceptual metaphors similarly using nouns (Chiu, 2001; Kilhamn, 2011), I use the verb forms (*collecting objects*, *moving-along-a-path, and measuring*) to emphasize and transform the original claims to consider the metaphorical mechanism as grounding the patterns of interacting with the world as part of an on-going dynamic system (Nurnberger-Haag, 2014).

Furthermore, when promoting one metaphor with students, such as the moving-along-a-path metaphor on a number line, we must realize that this metaphor does not prescribe how students move on a number line. The typical number line model promoted in curricular resources directs students to move backwards or forwards depending on the sign of a number and to move in a particular direction depending on the operation. In other words, these models inform students *which* direction to move. The walk-it-off model, in contrast, was designed to promote the opposite operator meaning of the negative sign necessary for algebra, but not afforded by other models (Nurnberger-Haag, 2007). Rather than written symbols indicating *which* direction students travel, the written symbols in the walk-it-off model emphasize to change direction by turning the *opposite direction* or not to change direction for addition or positive values.

Purpose of Study

Although broadly, hands-on learning or manipulatives have been extensively studied in mathematics education, this research has not attended to the ways the physical model-movements may represent or misrepresent the mathematics students learn. Yet, research from psychology has shown that consistency of physical motions with targeted ideas is a factor of metaphor comprehension (Glenberg & Kaschak, 2002). Thus, this study examined how two different conceptual metaphors and students' physical motions and related explanations affect initial learning of integer arithmetic in classrooms. With a goal of practical impact, I chose to compare models with which students physically represent integer arithmetic that could be or are easily implemented in schools and what I thought would be the best case of each metaphor. In order to capture the complexity of students' initial learning of integer arithmetic on all four basic operations and assess longer-term learning, this pre-post-delayed posttest study used multiple methods to address the questions: After using either a chip model, or a number line model that emphasizes opposites and magnitude, what do students demonstrate knowing about integers and what, if any, differences in learning are found between students who used each model?

Method

The most common *collecting objects* metaphor-based model (a chip model) or a *moving-along-a-path* metaphor-based model (a number line model see Nurnberger-Haag, 2007) was randomly assigned to eight intact classes of initial learners (four classes per model). Here I report findings from written pre/post/delayed posttests.

Settings, Participants, & Research Personnel

A power analysis indicated that including at least 50 students per integer model should detect a medium effect. To study initial learning, district sites that met the following criteria were recruited: curriculum had not yet addressed integer operations in the recruited grade and all students in this grade attended the same school with the same mathematics teacher. Two public rural districts in a Midwest state participated. According to the grade level data on the state website, 45% of the students I instructed had free or reduced lunch and were primarily European American. After removing students from analysis due to absences, 78 chips and 76 walk-it-off students remained in the analysis. The study instruction occurred in the grade prior to when integer arithmetic is typically taught in the district (School A first semester sixth grade, School B second semester fifth grade). As the researcher-teacher, with approximately 20 years of experience teaching mathematics (including integer arithmetic to K-16+ students), I taught all students in the targeted grade. The classroom teacher remained in the classroom to ensure safety of students, but not to teach. Only those students who themselves assented and whose guardians consented participated in the research by giving their written work and assessments to the researcher-teacher for an incentive the equivalent of a university folder and pencil.

Instruction and Measures

Each class experienced parallel instruction with the same tasks and activities, differing only by the integer model used (two colors of chips or ten-foot long empty number lines, the language about how to use those representations and model-movements). During each lesson students worked on tasks and played games in assigned trios or pairs and had the opportunity to participate in whole-class discussions. I planned and implemented eight approximately 50-minute lessons about negative numbers, ordering numbers, and operations with negative integers (addition, subtraction, multiplication, and division) including sums of additive inverses, hereafter called opposite sums. The written measures assessed these constructs as well as opposite operators (transfer problems) that were not taught during the lessons (e.g., -(-4) and – (6-8)). The data reported here are from a 46-item open response skill-based test *Integer Arithmetic Test* (IAT) and one of the items from a seven-item *Explain and Draw Test* (EDT). These measures were developed through several phases of piloting and analysis including factor analysis to remove items that did not perform as expected. Students could only use pencils when completing these written tests (neither chips nor number lines were provided).

Data Analysis

The IAT data reported here included item accuracy and qualitative assessment of student reasoning on the EDT Opposite Sums Item. The IAT total test score was scaled to a 100-point test by weighting the subtotals of the following constructs: ordering numbers (20%), addition and subtraction (35%), multiplication and division (35%), and opposite operations (10%).

Multiple methods were used to determine each student's level of opposite sums knowledge at pre, post, and delayed posttest. Two types of IAT questions (calculation problems such as -19 + 19= and generative problems ___ + ___ = 0) , were each separately subtotaled for accuracy 0 to 2. An example of the EDT Opposite Sums Item follows:

> Trina and Jaleesa are students in your grade at another school.
> Trina said that $^{-}8 + (^{-}7 + 7)$ does <u>not</u> give the same answer as $^{-}8 + (^{-}5 + 5)$.
> Jaleesa said they will. Circle who is right: Trina or Jaleesa.
> Draw and write an explanation in words to convince a friend that this student is right.

I coded student explanations with a qualitative coding scheme using a constant comparative approach (Glaser, 1965). A second trained coder assessed 20% of the randomly selected tests with 92.7% agreement. A K-cluster analysis informed determination of Leveled Opposite Sums knowledge profiles (no/low, moderate, or strong) using the three ways of demonstrating opposite sum knowledge (calculation problems, generative problems, and EDT Opposite Sums Item).

Statistical controls were built in to the study design and analysis including a pretest, whole number fact test, gender, and preconceptions of negative number multiplication and division. No significant differences were found between the eight classes or between integer models at pretest. Although I planned to include district and class as statistical controls, the model would not run with both and a statistical model that accounted for either accounted for 48.4% of the variance, so district, which had significant differences at pretest was included in spite of it not being a significant predictor of the statistical model. Scaled data (overall test and subtest scores) were analyzed using multivariate analysis of covariance (MANCOVA). I used an ordinal regression to analyze leveled data.

Results and Analysis

Which, If Either, Model Supports Better Overall Learning?

Multivariate analysis of covariance (MANCOVA) was conducted on the IAT post and delayed posttest total scores to compare student learning with the walk-it-off model to learning with a chip model controlling for pretest IAT, whole number fact test, gender, and preconceptions of integer multiplication and division. Both integer models supported statistically significant integer learning from pre to posttest, indicating that both models were reasonable models for integer learning. Statistically significant integer model differences were found between the overall learning of students using walk-it-off compared to chip models: $F(2, 146)=11.414$, $p<0.001$, $\eta\rho^2=.14$. On average in the short-term students using the walk-it-off integer model for initial instruction scored 11 points higher on this 100-point test than students using chips (posttest $\beta=-10.8$, 95% CI [-15.7, -5.9]) and 13 points higher in the longer-term (delayed posttest $\beta=-12.7$, 95% CI [-18.3, -7.0]).

Does the Way Model-Movements Represent Mathematics Impact Learning?

The IAT problems that I argue require chips students to move in ways that are inconsistent with the targeted integer operations, were grouped into Inconsistent Model-Movement Problems and those consistent into Consistent Model-Movement Problems. Inconsistent Model-Movements for example $^{-}4 \times {}^{-}3$ and $^{-}2 - {}^{-}5$ require students to put in enough chips to represent zero with sufficient numbers of chips to be able to remove 4 groups of 3 negatives or 5 negatives, respectively. Multivariate analysis of covariance (MANCOVA) was conducted on the IAT operation post and delayed post Consistent Model-Movement and Inconsistent Model-Movement problems (22 and 14 respectively) controlling for these scores at pretest and the rest of the controls used in the total test analysis. The differences were again statistically significant, but with more than twice the practical effect, ($\eta\rho^2=.34$): $F(4, 145)=18.358$, $p<0.001$. When the chip model movements were consistent with the mathematics of integer arithmetic operations, no significant differences were found between the integer model groups' test performance. Statistically significant differences were found, however, for those problems for which I argue that the chip model required inconsistent movements ($p<.001$).

Opposite Sums Knowledge

Ordinal regression analysis on the students' levels of opposite sums knowledge showed that the chips group did demonstrate greater learning at posttest than the walk-it-off model ($p=0.002$), but this difference was not maintained five weeks later. No significant differences on opposite sums knowledge were found between students who learned with the chip model or walk-it-off model on the delayed posttest ($p=0.090$).

To test if students who did not have strong opposite sums knowledge prior to instruction had more difficulty learning with this chip model than the walk-it-off model, multivariate analysis of covariance (MANCOVA) was conducted on the post and delayed post IAT scores only for the 118 participants whose opposite sums knowledge was not strong at pretest. These students assigned to the chip model did significantly worse overall on the IAT than students assigned to the walk-it-off model: $F(2, 110)= 13.35$, $p<0.001$, ($\eta\rho^2=.20$). Students using chips scored lower on the posttest -12.7, 95% CI [-18.4, -7.0] and delayed posttest -15.8, 95% CI [-22.1, -9.6].

Discussion & Conclusions

These overall results fit the theoretical reasons drawn from cognitive science, analysis of mathematical processes, and practical classroom experience. These issues converge to predict that the walk-it-off model should better support student learning, which the data confirmed. Several reasons for these results were identified: the walk-it-off model uses model-movements consistent with mathematical ideas (whereas the chip model is often inconsistent) and the chip model visually violates the meaning of zero students would expect when thinking of numbers using a collecting objects metaphor.

Consistency with Mathematics Matters: Model-Movements

Some theoretical work referred to the mathematical alignment of integer models as breaking or requiring model-rules that differ from the mathematics (Star & Nurnberger-Haag, 2011; Vig, Murray, & Star, 2014). This study offers evidence to support these theoretical arguments that incongruent mathematical alignment does impact students' learning outcomes. Moreover, this study offers reasons related to human cognition why these breaks are likely problematic. One predicted reason was that students move differently in order to interact with the representations with these models. If this difference and the consistency of the ways model-movements represent mathematics did not matter for student learning, then there should be no significant differences in performance on the Consistent and Inconsistent Model-Movement problems. This analysis, however, did show that when the chip model required model-movements that contradicted or were extraneous to the mathematical processes and ideas, this interfered with learning. In contrast, the walk-it-off model-movements consistently represent the mathematical ideas, so I classify this model as a Motion-Aligned-Model. When approaching integer arithmetic problems with model-movements consistent with the mathematics, the results demonstrated that either model could be equally effective. This lack of significant differences on Consistent Model-Movement problems further supports the claim that model-movement alignment with mathematics could be a factor in students' learning with models.

Consistency with Mathematics Matters: Conceptual Metaphor

In order to calculate almost every integer problem with chips, students need to represent the idea of cancelling opposite values (e.g., -9 and 9). Thus, due to repetition of the underlying metaphor of cancelling opposite things, one might suspect that a benefit of the chip model might be to better support student learning opposite sums. The results did fit this prediction, but the benefits of using a cancellation model for this purpose were only in the short-term significantly different from the number line model used in this study. Longer-term on average students performed equally well after learning with either model.

Opposite sums knowledge may actually be required in order to learn integer arithmetic with the chip model, because this model requires students to sum opposite values to calculate almost every integer problem. The findings seem to support this, because students without strong cancellation knowledge at pretest who used this collecting objects metaphor model, scored the equivalent of about 1.5 grades lower than students who used this particular moving-along-a-path metaphor model. A more global reason for these initial learners' challenges with the chip model may be because it visually violates a central feature of applying the collecting objects metaphor to numbers. Rotman (1993) articulated, that when thinking of numbers using a collecting objects metaphor, zero should be visually represented as nothing or "no thing." Yet, chip models require students to use multiple things to represent no thing.

Implications

This study that tested several aspects of integer learning, including all four basic operations, suggests that the walk-it-off model may be a parsimonious model for initial integer instruction. It also reveals for which aspects of integer knowledge a collecting objects metaphor (in the form of a chip model) might add richness to student thinking. The delayed posttest results reflect longer-term learning, which although rare in educational experiments, is crucial to make claims about educational impact that matters in students' lives.

Practical Implications

Given that the walk-it-off model was more effective overall and improved learning even more for those who have less integer knowledge prior to instruction, this model is likely the most parsimonious model with which teachers might begin instruction that meets the diverse range of learning needs in real classrooms. The sample was economically diverse (45% free and reduced lunch), but were primarily European American fifth and sixth grade students in a rural district, so the study should also be replicated with other populations to ensure that these results appropriately inform instruction for all students. Anecdotal evidence suggests the walk-it-off model, which a teacher developed and has shared with hundreds of other teachers, is a feasible model for teachers to implement (Nurnberger-Haag, 2007). Nevertheless, this study was conducted by an experienced researcher-teacher, so future investigations should confirm that students using these models with typical classroom teachers experience similar results.

Research could investigate beginning integer instruction with a moving-on-a-path metaphor in the form of the walk-it-off model, which works for every integer problem, and then integrating other conceptual metaphors in the real-life contexts in which these metaphors make sense (as well as have students assess in which contexts these metaphors make sense). The study reported here used a number line model designed to encourage students to move in ways that represent opposite operators, which differs from other approaches, so the findings of this study should not be generalized to other number line models. To further consider how learning with a model affords and constrains integer learning, other collecting objects, measuring, and moving-along-a-path metaphor-based models could be experimentally compared.

Theoretical Implications

Humans are always moving. Research in cognitive science shows that these movements influence what and how we think (Antle, 2013; Glenberg & Kaschak, 2002). Important work about moving to learn mathematics has begun (e.g., Gerofsky, 2012; Roth & Thom, 2009). Yet, more is needed, and it is crucial that mathematics education research attend to the *ways* that students move due to instructional models, instead of *whether* they move during instruction. This study contributed to this theoretical goal specific to integer arithmetic and findings suggest further investigating if motion-aligned models are more parsimonious instructional models across mathematics topics.

MENTAL MATHEMATICS AND ENACTMENT OF SPECIFIC STRATEGIES: THE CASE OF SYSTEMS OF LINEAR EQUATIONS

Jérôme Proulx
Université du Québecà Montréal
proulx.jerome@uqam.ca

This study on the mental solving of systems of linear equations is part of a larger research program, aimed to gain a better understanding of the potential of mental mathematics activities with topics/objects other than numbers. Through outlining the study details and the activities engaged with, the paper reports on the variety of strategies developed for mentally solving systems of linear equations. The analysis pays attention to specificities and particularities of these strategies, focusing on their economical, tailored, and spontaneous nature to solve the tasks. In reflecting on the context of mental mathematics, the paper closes with discussions of the potential and richness of these strategies for exploring systems of linear equations.

Keywords: Algebra and Algebraic Thinking; Problem Solving; Instructional Activities and Practices

Context of the Study

To highlight the importance of teaching mental calculations, Thompson (1999) raises the following points: most calculations in adult life are made mentally; mental work develops insights into number system/number sense; mental work develops problem-solving skills; and mental work promotes success in later written calculations. These aspects stress the nonlocal character of doing mental mathematics with numbers, where the skills being developed extend to wider mathematical abilities and understandings. Indeed, diverse studies show the significant effect of mental mathematics practices with numbers: on students' problem solving skills (Butlen & Pézard, 1992; Schoen & Zweng, 1986), on the development of their number sense (Murphy, 2004; Heirdsfield & Cooper, 2004), on their paper-and-pencil skills (Butlen & Pézard, 1992) and on their estimation strategies (Heirdsfield & Cooper, 2004; Schoen & Zweng, 1986). There is thus an overall agreement, and across contexts, that the practice of mental mathematics with numbers enriches students' learning and mathematical written work about calculations and numbers: studies e.g. conducted in US (Schoen & Zweng, 1986), France (Butlen & Pézard, 1992), Japan (Reys & Nohda, 1994), and UK (Murphy, 2004; Thompson, 1999). However, there is much more. For Butlen and Pézard (1992), the practice of mental calculations can enable students to develop new and economical ways of solving arithmetic problems that traditional paper-and-pencil contexts rarely affords because these are often focused on techniques that are too time-consuming in a mental mathematics context. In a similar vein, Poirier (1990), in reviewing historical curricular documents where the practice of mental calculations was salient, underlines the fact that mental calculations have their own processes, which differ from regular written calculations. Others, like Murphy (2004) or Threlfall (2002, 2009), focus on the aliveness and on-the-spot nature of mental calculations, where strategies are developed and tailored for the problem at hand and often differ from the writing processes that are usually focused on in paper- and-pencil contexts: something I have also discussed at PME-NA-35 (see Proulx, 2013a).

This being so, as Rezat (2011) explains, most if not all research studies on mental mathematics have focused on numbers/arithmetic. However, mathematics involve much more than numbers, and are predominantly studied through paper-and-pencil activities. This rouses interest in studying (1) what doing mental mathematics with mathematical topics/objects other than numbers (e.g., algebra, functions, trigonometry) might contribute to mathematical reasoning and understanding of these topics/objects, as well as studying (2) the kinds of strategies and solving processes engaged in to solve mental mathematics tasks related to other mathematical topics/objects than numbers. This paper focuses on this latter interest in relation to systems of linear equations, that is, studying the nature and specificities of the strategies developed through solving systems of linear equations tasks in a mental mathematics environment.

Defining Mental Mathematics

Because most work on mental mathematics is on numbers (often referred to as mental *arithmetic* or *calculations*), no definition of mental mathematics appears in the literature. For Thompson (2009), mental calculations represent a *subset* of mental mathematics; however he does not offer any definition of mental mathematics. This said, even if thought of in terms of numbers and mental arithmetic, definitions about mental calculations can be adapted to other mathematical objects/topics to help define mental mathematics. Building on Hazekamp (1986), who offers a definition that summarizes what is generally considered by mental calculations, one tentative definition is: Mental mathematics is the solving of mathematical tasks through mental processes without paper and pencil or other computational (material) aids.

In order to help develop a finer understanding of what is meant by mental mathematics, various dimensions about mental strategies with numbers are found in the literature (e.g. Butlen & Pézard, 1992, 2000; Kahane, 2003) and are adaptable to other objects/topics than numbers. One of these dimensions concerns *reasoned computations*, implying the elaboration of personal strategies, often nonstandard and adapted to the problem, versus *automatized computations*, which implies access to an immediate result through the use of known facts or memorized procedures. An example of this could be, for area, between using the formula $\frac{D\times d}{2}$ to find the area of the rhombus versus cutting the figure into triangles to find or compare the area. A second set of dimensions concerns *approximate computations*, based on estimation and approximation to gain an order of magnitude for the answer, versus the mental application of an algorithm or a fact to obtain an exact answer. An example for trigonometry could be between using the fact that $sin30° = \frac{1}{2}$ versus establishing a visual order of magnitude that the opposite side of a 30° angle enters approximately twice in the hypotenuse. A third dimension concerns *rapid computations*, which require quick execution to find the answer. Often criticized because it is perceived as a speed exercise detrimental to sense-making, it can also be seen as helping to develop new solving methods because it forces the solver, in trying to be economical, to abandon methods that may be slower (e.g. standard procedures) or less efficient for completing the task (e.g. one-on- one counting). In the case of algebra, an example could be the development of a *global reading* of an equation like $x + \frac{x}{4} = \frac{4}{x} + 6$ giving $x = 6$, avoiding numerous algebraic manipulations in order to isolate *x* (Bednarz & Janvier, 1992). These dimensions illustrate possible entries for solving mental mathematics tasks. In the case of systems of linear equations, what these dimensions represent is something probed into in this paper. In addition to having value for refining what mental mathematics can mean, these dimensions have value for data analysis and are reinvested in the subsequent analysis of strategies developed by solvers for systems of linear equations.

Methodological Considerations

This study is part of a larger research program that focuses on studying the nature of the mathematical activity in which solvers engage with through working on mental mathematics with objects/topics other than numbers. This is probed through (multiple) case studies that take place in educative contexts designed for the study (classroom settings/in-service education activities), where participants are asked to solve a variety of tasks. The reported study is one of these case studies, from a day-long session with 12 secondary-level teachers (Grade 9 to 12). The general organization took the following structure: (1) a task is offered to the group in writing on the board; (2) participants have approximately 15 seconds to solve the task; (3) at the signal, participants are asked to write their answers; (4) strategies are shared in plenary. The data comes from the strategies orally explained by participants, recorded in note form by two research assistants, who collected and compared their notes to produce more substantial information about the strategies developed. The session was also video-recorded, which allowed the research team to return to the tapes to enlarge on the notes and analyse the strategies in depth.

In this study, teachers are regarded as problem solvers; as would any participant solving the given tasks in this project. The decision to work with teachers is methodologically important. Indeed, these teachers are not novice solvers of systems of linear equations and thus are not in a new solving context or familiarization with the topic. This enables them to "enter" into tasks and attempt to solve them, giving access to their strategies and mathematical activity. This could be otherwise with participants who are newcomers to the topic, as they could experience significant difficulties with systems of linear equations and possibly would not be able to "enter" into the tasks for solving them. In that sense, the intention in this study is not to offer prescriptions for practice or to show how an approach through mental mathematics is "better" for learning about systems of linear equations than another focused on paper and pencil. The intention is neither to trace parallels between what these teachers do and what could happen with secondary-level *students* in a regular classroom. The analysis is focused, along the lines explained by Douady (1994), on the nature, meaning and functionality of the strategies developed in this mental mathematics context in order to analyse the mathematical activity engaged with and study the specificities of the strategies deployed for solving systems of linear equations tasks.

Findings

The tasks focused on for this paper consisted mainly in finding the solution, the intersection point, of a system of two linear equations (given algebraically), and then drawing the coordinate point on a sheet of paper displaying a Cartesian graph (with $y = x$ drawn as a reference line). Without being too caricatural, in a paper-and-pencil context the participants (as they explained during the session) would have resorted to algebraic manipulations and known algebraic strategies (comparison, elimination, substitution methods) to find these intersection points and then draw them on the graph. While solving the tasks, some participants opted for these algebraic methods, but in most cases they could not do this as the burden of algebraically manipulating without paper-and-pencil support became too important, and they had to develop alternative ways of solving. Below, I report on these alternative strategies to give a sense of their nature and analyse the mathematical activity involved. I first focus on the strategies given for solving the system of linear equations: "$y = x$ and $y = {}^{-}x + 2$". This is followed by other strategies developed for similar tasks, focusing again on their specificities for solving.

Strategies developed for Task 1 ("$y = x$ and $y = {}^{-}x + 2$")

Strategy 1: The role/influence of parameters. To solve this system, the participant focused on the fact that both lines would normally cross at (0,0). However, because the second equation was not "$y = {}^{-}x$" and had a y-intercept of 2, the answer was elevated by 2 on the y-axis, giving (0,2) as an answer. The focus on the parameter (y-intercept) played an important role in determining what and where the answer would be in the graph. This said, the answer (0,2) was not seen as the y-intercept, but mainly as an elevation of the point (0,0) toward (0,2); it ends up being the same, but at the time it was not thought of in these terms, as the participant expressed.

Strategy 2: Finding a "line" of possible solutions. The participant drew a vertical line at x=1, explaining that he did not have enough time to find the exact value of y, but that the solution was on that line because x=1 gave the same answer for both equations. Of interest is that substituting x=1 also gives the value for y. But in his algebraic manipulations for finding the value that gave the same answer for both equations, his focus was on finding a common x that gave the same answer for both equations ($x = ?$ and $^{-}x + 2 = ?$) and not on finding the value of *y*, even if it is the same. Both ventures were seen as separate. The first venture (focus on *x*) gave an infinite number of solutions within a restricted domain of *x*=1. He did not have enough time to look for *y*.

Strategy 3: Visualizing in the graph. The participant mentioned having found approximately where the point would be, in the 1st quadrant, by visualising the lines as one that crosses the first quadrant in the middle (y=x) and the other going through the 1st quadrant as well ($y = {}^{-}x + 2$, with a negative slope and starting from 2 on the y-axis), both intersecting on $y = x$ and in the 1st quadrant. Visualising the lines played an important role to position where the intersection point would be.

Strategy 4: Visualizing the lines with objects. Having pencils and pens on her table (for drawing the solution afterwards), the participant imagined them as lines in the graph and saw, as did the participant in Strategy 3, that the intersection point was in the 1st quadrant. It is through "seeing" the graph that the solution was developed, as the participant explained.

Strategy 5: Finding the right quadrant. For this participant, the first step was to realize that the solution would be in the 1st quadrant, because of the equations of the lines: one that splits the 1st quadrant in half and the other that goes through it (without being precise in exactly how). The point was not placed precisely in the graph (close to the *x*-axis, a little to the right of the origin), and the participant knew this, but the focus was on finding the right quadrant for the intersection.

Strategy 6: The y-intercept as a focus. Similar to Strategy 1, the *y*-intercept played a role in determining the intersection point. This time, with the difference that the *y*-intercept did not influence a previously obtained answer (as in Strategy 1 where the point (0,0) was elevated by 2), but influenced the fact that the solution had to be "in that area" of the *y*-intercept because it played a role in the position of the line $y = {}^{-}x + 2$ in the graph. Hence, the solution was placed at (0,2), mainly because of time constraints and because an answer had to be given. Here again, even if it is the same coordinate points, (0,2) is not thought of as the *y*-intercept for the participant (if it had been, it would have been discarded, because the participant knew that the other line did not have 2 as *y*-intercept). It was seen as a possible intersection point where both lines would cross each other.

Strategy 7: Visualizing the lines with gestures. Similar to Strategy 4, a participant imagined placing and crossing hands to represent the slopes of the lines, which is a common teaching practice. This gave an idea of where the intersection point would be. He considered the point to be in the 1st quadrant and saw that the intersection point could be in the "middle" of the crossing hands (not necessarily realizing that the point was on *y*=*x*, with the same value for *x* and *y*). Here too, the participant explained that it is through seeing the lines that the solution was developed.

Strategy 8: Trial and error. The participant attempted some numerical solutions (however not of the form *x*=*y*), but because it led nowhere he was unable to place any point of intersection (albeit knowing that there was one because both lines did not share the same slope).

In the following section, the above strategies are grouped and discussed in relation to their similarities, drawing out their specificities related to the context of mental mathematics. Since a strategy's attributes can be related to diverse groups, it can be placed in more than one group.

Discussion of strategies developed for Task 1 ("$y = x$ and $y = {}^{-}x + 2$")

Order of magnitude strategies: Strategies 2, 3, 4, 5 and 7. For these solutions, the focus is on having a good idea of where the solution is in the graph, of what is happening in the system of equations. These solutions can thus be related to the *approximate calculation* dimension. The focus is not on finding an exact answer, because time i s an issue in the mental mathematics context. This forces an analysis of the system to obtain an order of magnitude, an approximation, of where the solution would be: whether by focusing on the value of *x* as in Strategy 2, on the fact that the solution is on the line *y*=*x* as in Strategy 3, on gaining a visual idea of where the lines intersect as in Strategies 4 and 7, or of knowing in which quadrant the solution is as in Strategy 5. The need to develop an order of magnitude appears to derive from the mental mathematics context, a strategy quite removed from the algebraic manipulations that aim to find the exact solution to the system. The specificity of these solutions underlines important aspects, mainly visualizing the system and understanding what is happening. The focus on x=1 in Strategy 2 and on x=y in Strategy 3 are exam ples of how this focus on the order of magnitude offers significant information about the system, because, even if it may seem obvious, the value of x and the value of y need to be the same for finding a solution that satisfies both equations, one of them requesting that x=y! The same is true for the more visual strategies where lines are positioned, because one can directly see that there is an intersection point (something important to know about) and that the links between both algebraic and graphical representations are salient. Hence, one gets an idea of the system, how it functions, and what its possibilities are. It is in this sense that these strategies appear as specific for mental mathematics: not that they are better or worse, but simply different, provoked by the context of solving and offering another way into solving the system that a paper-and-pencil context does not necessarily afford.

Study of the equation: Strategies 1 and 6. Even if they give an answer that is mathematically inadequate, these strategies have something interesting to offer and can be related to the *rapid computation* dimension for a *global reading* of the equations. In particular, they are quite far removed from the usual algebraic manipulations that one would normally plunge into to solve the system. When solving algebraically in a paper-and-pencil context, the presence of the 2 in the second equation, the y-intercept, is not given much consideration or seen as important as it is simply a “2”, the number “2”, that is manipulated to find the value of x or y for solving the system. In algebraic manipulations, this “2” is not related to a “2” as the y-intercept, and the answer obtained is not considered as being influenced by this “2”; any more than would the negative sign affecting the x in the second equation (in algebraic manipulations, this negative sign affecting an x does not signify a “negative” slope). But, in Strategies 1 and 6, this “2” *is* the y-intercept and not simply a number to manipulate. Hence, consideration of the “2” is not related to the mechanics of manipulating algebraically, but for reflecting and thinking of the answer, the point of intersection of both lines. Thus, in these two strategies, one finds that the equation is studied, its attributes are considered and evaluated for finding something in it, for reading it so that it speaks differently than just algebraic symbols that need to be mingled. In this sense, these strategies call attention to the “-” sign affecting the x, to the “2” in the second equation, that makes the equation different from one that does not have the “2” (e.g. y=^{-}x). These strategies offer a focus on differences in equations that make a difference for determining the solution.

Because of time constraints, the effect of the “2” made the participants decide on an intersection that was about that “2”, but the specificity of these strategies is not about the answer obtained or the consideration of the “2”, but rather about the effect that this “2” had on the answer: the fact that it influenced and played a role in the answer (e.g. 2 more, 2 higher). The specificity of Strategies 1 and 6 concerns the focus on the *effect* of the parameters, here the y-intercept, on the solution to the system: something of lesser interest in algebraic paper-and-pencil manipulations.

Focus on numerical points: Strategies 2 and 8. These strategies focus on exact values for the solution by attempting to substitute possible answers to satisfy the system: being a hybrid between automatized and the opposite of *approximate computations*. It can be said that these strategies are elementary, as they are only an attempt to try out possible answers in a trial-and- error, unsystematic venture. However, their interest lies not in what they are not, but mainly in what they can be and can offer: that the solution needs to satisfy both equations simultaneously to be a solution to the system. Indeed, if there were only one equation to satisfy, the numbers attempted would have given a solution, and this would be it (e.g. x=2 in y=^{-}x+2 would give y=0 and this would be satisfactory for an answer to this equation). But, in the case of a system of equations, the solution needs to satisfy both equations simultaneously to be its solution. Hence both x and y need to be solution of both equations.

The x=1 answer in Strategy 2 illustrates this, as x=1 is explained as a solution for both equations, meaning that it gives the same answer in each equation. (Again, here the focus of the participant was on finding x first, and time did not allow for finding y, even if the "answer" and the "y" were the same). The next step would have been to find the value of y that was the same for both equations, which would satisfy both simultaneously. The same is true for Strategy 8, as the solutions attempted (here coordinate points) was intended to test a value for x and for y at the same time in both equations and to see if both satisfied the equations. The specificity of these strategies lies in the fact that the mental mathematics context provoked a need to find an answer, an x and a y, that satisfied both equations. In an algebraic manipulation context, this intention to find values that satisfy both equations simultaneously is often hidden behind the mechanical manipulations, and if it emerges it does so at the end of the process when establishing the values of x and of y that are solution to the system. It is in this sense that the trial and error, focused on numerical points, appears as specific in this mental mathematics context.

Discussion of a variety of other strategies developed for other tasks

In what follows, I discuss two other strategies developed to solve similar tasks. In detailing these strategies, I explore their specificities and what they focus on for solving.

Visualizing the lines in the graph through studying the equation. When solving the system "y=3x+1 and y=7x", one strategy was to analyse where the lines would be in the graph and then consider their intersection; related to a *global reading* dimension of the system. Thus the participant explained that y=7x passed by (0,0) and is quite inclined, whereas y=3x+1 "starts at 1", is less inclined, and thus crosses y=7x at a y greater than 1 and on the right of the y-axis (note that the analysis is made only in the 1st quadrant, as this participant knew where the lines would intersect from visualizing both lines, whereas an algebra-equation analysis would not offer the same information about the 1st quadrant). Another similar strategy was also related to the inclination of the lines, where the y=7x was seen much more inclined than the y=3x+1, leading to a value in x being between 0 and 1. Also, the value of y was seen as greater than that in x because one of the two lines, the y=3x+1, had a y-intercept of 1 (and a positive slope). In both cases, the analysis of the line is precise, focusing on aspects of the equation that gives information about the lines in order to visualize them for subsequently finding the solution. Understanding that the solution is in the 1st quadrant because of the inclinations of the lines, that the value of x is between 0 and 1, that the value of y is higher than 1, and so forth, is not a necessary part of the algebraic manipulating process, as these facts have little influence on the manipulations needed to obtain the solution. But in this case, in the mental mathematics context, these specific aspects are provoked in the strategies. And similar visualizations of the line in the graph, through studying and analyzing the equation, were made for other tasks. E.g., with the line "$y = x + 10$", one participant said that it was parallel to "$y = x$" but higher because of its y-intercept. Another example is with the system "$y = \sqrt{8}x + 5$ and $-\sqrt{18}x + 3y = 9$", where one participant approximated the value of the slope of $\sqrt{8}$ as being close to $\sqrt{9}$ and thus close to 3 with 5 as the y-intercept. For the second one, a mistake was made in relation to the sign of the slope, which was seen as positive rather than negative, but the participant considered the y-intercept as being of 3 (from dividing 9 by 3), and thus the solution in y as being between 3 and 5 in the 2nd quadrant. This analysis is quite impressive. For this participant, the intersection could not be lower than 3 in y, because it would be in the 1st quadrant, which is impossible because in that quadrant the other equation "starts" at 5 in y (its y-intercept being at 5). Thus by being a negative slope that has a y-intercept of 3, it had to intersect in the 2nd quadrant and between 3 and 5. These strategies represent specific ways to manage solving the system, performing a fine analysis of the equation combined with a visualization of the lines for solving it. It offers a specific way into the system, visualizing it, but mostly understanding how it works and where and how the solution can be. The specific analysis of the equation renders some "information" in the equation as significant to solve the system: something un-usual in a paper-and-pencil algebraic manipulations context.

Approximate algebraic manipulations. When asked to solve the system "$4x + y = 10$ and $x - 2y = {}^{-}6$", some participants opted for the elimination method by quadrupling the second equation, transforming it from $x - 2y = {}^{-}6$ to $4x + 8y = {}^{-}24$, and then subtracting it from the first (and obtaining$9y = 24$). Because of time constraints, the value obtained for y was said to be around 5; which can be related to the *approximate computation* dimension. Then, substituting the value of *y* in the first equation led to a value for *x* of around 1, for a coordinate point being about (1,5). Obviously, the degree of errors in regard to the solution is significant, because there is a first approximation for y, and then one for *x* based on that y. But of interest in this strategy is the approximation of the values in an algebraic system. This offers an order of magnitude for both values even if they were obtained through what is often seen as a precise strategy, that is, the algebraic route of elimination. Whereas earlier solutions focused on gaining an order of magnitude for situating the coordinate points in the graph, here the order of magnitude is in relation to algebraic manipulations: quite different from what is usually seen in an algebraic manipulation paper-and-pencil context.

Final remarks

These strategies reported illustrate some specificities of ways of engaging with the task in this context of mental mathematics. They are no doubt provoked by time constraints and because notes cannot be taken in writing, but this is the context of mental mathematics and it promotes these kinds of specific entries. It creates a need to grab something, to draw out aspects of significance for solving the problem. In addition to their specificities, these strategies have important potential for understanding or developing meanings about solving systems of linear equations, away from mechanical treatment and in relation e.g. to considerations of what is going on in the equations themselves, and how they behave. The reported "analyses/studies of the equations" represent such possibilities/potential for understanding systems of linear equations. Even if these strategies are not always optimal or do not render correct answers (precise or not), they offer ways of understanding what a system of equations is, ways that are different from what is usually done with algebraic manipulation strategies. These strategies are specific in the sense that they offer a way into the systems, an analysis of it, through drawing out particular aspects. Whether this is through analyzing the equations to gather significant information on the system, through having an order of magnitude of the solution or the system itself, through attempting to satisfy simultaneously both equations of the system, all this offers a specific way of engaging with solving systems of linear equations.

These results are promising. What comes out of this current work, and that on solving algebra equations (e.g. Proulx, 2013b) and operations on functions (e.g. Proulx, 2013a) in mental mathematics contexts, is the emergence of unusual ways of tackling and working on these mathematical topics, bringing forth varieties of strategies that focus on aspects not usually engaged in or focused on (here e.g. the *y*-intercept, the order of magnitude, the boundaries where the value in *x* and *y* could be). These strategies are creative and exploratory, and in this sense they suggest *extending* what can be done with these topics: not in terms of the tasks offered, but in terms of the meaning to be given to the topic itself. These strategies bring us elsewhere, focusing on different aspects and on other ways of solving. It is in this sense that they are specific, as is argued similarly for mental calculation on numbers, where they differ from the usual ways of solving and enable a focus on other aspects for solving. Clearly, more is to be studied and researched, but the focus on extending the scope of solving for these topics promise great value for mathematics teaching and learning.

This case study examined how a teacher's choice of numbers used in tasks designed to foster students' construction of a scheme for reasoning in multiplicative situations may afford or constrain their progression. This scheme, multiplicative double counting (mDC) is considered a significant conceptual leap from reasoning additively with units of one (1s) and composite units. A researcher-teacher's work with Jake allowed us to center on his gradual cognitive advance as different numbers chosen for the unit rate in problems (e.g., 5 cubes-per-tower) were used in the context of the Please Go and Bring for Me platform task. Our findings show that a child's use of an evolving scheme may initially depend on the numbers used in the task. We discuss the key recognitions that (a) a new way of operating does not evolve in a "once-and-for-all" way for all numbers and (b) the support our study provides for Pirie and Kieren's core notion of folding-back.

Keywords: Number Concepts and Operations; Elementary School Education; Teacher Knowledge

Introduction

In recent years, a growing body of research has been focused on various aspects involved in children's transition from additive to multiplicative reasoning (Empson& Turner, 2006; Hackenberg & Tillema, 2009; Sherin & Fuson, 2005; Tzur et al., 2013; Verschaffel, Greer, & DeCorte, 2007). However, unlike in other mathematical areas, such as numbers chosen for addition and subtraction tasks (Fuson, 1992), how a teacher may consider the use of numbers in tasks designed to help students overcome the conceptual leaps involved in progressing from additive to multiplicative reasoning has received little attention. To embark upon this lacuna, our study addressed the problem: How may specific numbers a teacher uses in tasks for promoting students' advance from additive to multiplicative ways of operating with/on different types of units (1s, composite), afford or constrain a child's conceptual progression when solving multiplicative problem situations? In particular, this paper examines such affordances and constraints as a child begins the transition from additive reasoning to the first scheme in which she or he coordinates operations on two types of composite units—the multiplicative double counting (mDC) scheme.

Conceptual Framework

A constructivist perspective on knowing and learning (Piaget, 1985) underlies this study. Specifically, we drew on von Glasersfeld's (1995) construct of scheme as a three-part mental structure: (a) situation, a recognition template into which a learner assimilates a problem situation (or task), that triggers her or his goal; (b) a mental activity the mind carries out to accomplish that goal; and (c) a result the learner expects to follow from the activity. The situation part includes recognition of and bringing forth of objects, such as numbers, upon which the mental activity operates.

Working within such a perspective, Steffe's (1992) seminal work contributed to distinguishing between additive and multiplicative schemes. He proposed to focus on the units on which one is operating mentally (1s or composite units) and the operations a learner uses that underlie her or his performance when solving tasks. He thus distinguished additive from multiplicative reasoning not on the basis of observable behaviors ("strategies") the child uses in and of themselves, but on the basis of inferences into what mental operations on units operations could give rise to those behaviors. Specifically, he asserted that multiplicative schemes involve a coordination of composite units in which the child distributes the items of one composite unit (e.g., towers made of 5 cubes each) over items of another composite unit (e.g., a compilation of 3 towers). Such a coordination may be manifested in the use of some figural items in place of the objects alluded to in the task (e.g., a finger standing for one tower) and later in the abstract, double counting of two sequences of composite units (e.g., first tower is 5 cubes, second-is 10, third-is-15). Tzur et al. (2013) recently proposed a developmental pathway of six schemes through which children's multiplicative reasoning may progress; this study focuses on the use of numbers to promote the transition from additive reasoning to the first scheme in the progression.

This study also drew on Pirie & Kieren's (1994) constructivist stance on the non-linear growth in learners' mathematical understandings, particularly the key construct of folding-back. Rooted in studies of children in other areas (e.g., fractions), they showed that an ordinary path to higher-level understanding (outer layers in their model) might include frequent 'regresses' to the use of lower-level, previously constructed understandings. Our tasks were designed to promote students' transition to the first of six schemes, multiplicative double counting (mDC), while allowing the research team to analyze how numbers chosen for these tasks would possibly bring about folding-back and upward shifts in the units/operations a child may use.

Methodology

The case study reported in this paper was part of a larger constructivist teaching experiment (Cobb & Steffe, 1983) we have conducted with four 4th graders identified by their western US school as requiring intervention in mathematics based on state assessments and classroom teacher recommendations. The two first authors conducted the video recorded teaching episodes with each child individually. This paper analyzes data from their work with one student, Jake (pseudonym), twice a week, from October through December of 2014, around 30-45 minutes each episode. The second author (Nina, pseudonym) served as the researcher-teacher in those episodes, as Jake was accustomed to working with her as the school intervention teacher.

All teaching episodes engaged students in playing the task-generating game of Please Go and Bring for Me (PGBM), which Tzur et al. (2013) described in detail. In a nutshell, PGBM is a turn-taking game played in pairs, with one's peers and/or the teacher. Each turn, a "Sender" asks a "Bringer" to build and bring back from a box containing individual cubes a compilation of same-size towers, one tower at a time (e.g., 3 towers, 5 cubes in each). Once all towers were brought to the Sender's satisfaction, she or he asks the bringer four questions (in our work – those are written on a poster to promote students' use of full sentences and explicit mention of units): (a) How many towers did you bring (emphasizes number of composite units)? (b) How many cubes are in each tower (emphasizes unit rate – number of 1s in each composite unit)? (c) How many cubes are in all the towers? (d) How did you figure this [total of 1s] out? (Last two questions emphasize operations child used to figure out number of 1s in the entire compilation of composite units.) Similarly, the poster included 'answer-starters' that enabled the bringer to express her or his answers as full sentences (e.g., "I brought __ towers"). Initially, the teacher constrains the game so children can only use particular numbers of cubes per tower (e.g., 2 or 5) and of towers in all (e.g., up to 6), while also asking children to use different numbers for each kind (e.g., a sender cannot ask to bring 5 towers of 5 cubes each).

Our line-by-line retrospective analysis of video records, transcripts, and researcher field notes taken during each episode focuses on the first two teaching episodes with Jake. Focusing on his initial transition to multiplicative reasoning serves the purpose of 'zooming in' on the interplay between his ways of operating and the numbers chosen in each task. The two first authors conducted ongoing analysis following each episode; the entire team of authors then conducted the line-by-line analysis of the four segments presented in the next section.

Results

To study how numbers chosen for tasks may afford and constrain a child's operations with different types of units as the teacher promotes Jake's transition to the mDC scheme, this section includes analysis of four data Excerpts. In the first episode (Excerpts 1 & 2), Jake worked with a peer on PGBM tasks constrained to unit rate of 2 or 5 and a number of composite units up to 5. In the later episodes (Excerpts 3 & 4), Jake played a bringer role with Nina as sender, with tasks allowing both unit rates and number of composite units to be 2, 3, 4, 5, or 6.

Starting Point: Less than Five Composite Units, Unit Rates of 2 or 5

Excerpt 1 shows data from Jake's first turn as a bringer, after he had produced (from single cubes), brought 4 towers of 5 cubes each, and properly responded to the first two questions (SS stands for Student-Sender).

Excerpt 1

SS: How many cubes did you bring in all?

Jake: (Glances at the towers for 1 second, then says) I brought … (uses his left hand to tap five times on the palm of his right hand); I brought 20 cubes altogether.

SS: How did you figure this out?

Jake: I figured this out by counting.

Nina (Teacher): How did you count?

Jake: I counted by 5s[1].

Nina: How did you know to stop counting?

Jake: Cause if you don't, cause if you can't … (reaches with his left hand and brushes over the towers that the SS is holding)

Nina: I can count by 5s too: 5, 10,15, 20, 25,30 ... So how did you know to stop at 20?

Jake: (Looks at the towers that the student sender is holding) It's … because that … (turns his head away from the towers for five seconds, then turns his gaze back on the towers). It's because I only brought 4 towers.

Nina: So you knew to stop because ... ? How did you know you had counted the four towers, Jake? I agree that you only brought 4 towers. How did you know that 20 was 4 towers.

Jake: I counted on my fingers.

Nina: Can you show me?

Jake: (Holds up his right hand, then folds his index finger while stating) 5; (folds middle finger) 10; (folds ring finger) 15; (folds pinkie finger) 20! (Body indicates, "I am done").

Excerpt 1 provides a glimpse into Jake's mental operations while solving a problem with 'easy number' unit rate 5. Jake first reestablished the number of 1s that constituted each composite unit (five palm taps). That is, he seemed to have created a figural mental template of the size of every composite unit. Because counting by 5s was within his capacity, his count of the accrual—which he demonstrated to the teacher, indicated a purposeful method of keeping track of the number of composite units so he would know to stop at four towers. His ability to perform such a purposeful action did not yet seem to support expressing how he did it. Rather, when prompted to explain how he knew to stop at 20, he initiated a shift to a different figural re-presentation, by using the fingers of his right hand to represent the composite units in the situation (towers) and his number sequence (by five) to re-present the accruing 1s (cubes). This seemed to assist his growing anticipation of the link between coordinated actions taken to figure out a progressive total and the effect of stopping the count of 1s when reaching the number of composite units (which fits his statement, "I brought 4 towers"). Jake, when operating mentally on a unit rate that is a known counting sequence (5s), could both initiate and complete the coordinated, goal-directed mental activity involved in multiplicative double counting.

It is important to note the purpose of the teacher's interventions (e.g., "how did you count"). A child may initiate and carry out goal-directed actions while not being aware of his own actions, let alone the steps he took to monitor those actions. By asking Jake to explain, she thus attempted to orient his reflection on and awareness of his own purposeful actions (e.g., he did keep track of the composite units). To explain his strategy, Jake used fingers, which the teacher intended as a means to promote two critical reflections in constructing the mDC scheme. First, she focused Jake's attention on a specific aspect of his coordinated counting—monitoring accrual of the composite units. Second, she simultaneously focused his attention on the key in his stoppage monitoring.

In the following PGBM task in which Jake played the bringer, he had to figure out and explain how many cubes are in 5 towers with 2 cubes each. Again, Nina pressed for his explanation of his solution, as his response (10) came after quietly nodding his head five times but not using his hands/fingers. Excerpt 2 shows he re-used the previous way of explaining.

Excerpt 2: Finding the total number of cubes in 5 towers of 2 cubes each

Nina: Can you show me?
Jake: Like this … (holds up right hand, folds down his index finger while saying) 2; (folds his middle finger) 4; (folds his ring finger) 6; (folds his pinkie) 8; (folds his thumb and concludes) 10.
Nina: So, again, each one of your fingers … this [seems] similar to something else you did. Each one of your fingers, you put them down: 2, 4, 6, 8, 10 (paraphrases J's motions and utterances); so you stopped here (wiggles her thumb); Why?
Jake: Its because I only brought 5 towers.

Excerpt 2 provides further evidence to the evolving regularity in Jake's ways of operating as well as the teacher's involvement in that process. Freed from a mental focus on the accrual of 1s in the sequence of multiples of 2, he initiated and completed a coordinated count of figural composite units(5 towers) through nodding his head and later through using fingers. He seemed to anticipate the need to coordinate two accruing number sequences: composite units (towers) with unit rate (cubes distributed over each of the towers). Similarly, when prompted to explain his thinking, Jake used the fingers of his right hand to re-present each composite unit in the sequence of 5 towers while keeping track of accrual of 1s via his number sequence (by 2s) to ten. Considering Excerpts 1 & 2 combined, Jake seemed to have established at least an enactive anticipation of multiplicative double counting as a means to accomplish his goal.

Starting Point: Composite Units of Less Than 5, Unit Rates of 4 and 6

Excerpts 3 & 4 present Jake's work two days later, with Nina serving as the sender. Based on his facility with double counting in tasks with unit rates of 5 or 2, she chose to send him to bring 3 towers of 4 cubes each—slightly harder numbers (for him) that he could still work out by using each hand separately. Excerpt 3 starts after Nina asked Jake how many cubes he brought in all.

Excerpt 3

Jake: I brought 11 cubes altogether.
Nina: (Lays the towers down on the table closer to Jake) Can you double check?
Jake: (Takes apart each tower into its individual cubes while counting them out loud but without keeping them as distinct groups) 1, 2, 3, 4,5,6,7,8,9,10,11,12!
Nina: So how many [cubes] did you bring altogether?

Jake: 12.
Nina: I want to know how you figured that out (she takes 4 cubes and reassemble them into a tower.
Jake: (Reassembles another tower, albeit from 5 cubes.)
Nina: (Reassembles another tower from the remaining 3 cubes, and asks him to give her a cube so she can make a tower of 4.) Jake, when you counted the first time, I saw you use your fingers (she folds her left hand's fingers to emulate his motions). Can you tell me what you were doing?
Jake: (Folds down 4 fingers on his left hand, then folds down a finger on his right hand; repeats the process for the second and third towers, while left-hand fingers seem to stand for 1s and right-hand fingers for composite units/towers.)
Nina: And why did you do this (replicates Jake's motions)?
Jake: Each finger was a tower.
Nina: Each finger was a tower? So can you show me again?
Jake: (Holds up his right hand with the palm face up) Each finger was a tower. (Folds down three fingers on his right hand, one at a time, while saying) That's the first tower, that's the second tower, and that's the third tower. (He then adjusts his hand motion and folds down four fingers on his left hand, one at a time, while saying)If we add them all up we go 1(folds down a finger),2 (folds down a second finger),3 (folds down a third finger), 4 (folds down a fourth finger),5 (looks at his hand as if having an 'oops' experience). (After 2 seconds, he opens his hand, says "No," then raises three fingers again on his right hand and says)No; this is three towers and you [have to] count by fours. He uses his left hand to put down one of the fingers on his right hand and says "Four." Then he raises his left hand, counts four fingers, and says "5-6-7-8." He then uses his left hand to fold another finger down on his right hand, then opens his left hand again and says "9-10-11-12."(Then, folds the third finger on his right hand.)
Nina: And you knew to stop at 12 because these were like the towers (touches the fourth finger on *his* right hand and this was like the 12th …
Jake: (Completes her sentence) … Tower
Nina: (Inquiring about the unit type) The 12th what?
Jake: Tower
Nina: (Places her hand on the real towers and says) How many towers do you have here?
Jake: (Corrects himself in response to her prompt) That was the last, third tower.
Nina: It was the last, third tower; but it was the 12th what?
Jake: Cube

Excerpt 3 provides further evidence of the role numbers in task played in his evolving way of operating, as well as the teacher's involvement in that process. Challenging him to solve a problem with 4 as the unit rate, Jake's mental system was no longer freed from focusing on the accrual of 1s. Thus, he folded back to a focus on 1s (single cubes) that composed each unit. Taking apart all 3 towers without any allusion to their grouping indicated his need to individualize units—no longer reasoning multiplicatively. Yet, when prompted to explain, Jake made several attempts to coordinate the use of his fingers to re-present, on each hand, a different type of unit (cubes on the left hand, towers on the right). In his first, unsuccessful attempt, he identified the right fingers as towers, but began counting them as cubes. In an "oops" moment, he realized that counting the figural tower re-presentations on his right hand was not moving toward his goal and started over. On his second attempt, Jake was able to accurately use his fingers to keep track of the unit rate of 4. He began his count not from 1 (cube) but from the first multiple of 4, indicating the coordination of a first composite unit with the numerical value of the unit rate. Due to lack of facility with the next two multiples of 4,heturned to using the left hand four counting accrual of 1s while keeping track of the composite units with fingers on the right hand. Indeed, Jake's solutions to this more challenging (for him) task differed, and folded back, from his coordinated actions to solve the previous tasks (with unit rates of 5 and 2). This suggested that Jake's goal-directed coordination of double counting operations on composite units was still evolving and thus dependent on the numbers used in the task (in the sense of his facility with the multiples of the unit rate).

To further demonstrate the interplay between numbers chosen for a task and a child's ways of operating, we present his solution to the task that followed (Excerpt 4). Here, the teacher decided to keep the number of towers at 3, but to increase the unit rate (6 cubes per tower) so it exceeds the number of fingers on one hand. This choice intended to explore how Jake would cope with the challenge of keeping track of composite units while using fingers on both hands to keep track of a sequence of multiples with which he was not facile.

Excerpt 4

Nina: How many cubes did you bring altogether?

Jake: (Silently touches each cube in the first tower, perhaps re-counting them all. He then holds up and stares at his two hands for 1 second, puts his hands down, reaches for a pen, looks back at the cubes, points to the cubes for 1 second, and writes on a small white board the number 6 first and then the letter "T" above it.)

T
6

He looks back at the towers on the table and writes on his white board another set:

T T
6 6

He looks back a third time at the towers, and completes his writing to correspond with the numbers given in the task:

TTT
6 6 6

Seemingly not knowing how to proceed, he turns back to the real towers; taps on each of 8 cubes individually (all cubes in the first tower and two from the second), stops, and erases the white board completely. At this point, he begins counting while pointing with his finger to each individual cube in the first tower, shifting to counting by 2s to expedite the process, finally saying): I brought 18 cubes altogether.

Nina: (Not indicating if he was correct or not) How did you figure it out?

Jake: (Picks up all of the towers and then puts them back on the table) I figured it out a different way; I just counted it this time. I used the cubes (picks up one tower). I pretended I broke it up like … (breaks off individual cubes from each tower); like 1-2-3-4-5-6;that is a tower I counted.

Nina (a little later): Did it get a bit harder today when the numbers got harder?

Jake: It was hard for me because I wanted to use the way I did last time (holds up both hands and shows the hand motions that he made when using his fingers to re-present a coordinate, double-count with 4s); but I don't have as much fingers.

Nina: So you couldn't, you couldn't, you don't have as much fingers so does that mean you couldn't? What do you mean by that (shows holding up of both hands)?
Jake: I had to do it a different way.
Nina: What do you mean you don't have as much fingers?
Jake: I only have 10 fingers and … (rebuilds the 3 towers of 6 using the cubes on the table) Since …So if there are towers of 6 (holds up both hands) and I went like that (begins to count out six on his right hand);So I wouldn't have enough fingers.

Excerpt 4 provided further evidence how the numbers Jake operates on make a difference in his goal-directed activity. When presented with a unit rate of 6, for which he had neither a mental number sequence nor enough fingers to re-present the items, he seemed unable to complete a coordinated count the way he did for unit rates of 2 or 5. Jake's first, spontaneous attempt to re-present the towers was to write a "T"(for tower) and the number"6" under each "T" to indicate how many 1s constituted that composite unit. While insightful and resourceful, this symbolized re-presentation did not proceed to a double-counting activity. Seemingly having no other recourse, Jake abandoned this initiative (e.g., erasing the white board) and instead folded back to counting each of the tangible cubes (albeit shifting from counting by 1s to counting by 2s to expedite the process). Jake's explicit utterance, about not having enough fingers, indicated he was acutely aware of the need to but unable to operate in a coordinated way when the number in one, unfamiliar composite unit precluded using each hand for a different component of the coordinated count. This was evident in his show of two hands, used to this end for 3 towers of only 4 cubes each, and the statements that followed ("I had to do it a different way"; I only have 10 fingers").

Discussion

This paper focused on a key consideration for teaching specific mathematical ideas to students, namely, the choice of numbers used in tasks. Particularly, our study focused on this consideration when using tasks to foster students' construction of the multiplicative double counting (mDC) scheme. Our study can contribute to the field in two important ways. First, it provides further support to the stance that construction of a particular scheme (e.g., mDC) is not a "once-and-for-all" event. Rather, when a shift in the child's way of operating is to be promoted, such as the cognitive leap from additive to multiplicative reasoning (Steffe, 1992), initial emphasis in task design and implementation needs to be placed on orienting the child's mental powers onto the novel coordination of operations on units. To this end, choosing 'easy' numbers seems highly productive, because the child can bring forth available knowledge of numerical calculations with which she or he seems facile (e.g., multiples of 2s and 5s). Initially solving tasks that involve 'easy numbers' enables the child to construct the intended goal-directed activities (a new scheme), which can then become an invariant way of operating she or he could apply to solving tasks with numbers that require engaging more complex mental capacities. (The scope of this paper did not allow us to provide data on how that change was successfully fostered in Jake after what we have seen in Excerpt 4.)

Second, our findings provide further support to the core construct of folding-back in Pirie & Kieren's (1994) model of growth in understanding. Specifically, we showed how Jake was able to use his newly constructed understanding of the coordinated count of composite units and begin operating in multiplicative situations when using 'easy numbers' (Excerpts 1 & 2). Nevertheless, he folded back to operating on 1s, while also conflating unit rate with the number of composite units (Excerpt 3), and was initially unable to solve similar (from an adult's point of view) tasks presented with numbers for which he had no facility with the multiples. He further folded back, foregoing use of double counting when the unit rate (6) exceeded what he could signify with one hand's fingers. As Tzur and Simon (2004) noted, folding-back may be a good behavioral indication for a stage in constructing a new scheme at which the child's evolving scheme (here, multiplicative coordination/distribution of composite units) is yet to become independent and spontaneous. This seemed to be Jake's case, when anticipating he would not have enough fingers to account for all 1s in a tower of 6 cubes, and thus producing the abstract diagram to create a tool for keeping track that seemed not yet readily available for him conceptually. Folding-back can thus also be a good indicator of the need to pay close attention to the child's conceptualization, in the following, threefold sense: (a) not simply attributing to the child too high a level of conceptual growth due to successful performance on 'easy-number' tasks; (b) not attributing to the child outright failure to conceptualize the intended math due to unsuccessful performance on 'harder-number' tasks; and (c) designing tasks and using tools that can gradually bring the intended mathematics to be within the child's mental reach.

STUDENTS' GENERALIZATIONS IN THE DEVELOPMENT OF NON-LINEAR MEANINGS OF MULTIPLICATION AND NON-LINEAR GROWTH

Erik Tillema
Indiana University—IUPUI
etillema@iupui.edu

Andrew Gatza
Indiana University-IUPUI
agatza@iupui.edu

The study reported on in this paper is an interview study conducted with 20 7th and 8th grade students whose purpose was to understand the generalizations they could make about non-linear meanings of multiplication (NLMM) and non-linear growth (NLG) in the context of solving combinatorics problems. The paper identifies productive challenges for the students, and thus fruitful areas where the students could generalize their reasoning about NLMM and NLG.

Keywords: Cognition; Number Concepts and Operations; Middle School Education; Algebra and Algebraic Thinking

As students progress into the middle grades they are expected to begin to understand situations that involve NLMM and NLG. Despite this curricular structure, studies in this area have highlighted the difficulties that students have in reasoning about a broad range of contexts that can involve NLMM and NLG (Van Dooren, De Bock, Janssens & Verschaffel, 2008). These difficulties include a tendency for students to generalize linear meanings of multiplication (LMM) and linear growth (LG) to situations that involve NLMM and NLG. For example, students frequently conclude that scaling the side lengths of a square by a factor of k produces a change in the area of the square by a factor of k rather than k^2 (DeBock, Van Dooren, Jansenns, & Verschaffel, 2007; Vlahovic-Stetic, Pavlin-Bernardic, & Rajter, 2010), and treat non-linear functions, for example quadratic functions, as if they have similar properties as linear functions (Chazan, 2006; Ellis & Grinstead, 2008; Zaslavsky, 1999). Thus, an important issue for researchers to investigate is how to support middle grades students to begin to establish NLMM and NLG, and further, to identify productive generalizations students can make in the context of establishing NLMM and NLG (Ellis, 2011). The purpose of this study, which is currently underway, was to address these two issues.

We addressed these issues by presenting 20 7th and 8th grade students with combinatorics problems whose solution could be represented with a two-dimensional array. Thus students had the potential to establish NLMM and NLG, and generalizations about NLMM and NLG as a result of reasoning about relationships among one and two-dimensional quantities. Here we report results from the first of two interviews. The purpose of the first interview was twofold: (a) to establish which of three qualitatively distinct multiplicative concepts students were using (Author, 2009; Steffe, 1994); and (b) to identify productive challenges in the domain of NLMM and NLG for students that were using each multiplicative concept. Once productive challenges were identified for students using each of the three multiplicative concepts this information was used to design tasks for the second interview whose purpose was to examine the generalizations that students using the three different multiplicative concepts could make.

Perspectives and Theoretical Framework

A Quantitative Approach to Non-Linear Meanings of Multiplication and Growth

We developed NLMM and NLG using combinatorics problems like the *Digit Problem*.

Digit Problem: You have a deck of cards with the digits one through seven written in black on them. You draw a card, replace it, and draw a second card. How many possible coordinate points (e.g., (1,7) is one coordinate point) could you make using this process?

We specifically selected combinatorics problems to investigate these issues because of their potential to support students to establish one and two-dimensional quantities, and relationships between them.

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

That is, combinatorics problems can involve *ordering* the digits in the deck of cards (a first digit, second digit, etc.), and *ordering* the draws from the deck of cards (a first draw, and a second draw) (Author, 2013). We considered this to be a potential basis for spatially structuring the units on the axes, and the axes themselves, which in turn could create a spatial structuring for the coordinate points in the array. Further, we considered that these problems could involve *pairing* a digit from the first draw with a digit from the second draw (Author, 2013), and thus give students an operative way to create what we considered two dimensional units (i.e., coordinate pairs) from one dimensional units (i.e., digits).

We considered that the solution of the digit problem could involve students in establishing a meaning for 7^2, an NLMM (Figure 1a). Once students solved this initial problem we were interested in introducing NLG by having students consider how changing the number of digits would change the number of coordinate points, which we considered to involve whole number co-variation[1]. We wanted to investigate this issue through two types of problems: (a) having students consider how adding additional digits to the deck of cards (e.g., adding the digit 8, then adding the digit 9) would change the total number of coordinate points by considering how many *new* coordinate points there would be after a given change in digits; and (b) having students consider how doubling, tripling, etc. the number of digits would change the number of coordinate points. The goal of the first task was for students to have an experience of NLG by investigating how *equal* changes in the number of digits (e.g., changing the number of digits from 7 to 8, and then from 8 to 9) yielded growth in the number of coordinate points that was *not constant* (e.g., 15 new coordinate points when the number of digits increased from 7 to 8, and 17 new coordinate points when the number of digits increased from 8 to 9) (Figure 1b).

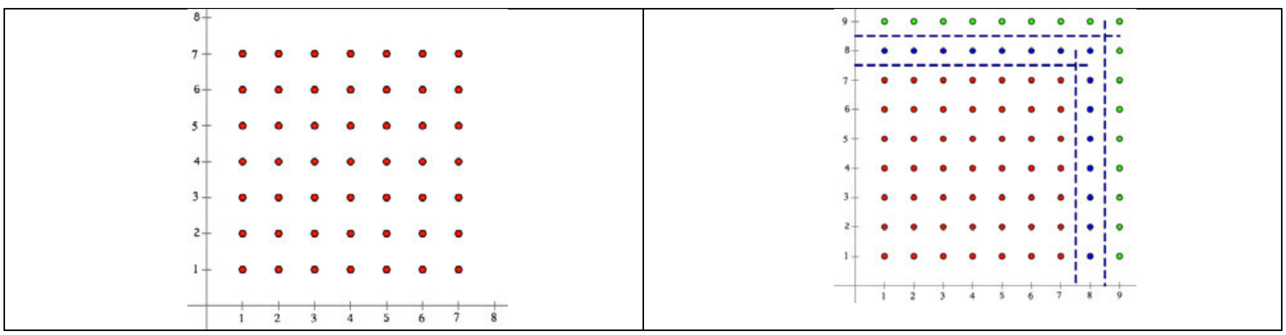

Figure 1a (left) & 1b (right): Arrays for the Digit Problem

The goal of the second task was for students to have an experience of NLG by investigating how multiplicatively increasing the number of digits (e.g., doubling) increased the number of coordinate points by the square of the increase in the number of digits (e.g., quadrupled) (Figure 2). Both of these problems we considered important to students' initial understandings of NLG.

Discussion of Students' Multiplicative Concepts

Prior research has identified three qualitatively distinct multiplicative concepts, all of which are rooted in students' units-coordinating activity (Author, 2009; Steffe, 1992, 1994). We outline the second and third of these multiplicative concepts because we report on data related to students using each concept. We use the Candy Problem to outline the concepts:

> *Candy Problem:* Brandy has 3 packages of candy each containing 6 candies. How many candies does she have in all?

A student using the second multiplicative concept (MC2) has interiorized two levels of units, which enables her to strategically reason with sixes in solving the Candy Problem. For example, to solve the candy problem a student might reason that six and four is ten, and that two more is twelve

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

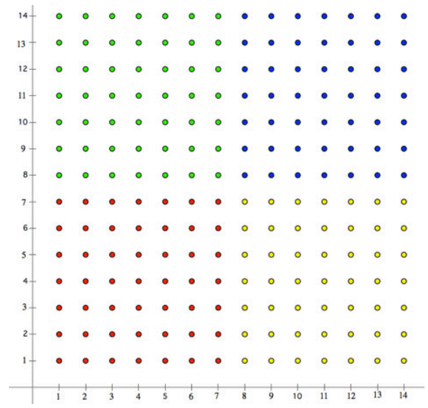

Figure 2: Array for the Digit Problem

and then finish the solution by reasoning that six more than twelve is eighteen. The ability to operate on each six by breaking it into, for example, four and two and strategically combining the parts is a hallmark of MC2 students because it is one indication that they are able to operate on a unit of six units. MC2 students are also able to produce three levels of units in activity. That is, once they have solved the Candy Problem they may regard the 18 candies as a unit of three units of six units, but they cannot use this three level of unit structure in further operating. For example, if these students were told that Brandy received 8 more packages, they could determine that this was 48 more candies, producing 48 as a unit of 8 units of 6 units. They could then unite 18 candies and 48 candies to determine there were 66 candies in all. However, determining that 66 candies was 11 packages would be a separate problem for an MC2 students because they would not retain the 18 candies as a unit of 3 units of 6 units and the 48 candies as a unit of 8 units of 6 units. This means that MC2 students are able to create three levels of units in activity, but are not able to operate on this third level of unit.

In contrast, students using the third multiplicative concept (MC3) have *interiorized* three levels of units. This means that an MC3 student would be able to determine that the 66 candies constituted 11 packages because the 18 candies would retain there status as a unit of 3 units of 6 units, and the 48 candies would retain there status as a unit of 8 units of 6 units. So when they united 18 and 48 they would establish the 66 candies as a unit of 11 units of 6 units.

Methods

The data for this research was drawn from clinical interviews (Clement, 2000) with 20 7th and 8th grade students who were attending an urban public school in a large Midwestern city during the 2014-2015 academic year. The school population, of which the study population mirrored, is approximately 69% African American/Black, 16% Hispanic/Latino, 13% White, and 2% multiracial, with slightly over 85% of students qualifying for free or reduced lunch. The study consisted of three hour-long interviews. The first interview was a selection interview and helped identify the multiplicative concept students were using as well as identified potential productive challenges in the domain of NLMM and NLG. Using the information gathered in the first interview, the second and third interview explored generalizations that students using each of the three different multiplicative concepts made. There were seven tasks in the selection interview protocol, however, tasks were altered based on the interactions with individual students in order to gain authentic insight into students' thinking processes (Clement, 2000). All interviews were video recorded and conducted in the presence of two researchers. Following the interviews, written notes were taken and discussion within the research team served as a form of data triangulation.

Results

We present two data excerpts from the first interview in order to illustrate how we identified what kind of generalizations would be productive for us to work on with MC2 and MC3 students

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

during the second interview of the study. The first data excerpt is from an MC2 student, Keon, who was presented with the digit problem, which he solved and then created a seven by seven array. He was then asked how many new coordinate points there would be if he was given an eighth digit. The interviewer asked Keon to determine a solution to this problem without initially drawing the coordinate points on the array. This condition was presented by the interviewer in order to test the extent to which Keon could monitor the number of new coordinate points he created as he created them, and to see how he structured his creation of the new coordinate points. Moreover, the goal was to avoid having him put the points on the array and then count the number of points he had put in the array because such a solution had the potential to significantly simplify the problem because it would be less clear in this case if the points retained there status as two-dimensional coordinate points or if they were simply enumerated as units of one.

Excerpt 1: Keon's Solution to Adding a Single Digit

I: Would you say what all of them (new coordinate points) are so you can figure out how many there would be?
K: Eight, one; eight, two; eight, three; eight, four; eight, five; eight, six; eight, seven. Yeah. It's eight times seven, right?
….
I: Would there be any others?
K: Oh, and eight, eight.
I: Eight, eight. Yeah that is good. So how many total is that?
K: Just the new ones? It would be eight, right?
I: Okay. So you said eight, one; eight, two; eight, three...Are there any others you could get?
K: [sits in concentration for 5 seconds]: Oh, one, eight.
I: Mm-hmm.
K: Two, eight; three, eight; four, eight; five, eight; six, eight; seven, eight; and eight, eight.
I: Mm-hmm. So how many total new ones would there be?
K: It'd be sixteen, right? No. It'd be sixteen, right? Cause it'd be eight, one; eight, two; eight, three; eight, four; eight, five; eight, six; eight, seven; eight, eight [puts up each finger on his right hand and his thumb, index finger, and middle finger on his left hand as he says the pairs]. One, eight; two, eight; three, eight; four, eight; five, eight; six, eight; seven, eight; eight, eight [puts up his ring finger and pinky on his left hand, and then reuses the fingers on his right hand and the thumb on his left hand as he says each pair]. So sixteen.
I: Sixteen. Did you count any of them twice?
K: Huh?
I: Did you count any of them twice? Check and just see.
K: Count any of them twice?
I: Mm-hmm. Say them again, and just think about if you counted any of them twice.
K: Eight, one; eight, two; eight, three; eight, four; eight, five; eight, six; eight, seven; eight, eight.
I: Mm-hmm and what were the other ones you counted?
K: One, eight; two, eight; three, eight; four, eight; five, eight; six, eight; seven, eight. Oh, and then eight, eight, I can't say that one no more cause I already said it.
I: Yeah that is right.
K: So it'd be fifteen.

Keon's initial response in which he said aloud seven new coordinate points (eight, one through eight, seven), and then said, "It's eight times seven, right?" indicated that he anticipated that the problem would involve linear growth. That is, he anticipated that if he added one new digit this would produce seven new coordinate points because when he had created his seven by seven array each digit produced seven coordinate points. Upon questioning, he realized that eight could also go with itself, and that this meant he produced eight new coordinate points. Moreover, after he produced the coordinate point eight, eight, he had the insight (with the support of further questioning) that eight could also be the second digit in a coordinate point, and was able to state the rest of the coordinate points that he could create.

After he had stated all of the coordinate points, he thought that there would be sixteen coordinate points although was not positive, “It'd be sixteen, right? No.”, and so restated all of them again counting each coordinate point using his fingers as he said them, and concluded there would be a total of sixteen coordinate points. This portion of the data excerpt is of interest for two interrelated reasons: first, Keon was not totally certain about how many new coordinate points he had created and so stated them again in order to count them; and second, he double counted the eight, eight coordinate point, an issue that has been reported frequently in prior research on students’ two-dimensional reasoning (Battista, 2007). He was subsequently able to conclude that he had double counted the eight, eight coordinate point after questioning on the part of the interviewer, and re-stating all of the coordinate points again, to check to see which, if any, of them he had counted twice.

We account for these features of his solution by appealing to the levels of units coordination that are likely involved for a student to immediately conclude that, for example, he had created sixteen new pairs, and that this number of new pairs contained the coordinate point eight, eight twice. That is, our inference is that Keon created the first eight coordinate points as a unit of eight pairs in activity, and that the creation of such a unit structure is equivalent to establishing a three level of unit structure in activity because each of the coordinate points can be considered equivalent to a unit that contains two units (and so a unit of eight pairs is like a unit of eight units of two units). Keon could create a unit of eight pairs in activity but could not operate further with this unit structure; had he been able to operate further with this unit structure our inference is that he would have simply combined the first unit of eight pairs he created with the second unit of eight pairs he created to determine the total number of new coordinate points to be a unit of sixteen pairs without re-creating and counting each of the pairs. Additionally, our inference is that he would have identified, without re-creating all of the pairs, that each unit of eight pairs contained the coordinate point eight, eight.

Nonetheless, this data excerpt suggested to us that for Keon, and students like him, an appropriate and productive challenge would be considering the relationship between a change in the number of digits and the number of coordinate points as a single digit was added. Moreover, we identified that a productive challenge would be structuring the new coordinate points as seven new coordinate points that contained eight as the first digit *only*, seven new coordinate points that contained eight as the second digit *only*, and one new coordinate point that contained eight as both the first and second digit.

The second data excerpt is from an MC3 student, Armando, who was also presented with the digit problem, which he solved and then created a seven by seven array. He was then asked how many times the number of coordinate points he could make if he had twice as many digits. The goal of the interviewer was to have Armando use his array to quantitatively establish the relationship between the number of old and new coordinate points. Once Armando had accomplished this goal, then the interviewer wanted to determine whether Armando could symbolize the situation as 14 x 14 = (7 x 2) x (7 x 2) = 7^2 x 2^2 so that he could also use his symbolic statement to see why there were four times as many coordinate points.

Excerpt 2: Armando’s Solution for Doubling the Number of Digits

I: [A extends the axes of the array, and puts in the digits eight through fourteen on each axes] How many times more numbers are you going to have if you fill those all in?

A: Um...can I just write it out?
I: Well what are you going to do?
A: Multiply fourteen times fourteen.
I: Yeah okay so I want you to try to use your picture to figure it out.
A: Hmm, okay. How can you use the picture?
I: That is a good question. So like this would be like one time, right? [Points to the seven by seven array that is filled in].
A: Mm-hmm.
I: And how many were in here [circles the 7 x 7 part of the array]?
A: Forty-nine.
I: Are there going to be any equivalent sections that are going to be this size in your picture?
A: No ish. Wait yes.
I: Okay so make another one that is going to be the same size as this.
A: Hmm, I could do...hmm. I just got this small picture in my head in some way. So since there are seven xs over here [points to the digits eight through fourteen on the x-axis of the array] and going up is seven [points to the digits one through seven on the y-axis] all this area over here is actually also going to be forty-nine[draws the box in the lower right corner].
I: Okay good.
A: And the same thing with up here [puts a square in the upper right], and also over here [puts a square in the upper left]. So there is forty-nine four times.
…
I: What were you going to multiply when I said to use the picture?
A: Oh, I was going to multiply fourteen by fourteen.
I: Okay so will you write horizontally fourteen times fourteen. And that is equal to? How many times did you have seven in fourteen?
A: Once, er, what do you mean? Oh! Twice.
I: Twice here. So can you write fourteen as seven times. Fourteen is seven times what.
A: Equals seven times two [writes 7 x 2].
I: And what about on this side.
A: Um, same thing [writes 7 x 2 x 7 x 2, and then (7 x 2) x (7 x 2) so that he has written on his paper that 14 x 14 = (7 x 2) x (7 x 2)]
I: Do you see any number squared in your picture?
A: Ah, seven squared.
I: And then do you see some other number squared in your picture?
A: The other forty nines. Those would also be seven squared [writes $7^2 + 7^2 + 7^2 + 7^2$, and now has written on his paper that $14 \times 14 = (7 \times 2) \times (7 \times 2) = 7^2 + 7^2 + 7^2 + 7^2$].
…
I: And how many seven squareds did you say you have?
A: Four.
I: So rather than adding them. What could you do?
A: Seven squared times four [writes 4×7^2 and sets it equal to what he already has on his paper].
I: The four is that any number squared?
A: Two.
I: Do you see two squared somewhere in your picture, and if so where?
A: Would it be that [points to the digits one through four on the horizontal axis]?
I: Okay so say a little bit more.
A: Like four is two squared. Oh, since, um, eh. Since this right here would be four squared, I mean two squared [circles the four coordinate points in the bottom left of his array].

Our interpretation of this excerpt is that Armando established multiple three level of unit structures in his solution of the problem: he established the fourteen digits on each side of the array as a unit of 2 units of 7 units, and each of the four regions contained in the array as a unit of 7 units of 7 pairs. We make this interpretation because of how he operated to determine that the 14 by 14 array would contain forty-nine coordinate points four times, and the way he subsequently symbolized his reasoning. He first established that there would be a second region that would contain forty-nine coordinate points by identifying that the digits eight through fourteen on the x-axis could be paired with the digits one through seven on the y-axis, which he envisioned could create another region in the array that contained forty nine coordinate points. He then envisioned two other similar 7 by 7 regions. The fact that he could establish these regions without actually having to create any of the coordinate points provided initial indication that he could take these regions as something to operate with, and so was treating the forty-nine coordinate points as a unit of 7 units of 7 pairs.

The assertion that he was operating with three level of unit structures is also supported by how he symbolized the problem: he was able to see 14 x 14 as a product of 7 x 2 and 7 x 2. In particular, once the interviewer supported him to consider that 14 was equal to 7 times 2, he independently contributed writing 14 x 14 as equal to the product of 7 x 2 and 7 x 2. This way of symbolizing the problem provides indication that after he established fourteen as containing two sevens he could envision operating further with the two sevens by taking the product of two sevens and two sevens. It is important that he considered this to be a product, and not a sum, because considering it a product was essential for him to see that the product was equivalent to $7^2 + 7^2 + 7^2 + 7^2$: each of seven digits could be paired with seven other digits to produce a region that contained 7^2 coordinate points. Our contention is that to see two sevens and two sevens as a product required maintaining 14 as a unit of 2 units of 7 units because it entailed envisioning operating further with each seven, namely each of seven digits could be paired with another seven digits to make coordinate points without actually having to carry out these operations.

An interesting feature of Armando's solution is that he did not constitute the product as 2^2 x 7^2. The interviewer attempted to find out whether he saw the product in this way at first with an indirect question: "I: Do you see any number squared in your picture? A: Ah, seven squared. I: And then do you see some other number squared in your picture? A: The other forty nines. Those would also be seven squared." The interviewer intended the second question to be about whether Armando saw 2^2 in his picture, but Armando answered that what he saw were the other regions in the array that were 7^2. The interviewer then tried to ask Armando more directly about this issue once Armando had written that the array was equal to 4 x 7^2: "I: The four is that any number squared? A: Two." Computationally Armando was able to state that two squared was four, but when asked to identify where this would be in his picture he initially marked the digits from one to four on the x-axis, and then circled the four coordinate points in the lower left corner of his array—indicating that he did not see the four 7^2 sections of the array as 2^2.

Discussion

The initial interviews in the study have helped us to identify what kind of work is challenging for MC2 and MC3 students related to NLMM and NLG, and thus the kind of problems that are likely to produce interesting generalizations for these students. For MC2 students, the data suggests that problems in which students are asked to consider how the number of coordinate points changes as the number of digits is increased by one are likely to be challenging, but solvable. We think that the potential exists for these students to consider that, for example, $8^2 = 7^2 + 7 + 7 + 1$, and $9^2 = 8^2 + 8 + 8 + 1$, to understand these symbolic statements show that the new number of coordinate points is equal to the old number of coordinate points plus the change in coordinate points where the change in coordinate points is structured as 7, 7, and 1 based on classifying them according to which position the new digit appears in the new coordinate point, and to generalize this understanding.

For MC3 students, the data suggests that problems in which they are asked to consider how multiplicatively changing the number of digits changes the number of coordinate points are likely to be challenging, but solvable. In particular, the challenge appears to lie in seeing that, for example, a 14 by 14 array can be structured as 7^2 x 2^2. We conjecture that a problem like the following may support them to establish this way of seeing an array.

Two Color Digit Problem: You have a set of cards where the numerals 1 through 7 are written in blue. You have a second set of cards where the numerals 1 through 7 are written in orange. You select a card, replace it, and select a second card. What different color combinations could you get? What coordinate points could you get in each color combination?

We make this conjecture based on the fact that the problem includes two levels of pairing—pairing colors and pairing digits within a particular color combination. We make this conjecture because pairing digits seemed integral to Armando establishing the 49 coordinate points as 7^2. We expect that from this type of problem students will be able to generalize that given n colors and x digits in each color that $(nx)^2 = n^2x^2$. We will report on the generalizations that students made in these contexts as part of the presentation.

UNDERSTANDING OF PLACE VALUE EXPLORED THROUGH NUMERICAL COMPARISON

Susana Andrade
Center for Research and Advanced Studies
sandrade@cinvestav.mx

Marta Elena Valdemoros
Center for Research and Advanced Studies
mvaldemo@cinvestav.mx

We present part of an investigation related to place value subject with first grade elementary school students (6 years old). Through this research, we look to analyze students' understanding of place value and difficulties evidenced during an experimental teaching that incorporates briefly other numerical bases and the use of manipulative material in a way that reflects the structure of our number system. For that purpose, we conducted individual interviews with students before and after experimental teaching. The results obtained in one of the tasks included in the interviews regarding numerical comparison show an improvement in understanding place value as a result of the experimental teaching.

Keywords: Number Concepts and Operations; Elementary School Education; Instructional Activities and Practices

Introduction

Place value is a fundamental mathematical idea. Several studies have demonstrated that there is a relationship between understanding place value and the arithmetic performance of students (among others, Moeller, Pixner, Zuber, Kaufmann, and Nuerk, 2011). However, it "is a highly sophisticated concept that is not really understood by many children even at the end of their primary schooling" (Thompson, 2000, p.292).

Based on the above, we are developing a research in which we approach the place value from the perspective of teaching and learning. In this article we focus on one of the objectives of this study: to describe what is the students' understanding of place value at the beginning and the end of an experimental teaching, for which we analyzed the results of one of the tasks of the interviews applied to students about numerical comparison.

Theoretical Framework

There are diverse factors associated to the difficulties of students of the place value understanding; one of them is the language. Miura, Okamoto, Kim, Steere and Fayol (1993) consider that understanding place value and mathematical performance of children may be influenced by the characteristics of their numerical language, in particular, by the level of correspondence between written and oral number system.

Another issue related to difficulties in understanding place value is the teaching itself. For example, Fuson (1990) observes that in usual teaching the multi-digit numbers are treated as linked single digits. So, "for most of the children, a number is a digit alignment" (Bednarz and Janvier, 1988, p. 300).

Considering the issues associated to difficulties presented in understanding place value, some of which we have mentioned before, several studies have proposed alternative ways for its teaching. In some of these studies, it has been taught the explicit number names (e.g., 1-ten 1, 1-ten 2, 1-ten 3 … 2-ten, Cotter, 2000). In others, it has turned to the game (e.g., Association of Independent Schools of South Australia, 2004) and to manipulative materials for teaching of the decimal number system and the place value.

Furthermore, in the teaching and learning of number system the introduction of different number bases, particularly small bases, represents diverse advantages according to Vergnaud (1991): the formation of groupings of second and third order does not represent a difficulty in comparison to the base 10 since the number of objects to handle is smaller and the number system rules are essentially the same in all bases, and so they will be built by the student regardless the number base.

Method

This study was conducted with a first grade group of twelve students (6 years old), in a public elementary school in Mexico City. In this group, we implemented an experimental teaching, consisted in 20 sessions of approximately 45 min each one, in order to benefit the understanding of decimal number system and place value.

The teaching sessions scene was an adaptation of *The Base Ten Game* presented by Pengelly (1991), consisting in throwing two dice, add the points, take the same number of wood sticks and place them on a board that contains place value columns. The game rule is that there can be no more than nine items in any column. So, once there are more than nine sticks in the unit column, ten sticks must be grouped and placed in the ten column (Association of Independent Schools of South Australia, 2004; Pengelly, 1991). The adaptation of this game consisted of a brief introduction of different number bases, as other investigators have done, by the advantages that this represents (Vergnaud, 1991).

Our main contribution to the game was the introduction of an abacus of own design with an unique peculiarity of two columns for the units order and two for the tens order (with ten beads each), to facilitate the exchange: ten for one or one for ten depending on the case; the hundreds order is limited to one column because it was expected that students understand numerals up to three digits. Furthermore, the first five beads of each column of this abacus have different color in order to facilitate the recognition of quantities (Cotter, 2000). This abacus was used by students in *The Base Ten Game*. Thus, when they had more than nine beads in the unit column, they had to trade ten (units) for one (ten).

Students who participated in this study were interviewed individually in order to explore their understanding of place value before and after the experimental teaching. In both interviews, the following tasks were presented: a) Cognitive representation of number (Miura et al, 1993), b) Digit-correspondence (Ross, 1986), c) Positional knowledge (Ross, 1986), d) Additions and subtractions and e) Numerical comparison.

Through numerical comparison, task that we focus in this report, we pretend to know if students consider the value of the digit according to its position when they compare numbers. In the initial interview, there were presented the next pair of numerals to the students on a sheet: 32 and 28, they were asked which was the biggest and why or how they knew it. This allowed us to know the strategy they used and their place value understanding. The same task was performed with the numerals 71 and 59, this time asking what was the smallest. In the final interview the following numerals 139 and 151, 198 and 231 were include, since it was expected that as a result of the experimental teaching students could transit from two-digit numerals to three-digit numerals.

Results

In the initial interviews, a third part of the students considered that 28 was bigger than 32 and more than half said that 71 was smaller than 59. In contrast, in the final interviews, almost all students (except two of them) offered correct answers when comparing the four pairs of numerals. The latter two children considered that 151 was smaller than 139, this comparison was the most difficult for children since hundreds digits were the same and they needed to pay attention to tens digits.

As mentioned before, in the interviews we also found out the reason of their answers, which allowed us to explore their understanding of place value before and after the experimental teaching.

First we approached the lack of arguments, which did not allow us to know if their answer was a random decision or what was the strategy employed.

In the initial interviews, almost half of the children did not provide any argument about why the numeral selected was the biggest in the case of 32 and 28. In the comparison of 71 and 59, a third part of the students did not offer argument about their choice of the smallest numeral. In these cases, when students were asked about why or how they knew it, some children did not respond and others simply said the word or number words associated with the numerals ("Because this is the 32 and this 28"). In contrast, in the final interviews only 2 of the 12 children interviewed gave no argument only in one of the four tasks.

The strategies used by children in the numerical comparison task, explicit through their arguments were organized according to the strategies proposed by Sinclair and Scheuer (1991): a) Ordinality-cardinality, b) Face value and c) Place value (Table 1).

a) Ordinality-cardinality. Within this category the students refer “to the number relation of the two numbers (cardinality) ... or to the position of these numbers in the counting sequence (ordinality)" according to Sinclair and Scheuer (1991, p. 208). Some of the arguments presented by the children in this category were: "Because 32 is farther away than 28"; "Because ... 71 is a lot and 59 is a little"; 3 of 24 responses corresponded to this category in the initial interview and 5 of 48 responses in the final interview.

b) Face value. Children grouped within this category generally focused only in one of the digits of numerals compared regardless of its position and all their answers were incorrect. Examples of the arguments offered by the children in this category were: "Because it has 1" (71 <59), "3 is less than 8" (28> 32), "This (151) is the smallest because this (139) has no another one" (151 <139). In initial interviews we found 8 answers within this category while in the final interviews we found only 1 answer.

Table 1: Numerical comparison strategies used by students

Strategy	32 & 28		71 & 59		139 & 151	198 & 231
	Initial	Final	Initial	Final	Final	Final
Without argument	5	0	4	0	2	0
Ordinality-cardinality	1	3	2	0	1	2
Face value	4	0	4	0	1	0
Place value	2	9	2	12	8	10

Note: Initial = Initial interview, Final = Final interview, Total students = 12.

c) Place value. In this category, there are children who considered the value of the digits according to its position in the numerical comparison. Generally, they focused in one of the positions and all their answers were correct. In this category is where we appreciate the most important changes resulting from the experimental teaching. In the initial interview, only 2 of the 12 children interviewed considered the value of the digits according to its position when they compared numbers. In contrast, in the final interview most of the children interviewed offered an argument that showed an understanding of place value (39 of 48 responses).

Some of the arguments offered for 32 and 28 (the biggest) were: "Because 30 is bigger than 20"; "... And it does not matter that this (8 of 28) is bigger but the first is larger (3 of 32) that this (2 of 28)"; “Because from 20 … it follows 30".

When comparing 71 and 59 (the smallest): "Because 5 ... ... is smaller than 7"; "Because this (71) takes 7 and this (59) takes 5”; “Because it has 1 (the child points 1 of 71) does not mean that it is smaller, this (59) although it has 9 does not mean it is big"; “And it doesn't matter that this (1 of 71) is. If only was 1 (the child covers 7 of 71 with his finger) then this (1) would be".

For 139 and 151 (the smallest), some of the arguments were: "... because it's 10, 20, 30 (139) and this (151) is 10, 20, 30, 40, 50, and they would be missing other two to be like this (151)”; "The two would be equal, wouldn´t they?, but here it changes ... because here is like they were just these (39 y 51, the child hides with her fingers the hundreds of both numerals) and this (39) is smaller".

In the last comparison, 198 and 231 (the biggest), some of the reasons given by the children were: "Because this takes 200 ... and this only takes 100". "And if these two were not here (98 of 198 and 31 of 231), who would win?” As we can see, within this category children's arguments reflect an understanding of place value, understanding that will favor their arithmetic performance as evidenced in previous studies (e.g., Moeller et al., 2011).

Conclusions

Based on the results of the numerical comparison task presented above, it is clear that the experimental teaching implemented benefit the students' understanding of place value. This research shows the benefits of implementing alternative approaches in teaching place value, including the use of manipulative materials in a way that reflects the structure of our decimal number system. It remains to analyze the rest of the tasks that were part of the interviews applied to students, which will allow us to comprehend better the development of understanding of place value and the difficulties presented by students.

We detail a learning progressions approach to early algebra research and how existing work around learning progressions and trajectories in mathematics and science education has informed our development of a four-component theoretical framework consisting of: a curricular progression of learning goals across big algebraic ideas; an instructional sequence of tasks based on objectives concerning content and algebraic thinking practices; assessments; and posited levels of sophistication in children's reasoning about algebraic concepts within big ideas of early algebra. This research balances the goals of longitudinal research on supporting students' preparedness for algebra while attending to the practical goals of establishing connections among curriculum, instruction, and student learning.

Keywords: Learning Trajectories; Curriculum; Algebra and Algebraic Thinking

Learning progressions and trajectories are currently receiving much attention in mathematics and science education, especially in advancing recommendations for standards, curriculum, assessment, and instruction (Daro, Mosher, & Corcoran, 2011). Some key issues within this domain of research include the use and meaning of terminology, methods of assessing sophistication in student thinking, and connections among curriculum, instruction, and student reasoning (Barrett & Battista, 2014; Ellis, Weber, & Lockwood, 2014). This paper addresses these issues, with particular attention to the ambiguous use of the term *learning progression*—"sometimes indicating developmental progressions, and at other times suggesting a sequence of instructional activities" (Clements & Sarama, 2014, p. 2). We take the stance that a learning progression includes both.

This research is situated within the Learning through an Early Algebra Progression (LEAP) project, which is grounded in a research agenda concerned with a fundamental question of how to prepare students in the elementary grades for success in middle grades algebra and beyond (Blanton, Stephens, Knuth, Gardiner, Isler, & Kim, 2015). The LEAP project builds on Kaput's (2008) framework for early algebra in documenting changes in students' learning of both algebraic content and algebraic thinking practices over time. Our purpose is to elaborate a theoretical framework for an *Early Algebra Learning Progression* (EALP), making progress in a program of research whose aim is to support an integrated system of curriculum, instruction, and student learning in early algebra.

Theoretical Framework

The EALP advanced in this research includes four components: (1) a curricular progression of learning goals across five big ideas and corresponding core concepts, (2) a sequence of instructional tasks based on objectives for content and algebraic thinking practices across big ideas, (3) assessments and coding schemes for analyzing student strategies, and (4) levels of sophistication in children's thinking about core concepts in early algebra. See Table 1.

Table 1: A Theoretical Framework for an Early Algebra Learning Progression (EALP)

EALP	Description and Sub-Components
Curricular Progression	The foundation from which a sequence of instruction and hypothesized paths of student thinking were built and investigated over time: • Big ideas and algebraic thinking practices (cf. Kaput, 2008) • Core concepts (Battista, 2004) or constructs (cf. Shin, Stevens, Short, and Krajcik, 2009) • Learning goals (cf. Clements & Sarama, 2004) or claims (cf. Shin et al., 2009)
Instructional Sequence	A sequence of instructional materials and tasks designed to guide activity around the Curricular Progression: • Lessons and lesson objectives • Tasks (jumpstarts, problem-solving tasks)
Assessment Items	The primary means to measure students' understanding of concepts within big ideas (cf. Battista, 2004) of early algebra. All items have multiple entry points; "anchor items" appear in multiple grades to track growth over multiple years.
Levels of Sophistication in Children's Thinking	Levels represent qualitatively distinct ways of thinking, capturing patterns in students' thinking and reasoning. For a core concept a level includes a description of a way of understanding (which could be a misconception), evidence (i.e., responses to assessment items), and an assessment item or subset of items.

This work builds on several related perspectives across "progressions" research in both mathematics and science education, elaborated next across each dimension of the framework.

Curricular Progression

The multi-year scope of the LEAP project warrants attention to a continuum of levels of specificity in content across grades and within grades and lessons. Thus we define our *curricular progression* to encompass various grain sizes (from largest to smallest): big ideas, core concepts, and learning goals (or claims). The curricular progression establishes a foundation of targeted learning goals from which instruction, assessments, and levels of student thinking are based.

Big ideas are "key ideas that underlie numerous concepts and procedures across topics" (Baroody, Cibulskis, Lai, & Li, 2004, p. 24). Drawing from early algebra the big ideas of the EALP are: (a) equivalence, expressions, equations, and inequalities (EEEI), (b) generalized arithmetic, (c) functional thinking, (d) variable, and (e) proportional reasoning. The multi-year curricular progression is organized around these content strands and the *algebraic thinking practices* of generalizing, representing, justifying, and reasoning with mathematical relationships (Blanton et al., 2015; Kaput, 2008). A *core concept* is an idea critical to understanding a big idea. For the big idea of EEEI, a core concept is "The equal sign is used to represent the equivalence of two quantities or mathematical expressions." We take a *learning goal* (Clements & Sarama, 2014) to include claims about the nature of understandings or skills (Shin et al., 2009) expected of students regarding a concept. For example, in our work a learning goal for the big idea of EEEI is to "understand the equal sign as a relational (rather than operational) symbol," evidence of which is seen through students' actions in interpreting true/false and open equations.

Instructional Sequence

The EALP *instructional sequence* is defined to include a sequence of lessons that entail lesson objectives, jumpstarts, and problem-solving tasks designed to address both concepts and algebraic thinking practices. *Lessons* are defined as guides for an instructional intervention session (typically one 60-minute class period). *Lesson objectives* are defined as statements of targeted performances; they are derived from the curricular progression's learning goals and offer a systematic framework for designing or adapting tasks and allow for the revisiting and extending of algebraic ideas across the grades. Each lesson begins with a *jumpstart* designed to engage students in revisiting and strengthening their understanding of core concepts and algebraic thinking practices addressed in previous lessons. New concepts are introduced through *problem solving tasks*, or structured opportunities for students to build and extend understandings and practices around a goal-driven assignment. As an example for EEEI, students are asked to engage in tasks adapted from research (e.g., Carpenter, Franke, and Levi, 2003) that have been successful in supporting students' relational understanding of the equal sign.

Shin and colleagues (2009) note that learning progressions do not set forth a single, linear path to understanding, but a web of interconnected constructs within a big idea. We likewise acknowledge that our instructional sequence represents one possible path for supporting the development of algebra understanding, and different productive paths certainly exist.

Assessments

Written assessments for each of grades 3-7 were designed to elicit student reasoning across the big ideas and algebraic thinking practices. Assessment items were often adapted from those that had performed well in previous research (e.g., for equivalence items see Knuth, Stephens, McNeil, & Alibali, 2006) and were piloted and revised prior to administration. The assessments include several "anchor items" that appear in multiple grades to allow us to measure growth on the same item over multiple years. Assessment items offer multiple points of entry so that students at the very beginning of the progression as well as those more experienced in early algebra can demonstrate what they know regarding algebraic content and thinking practices. For example, the *True/False* task 57 + 22 = 58 + 21is posed across grades 3-5 to elicit understandings of the equal sign and equation structure and can be solved in multiple ways.

Levels of Sophistication in Children's Thinking

The final piece of our approach to learning progressions in early algebra research concerns the documentation of changes in students' learning over time. Levels of sophistication are "benchmarks of complex growth that represent distinct ways of thinking" (Clements & Sarama, 2014, p. 14). We initially conjectured levels of sophistication in student thinking based on extant empirical research on student conceptions, misconceptions, and difficulties. We then refined these after analyzing students' responses to assessment items (i.e., student strategies)across grades to discern patterns in children's thinking. Each level of sophistication represents a level of understanding as evidenced in their responses to one or more assessment task(s).

For example, the levels of sophistication we conjectured and observed for students' developing understanding of the equal sign range from Level 1's "Student has operational view of the equal sign and inflexible view of equation structure" to Level 5's "Student has advanced relational-structural understanding of the equal sign and flexible view of equation structure and can consider relationships across equations." We view the levels of sophistication identified in our work as dependent on the learning goals and sequence of tasks that drive the intervention.

Conclusion

The large-scale nature of the LEAP project and our desire to speak to both research and practitioner audiences led to practical decisions about our theoretical frame. This included clearly stated objectives and assessment tasks that integrate algebraic thinking across several grades. We also integrate several perspectives across learning progressions and learning trajectories. Science education literature on learning progressions (e.g., Shin et al., 2009) provided an initial frame for coordinating disciplinary and research-based perspectives on student thinking. It also led to our organizing the content of our EALP according to big ideas, core concepts, and claims. In mathematics education, our EALP parallels Battista's (2004) emphasis on connections among core concepts, assessment items, and levels of sophistication. We also emphasize that the observed levels of sophistication in student strategies are inseparable from the curricular and instructional context in which the learning was supported, yet given the large scale scope of the LEAP project, these connections are not as tightly linked as in some learning trajectories research (cf. Clements & Sarama, 2004).

Our continued research on a comprehensive approach to curriculum, instruction, and student learning is important work to share with the research community towards the goal of coordinating efforts to promote effective early algebra education and identifying important milestones in students' thinking. We also feel it is important that this work be available in a practical form for teachers (e.g., lesson plans and professional development) as they engage in the day-to-day and year-to-year work of developing students' algebraic reasoning. A feasible future direction of this work is to more closely examine paths of students' thinking across grades and in turn, to posit tighter links between tasks and instructional strategies that could be productive in supporting students' engagement in more sophisticated ways of reasoning.

We illustrate conceptions of fractional quantity, evidenced through problem solving strategies and observable operations, of a fifth grade child with learning disabilities (LD) before, during, and after seven instructional sessions situated in equal sharing. The child's work documents levels of conception reflective of a trajectory. Implications for future research are discussed.

Keywords: Cognition; Rational Numbers; Learning Trajectories; Equity and Diversity

Much of the intervention literature in special education reports children's responses to strategies or representations imposed through the teacher's instruction as opposed conceptual development within children's thinking (Hiebert & Grouws, 2007). Because conceptions cannot simply be imposed onto children (Baroody, Cibulskis, Lai, & Li, 2004), a depiction of the informal notions of fractions children with learning disabilities (LD) *do* possess along with examples of how varying idiosyncratic advances in conceptions may occur is needed to conceptualize possible teaching and learning environments. Trajectories (Daro, Mosher, & Corcoran, 2011; Simon, 1995) model critical transitions in how a child conceives of a mathematical idea along a series of dynamic (i.e., changeable) tasks to elicit cognitive dissonance. Documenting trajectories of children with LD is an important initial step to address the needs of a historically marginalized population in school mathematics. Accordingly, we explored the following research question: What conceptions of fractional quantity, observable through problem solving strategies and operations does a fifth grade child with LD display before, during, and after tutoring situated in equal sharing?

Conceptual Framework

Problem solving strategies, language, and observable mental operations within equal sharing tasks provide evidence of a child's conceptions. We synthesized existing research (e.g., Empson & Levi, 2011; Steffe & Olive, 2010; Tzur, 1999) on children without LD and used it as a framework for the study. Initially, children may not view the whole as divisible. A child sharing, for instance, three sticks of clay among four people may add to the quantity to be shared (i.e., adding a fourth stick) or create unequal shares (e.g., one of the four people does not receive a share). Once the child accepts the divisible whole, they employ skip counting or knowledge of halving to create enough shares for each person. Yet, the child does not yet determine the number of parts needed to exhaust the wholes before their activity because they do not relate their partitioning plan with the number of sharers. Through their activity, the child begins to develop a notion of equality and size of the parts relative to each other but does not yet unitize one whole when they conceive of the size of the quantity they create (Steffe & Olive, 2010). The child views the unit fractions as a number of pieces whose magnitude, to the child, may or may not be equivalent to each other but not yet be different from that of the whole. The exception is the case of one-half, for which the child has strong informal notions.

As children's conceptions of fractional quantity advance, they begin to use the number of sharers as an a priori plan to create a predetermined number of parts. Their partitioning activity is no longer counting based partitioning in activity but a mentally planned relation supported by an interiorized unitization of the whole. The child now considers one whole as a quantifying unit (i.e., Part whole scheme) and knows that the parts they create must exhaust each whole. A flexible understanding of composite units (e.g., four is four units of one or one unit of four) may aid in the child's a priori partitioning plan (Olive, 2001; Steffe & Olive, 2010). A partitive unit fraction conception and use of an iterating mechanism to prove parts equal and related to the whole is surmised to underscore developing multiplicative notions. Over time, children's mental records concerning the equal sharing division becomes distributive (3 clay sticks shared by 4 people is now, to the child, "3 ÷ 4", or (1 ÷ 4) + (1 ÷ 4) + (1 ÷ 4)) and independent of modeled activity. Anticipatory strategies reflect the child's mental recall of the relationship between a value of fraction (e.g. three-fourths of a whole unit) and dividing the numerator by the denominator (e.g., 3 divided by 4).

Method

The data used in the current study focuses on the case of a fifth grader who we refer to as Stu. Stu (age = 12 years) attended elementary school in the Northwestern United States. He was purposively chosen to participate in the teaching experiment because he was identified by his school system as LD in mathematics and by his teacher as needing additional instruction in fraction concepts and operations. Stu was diagnosed as LD by subtracting his score on an academic achievement test from his standard intelligence quotient. Stu has documented, sustained low achievement in mathematics and a processing disorder documented by the school.

Teaching Experiment

Data collection was facilitated through a teaching experiment (Steffe & Thompson, 2000). We worked with Stu one-on-one in seven 40-minute tutoring sessions between mid February and late April. Sessions were held during school hours and were in addition to the child's regular mathematics class time. Researchers collected three sources of data in the teaching experiment: a) transcribed video-recordings, b) the child's written work, and c) observation field notes. The first and second researcher attended all tutoring sessions and collaborated throughout the ongoing analysis of teaching episodes. The first author was the researcher-teacher. The second author observed the interaction between the researcher-teacher to provide an outsider's prospective during on-going analysis and deter ineffective interactions from continuing.

Task trajectory. We designed an initial sequence of problem tasks and possible teaching moves (i.e., questions) based on the theoretical framework of how children with LD might advance their strategies, language, and operations. Tasks were planned to be dynamic (i.e., adaptable to the child's current conceptions), situated in equal sharing (e.g., 2 people share 5 items; 7 people share 4 items), and presented to Stu in realistic contexts that we changed according to his preference. In each task, the number of sharers ranged from two to ten and the number of objects shared ranged from three to 13. The problem solving tasks were designed so that Stu could use a variety of strategies and representations to reason about the mathematics.

Analysis

Ongoing analysis of events that appeared critical (Powell, Francisco, & Maher, 2003) for the child's thinking and learning were noted and discussed before and after each session. The focus was on generating (and documenting) initial hypotheses as to what conceptions could underlie the child's apparent problem solving strategies during these critical events. These hypotheses led to (a) planning the following teaching episode. We used retrospective analysis after all data were collected to delineate Stu's informal conceptions of fractional quantities, how his strategies and language shifted during each tutoring session, and what his conceptions were during the final session. Finally, identified possible indicators of Stu's conceptual growth using the constant comparison approach

(Leech & Onwuegbuzie, 2007). The first and second author read through the initial clinical interview and the first two tutoring sessions as a team. We coded the child's evidenced problem solving strategy by task and coded any associated apparent operations and language employed by the child within problem solving strategy by task. We compared each set of codes generated for each problem solution and task with previously generated coded data to ensure consistency. This led to the creation of an initial codebook. We then independently coded two more sessions using the initial codebook. Codes were then compared using peer debriefing and collaborative work. Researchers used the amended codebook to independently code all remaining sessions (Intercoder reliability = 95%).

Selected Results

Initial Conceptions: Level 1

In the initial clinical interview, the child had just solved a task involving 12 cookies and four people by directly modeling 12 cookies with unifix cubes, dealing out each cookie into four piles until he arrived at a solution of three cookies. The excerpt below depicts an extension of the situation to involve a 13th cookie ("I" stands for the researcher- teacher instructor, "S" for Stu, and italicized text in parentheses indicates actions or gestures).

S: There would be one left over. One remaining (smiles).

I: What if we didn't want it to remain? Suppose they wanted to eat that one, too.

S: All of them? (Long pause) OK. (Deals out 3 unifix cubes, one at a time, into four piles) So we can take this little cookie (grabs a 13th unifix cube) and this equals… four of them? (Grabs four unit cubes, stacks them, and compares the size to the Unifix cube) But oh…no no. It doesn't work like that. We need…another four?

I: Another four?

S: To make it the same size!

I: Oh, I see. That's pretty clever.

S: So we did three to this one, three to this one, three to this one, three to this one. And they want more (deals out the smaller unit cubes, one at a time, to each of the four piles until none remain). Two small pieces of cookie with two big pieces for each one. And it's called three and a half two.

In Level 1, Stu (a) creates fractions in his activity yet does so reluctantly and (c) does not yet employ a plan for creating a known number of total pieces across the wholes. Interestingly, Stu seems to use a ratio like correspondence (i.e., "trade in" the larger Unifix cube for some number of smaller unit cubes as opposed to a halving strategy, such as partitioning through repeated halving) to share the leftover cookie. Yet, Stu uses the correspondence in a manner that reflects his focus on the size of the objects versus the creation of an anticipated number of parts. He also evidences a guess and check conception rather then one supported by a planned number of parts in the whole.

Level 4 Conceptions

In later sessions, we exclusively utilized tasks that result in a non-unit fractional quantity less than one. Stu's thinking in previous tasks showed his negotiation of the total parts within one whole through his partitioning plan (as opposed to across wholes) along with his increased attention on the necessity of the parts being equal with respect to each other. Stu also quantified the equal share in terms of one whole with language and was beginning to attach this language to symbolic representations that he may have gleaned from previous school based experiences. The following excerpt shows Stu's first thinking in two tasks from the final sessions involving five sandwiches and six sharers.

S: You just start with one and break it into six (draws a rectangular shaped bar. Draws a part within a bar; looks at the size of the piece he creates. Pauses, and then creates next piece methodically. Erases; redraws the part until he is satisfied they are equal. Repeats process until he has six parts exhausting the first whole) There.
I: How many more bars will you draw?
S: Imagine there are more. From each, they would get…one, one, one, one, and one (puts a dot on the board for each "sandwich"). Six-sixths in each!
I: Ok. If I was one of the sharers, what I would get?
S: Well, if there was one sandwich you'd get one- sixth.
I: Oh ok. So we can write one-sixth over here for one sandwich?
S: Yep (writes "1/6"…process continues to "5/6").
I: OK, so how much does he get all together?
S: Five. Five parts of six.

In Level 4, Stu (a) comes into the sharing situation with a definitive plan for how each item will be shared before enacting activity, (b) seems to base his plan in sharing one item and then projects his plan across the rest of the items to be shared, and (c) verbalizes previous directly modeled thinking. Stu's increased need to create equal pieces through his correspondence-based partitioning activity seems to fall away it is not observable to us now because he is relying on verbal actions to engage in the activity.

Discussion

It is noteworthy that Stu's use of correspondence seemed to be instrumental to his ability to conceive of a number of parts within one whole prior to activity. It is possible that children with LD rely on correspondence as a mechanism to through which to build and solidify notions of unit fractions as opposed a halving mechanism. More research is needed to test this assertion. The case of Stu also provides preliminary evidence children with LD evidence similar understandings of children without disabilities as they grow in their conceptions of fractional quantity (Empson & Levi, 2011; Steffe & Olive, 2010). We hypothesize such pathways may show again in future research with more children labeled as LD and advocate for further inquiries in intervention research.

UNDERSTANDING ISSUES OF QUANTITY THROUGH COMPARISONS: MATH LEARNING DISABILITIES AND FRACTIONS

Katherine E. Lewis
University of Washington
kelewis2@uw.edu

Although many students struggle with fractions, students with math learning disabilities (MLDs) experience pervasive difficulties because of neurological differences in how they process numerical information. When comparing fractional quantities, students with MLDs make errors on the easiest fraction comparison problems and these errors persist over the years. To investigate the origin of these difficulties I conducted a detailed analysis of videotaped tutoring data with two students with an MLD. Their explanations revealed that both students relied upon atypical understandings of fractional quantities, which may help explain the unique and persistent error patterns identified in students with MLDs.

Keywords: Rational Numbers; Cognition

Many students struggle with fractions, but not all students struggle for the same reasons. For students with math learning disabilities (MLDs) their difficulties stem from a cognitive origin, specifically difficulties processing quantitative information (Butterworth, 2010). Because of these cognitive differences, students with MLDs make qualitatively different kinds of errors than their peers. For example, Mazzocco Myers, Lewis, Hanich, and Murphy (2013) determined that students with MLDs make errors on the *easiest* fraction comparison problems (i.e., comparisons of fractions with the same denominators and comparisons involving the fraction 1/2). Although these error patterns differentiate the performance of students with MLDs from their peers, it remains unclear what the origin of these error patterns are and *why* these qualitative differences emerge and persist over time.

To begin exploring what underlies these unique patterns of error, I conducted a secondary analysis of two students with MLDs. The case studies were originally conducted as part of larger study that investigated MLDs during students' attempt to learn basic fraction concepts during one-on-one videotaped tutoring sessions. This study addresses the following research questions:

Do the case study students demonstrate errors similar to those documented in Mazzocco et al., (2013), specifically difficulties comparing fractions with the same denominator and comparing fractions with 1/2?

What do the students' explanations reveal about their reasoning and how does this relate to their pattern of errors on comparison and non-comparison problems?

Theoretical Framework

In this study, I depart from the predominant deficit approach used to conceptualize MLDs (e.g., Geary, 2010) and rely upon a cognitive *difference* model proposed by Vygotsky. From this perspective, a child with a disability "is not simply a child less developed than his peers, but is a child who has developed differently" (Vygotsky 1929/1993, p. 30). Students with disabilities develop differently because sociocultural (i.e., mediational) tools that have evolved over the course of human history may be incompatible with the student's biological development. For example, for students with MLDs, standard mathematical mediational tools (e.g., numerals, drawings, manipulatives), which support the development of typically developing students, may be inaccessible due to incompatibilities with how students with MLDs cognitively process numerical information.

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

These incompatibilities may result in a student developing atypical understandings of standard mediational tools.

Methods

Data collected for this study were used for two purposes: determination of the student's MLD status and case study analysis (see Figure 1 for an overview of the design of the study). Out of the 11 students with potential MLDs who were initially recruited, only two students, "Emily" (a White 18-year-old recent high school graduate) and "Lisa" (a White, 19-year-old community college student), met all the qualifications for having an MLD. Both students demonstrated (1) persistent low mathematics achievement, (2) no social or environmental factors that could explain their low mathematics achievement, and (3) a lack of response to a tutoring protocol that had been effective for typically achieving students (see Lewis, 2014 for more details).

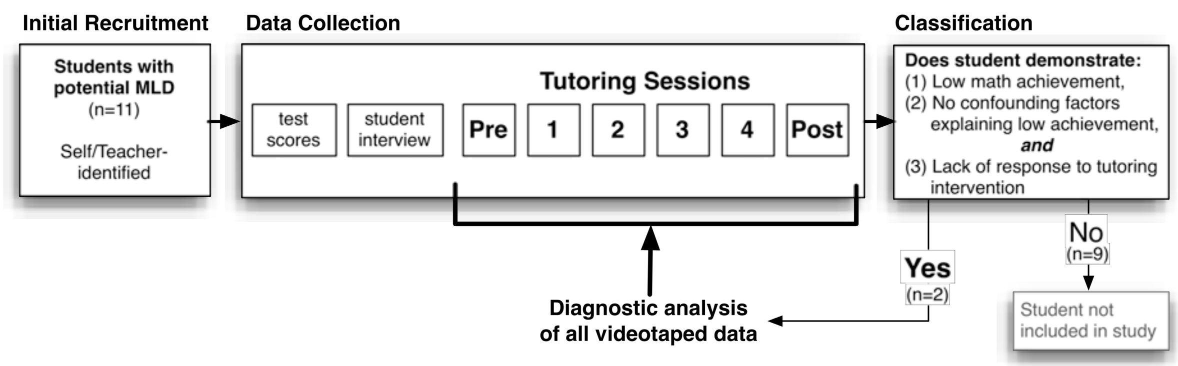

Figure 1: Schematic overview of methods used in this study

Analytic Approach

The videotaped tutoring sessions were transcribed, and parsed into individual problem instances. In addition to evaluating the errors on comparison problems throughout the tutoring sessions, a systematic grounded analysis (Glaser & Strauss, 1967) of the data was conducted, which revealed persistent atypical understandings of fractional quantity (Lewis, 2014). These atypical understandings provide insight into the nature of the errors made on comparison problems and will be discussed in the results section.

Results

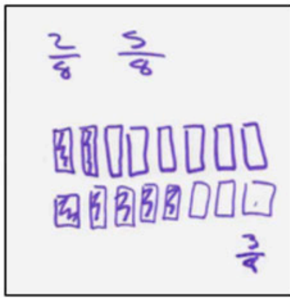
The results of this study are presented in two parts. First, the students' performance on comparison problems are considered to evaluate whether Emily and Lisa experienced the same error patterns noted in the Mazzocco et al. (2013) study. Second, exemplar excerpts are presented for each kind of problem to highlight the ways in which the students incorrectly reasoned about (1) comparisons of fractions with the same denominators and (2) comparisons involving the fraction one-half. For each of these problem types, I consider how these kinds of atypical understanding were supported by the systematic analysis of the data.

Error Analysis

An evaluation of comparison problems was used to establish that Emily and Lisa demonstrated a similar pattern of errors to those documented in the Mazzocco et al., 2013 study. Emily answered 63% of all same denominator problems incorrectly and 37% of all problems involving 1/2 incorrectly. Similarly, Lisa answered 14% of comparison problems with the same denominator incorrectly and 76% of problems involving 1/2 incorrectly. At the time of the post-test both students answered same denominator comparison problems and one-half comparison problems incorrectly. Given the high percentage of errors made on these problems and the continued evidence of errors during the posttest, Emily and Lisa's performance was judged to be consistent with the findings of the Mazzocco et al. (2013) study. To understand why the students answered these questions incorrectly I consider the student's solution process and explanation when solving comparison problems. The examples presented highlight the atypical understandings that the students relied upon when reasoning about fractional quantities both during comparison and non-comparison problems.

Same Denominator Comparison Problems

During the pretest Emily was asked to compare the fractions 2/8 and 5/8. To solve the problem she correctly drew a representation of both fractions. However, once she drew these two representations, she began interpreting 5/8 as 3/8 and attending to the *non-shaded* pieces (relevant transcript bolded in Figure 2).



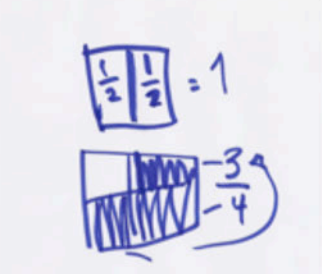
Tutor: What if we had the problem, two-eighths and five-eighths, which one would be bigger there?
Emily: *(writes 2/8 and 5/8. Draws 8 rectangles, shades in two. Draws 8 rectangles, shades in 5)* So, this is... *(points to the 5 shaded pieces in drawing of 5/8. Points to the* ***3 non-shaded*** *pieces of drawing of 5/8)* Um. *(writes* ***3/8.*** *Points to the* ***6 non-shaded*** *pieces in the drawing of 2/8.)* I don't know.

Figure 2: Scanned artifact of Emily's solution to the comparison of 2/8 and 5/8

Although Emily correctly represented both fractions, these drawings did not support her comparison of the fractional amounts. Once drawn, Emily shifted from attending to the 5 shaded pieces to attending to the 3 non-shaded pieces for 5/8 and interpreted her drawn representation as 3/8 – the fractional complement. In addition, Emily also attended to the six non-shaded pieces of 2/8 by pointing to each of the pieces in turn, before determining she did not know how to answer the question. What this excerpt reveals is not that Emily had difficulty comparing 2/8 and 5/8, but that when presented with the fraction 2/8 and 5/8, she was unsure whether she should be comparing the shaded pieces (representing the fractional quantity) or the non-shaded pieces (representing the fractional complement). As in the above example, the tendency to attend to the *fractional complement* was evident in both Emily's and Lisa's sessions in comparison and *non*-comparison problems. The students' attention to the fractional complement provides a potential explanation for why both students would make errors on fraction comparison problems involving the same denominator.

One-Half Comparison Problems

During the first tutoring session Lisa was asked to compare the fractions 1/2 and 3/4. She incorrectly determined that 1/2 was larger than 3/4, and justified her answer by explaining that 1/2 had larger pieces than 3/4 (see Figure 3).



Tutor: So if we were comparing three-fourths and one-half. Which one of those is going to be bigger?
Lisa: The half.
Tutor: Ok, and how do you know?
Lisa: Because it's larger, because it's closer to a whole. You have to split this (pointing to 3/4) up four ways to create a whole. Whereas the half only needs to get split into two.

Figure 3: Transcript and written work for Lisa's solution to the comparison of 1/2 and 3/4

Lisa justified her determination that 1/2 was larger than 3/4, focusing exclusively on the number of partitions. As in this example, the fraction 1/2 was not understood as a quantity but as the splitting into two pieces (i.e., "halving"). Both Lisa and Emily understood the fraction 1/2 as the act of splitting something in two, rather than the quantity 1/2. This "halving" understanding was evident at the time of the posttest for both students. The persistence of the halving understanding for both Emily and Lisa suggests why these students would make errors on fraction comparison problems involving the fraction 1/2.

Conclusion

Emily and Lisa experienced unusual difficulties comparing fractions with the same denominators and comparing fractions to 1/2, which were consistent with the errors documented in Mazzocco et al. (2013). The students' explanations revealed that they understood standard representations of fractions in atypical ways. These patterns of reasoning persisted throughout the tutoring sessions and were problematic for non-comparison problems as well. As in Emily and Lisa's cases, it may be an atypical understanding of fractional quantity may underlie the fraction comparisons errors documented in students with MLDs. Therefore, investigations of students' atypical understandings of quantity may be a productive avenue to consider in future studies of MLDs.

FLIPPING NUMBERS AND TURNING ARRAYS: STUDENTS' JUSTIFICATIONS AND CONCEPTIONS OF THE COMMUTATIVE PROPERTY OF MULTIPLICATION

Sarah Lord
University of Wisconsin - Madison
salord@wisc.edu

This interview study explores how 19 students from grades 4 through 12 attempt to justify the commutative property of multiplication (CPM). Harel and Sowder's (1998) taxonomy of proof schemes is used as a general framework for interpreting students' justifications. Students showed evidence of symbolic, authoritative, empirical, quasi-transformational, and transformational proof schemes. An important relationship was noted between students' ability to articulate why it makes sense to multiply to enumerate the number of objects in an array, and the production of a transformational justification of the commutative property. Two types of conceptions of the commutative property emerged from students' justifications: syntactic and structural conceptions.

Keywords: Number Concepts and Operations; Reasoning and Proof

Introduction

According to the Common Core State Standards for Mathematics (CCSS-M), beginning in the third grade students should "understand the properties of multiplication" including the commutative property (National Governors Association Center for Best Practices and Council of Chief State School Officers, 2010, p. 23). It is relatively simple to describe the commutative property of multiplication (CPM): $a \times b = b \times a$. It is less clear, however, what it means to "understand" it. The CCSS-M, in fact, do not specify what it means to understand the commutative property, nor how that understanding is to be attained, though the writers note that "one hallmark of mathematical understanding is the ability to justify, in a way appropriate to the student's mathematical maturity *why* a particular mathematical statement is true or where a mathematical rule comes from" (p. 4). The purpose of this study, then, is to explore how students justify the commutative property of multiplication. Identifying the ways in which students justify the commutative property can contribute to our knowledge of how children use and understand multiplication.

This study draws from research into several aspects of children's understanding of multiplication, including the classification and relative difficulty of different problem types (Carpenter, Fennema, Franke, Levi, & Empson, 1999; Vergnaud, 1983), the strategies children use to solve multiplication problems (Ambrose, Baek, & Carpenter, 2003; Carpenter et al., 1999), and the schemes of action and operation that underlie children's strategies (Confrey, 1994; Steffe & Cobb, 1998; Steffe, 1988, 1994).

Several previous studies specifically investigated children's use and understanding of the CPM. Two studies found that populations who do not study multiplication in school (e.g., indigenous groups in Africa and Brazilian street sellers) are unlikely to apply the CPM, while those who do study multiplication in school routinely apply it (Petitto & Ginsburg, 1982; Schliemann, Araujo, Cassundé, Macedo, & Nicéas, 1998). Various studies found that young children generally do not apply the CPM when solving contextual problems in which the multiplier and multiplicand are clearly defined, though they may apply it to number-only problems (Ambrose et al., 2003; Baek, 2007; Carpenter et al., 1999; Nunes & Bryant, 1995; Vergnaud, 1983). Some authors suggest that children may find it more intuitive to apply the CPM to problems involving an array context (Ambrose et al., 2003; Carpenter et al., 1999; Nunes & Bryant, 1995). Battista and colleagues, however, caution that children do not initially see arrays as multiplicative structures; this is something they must construct over time (Battista, Clements, Arnoff, Battista, & Van Auken Borrow,

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

1998). Finally, two studies describe some of the justifications of the CPM produced by children in grades 3 and 6. Children justified the property by citing a rule, generating examples, and using array-based justifications (Bastable & Schifter, 2008; Valentine, Carpenter, & Pligge, 2005).

Method

Nineteen students spanning grades 4 through 12 from a rural public school district were interviewed in order to learn more about how students justify the CPM. The interviews were semi-structured, (Bernard, 1988). During the first two segments of the interview, students solved a range of contextual and number-only multiplication problems and described their strategies. Contextual problems were of two main types: (a) problems in which the multiplier and multiplicand were clearly defined, and (b) problems involving rectangular arrays and area. Number-only problems varied in difficulty, but all were intended to be solvable mentally. During the final segment of the interview, students were asked to justify the CPM in reference to the times they used the property while solving problems from earlier interview segments. The interviews were video recorded and students' written work was collected. The videos were transcribed, and transcripts were analyzed to identify how students justified the CPM. Harel and Sowder's (1998) taxonomy of proof schemes was used as an initial framework for categorizing students' justifications of the CPM. A process of open coding was used to identify subcategories, although this process was also informed by the research literature (e.g., Bastable & Schifter, 2008; Nunes & Bryant, 1995; Valentine et al., 2005).

Results

Students articulated numerous justifications of the CPM that can be broadly categorized as authoritarian, symbolic, and empirical using Harel and Sowder's (1998) taxonomy of proof schemes. Students' most interesting attempts to justify the commutative property, though, are—or come close to being—examples of what Harel and Sowder (1998) call transformational proof schemes. Transformational proof schemes are characterized by goal-oriented operations on objects and anticipations of the operations' results. These schemes are also characterized by considerations of generality. Some of the justifications for the CPM were classified as "quasi-transformational" because they (a) involve reasoning that goes beyond external and empirical proof schemes, and (b) share some of the characteristics of transformational proof schemes, such as transformations of mental objects, and considerations of generality; yet, they fall short of demonstrating the logical necessity of the CPM. The quasi-transformational and transformational justifications are the most interesting because they reveal the most about how children's conceptions of multiplication and commutativity.

Quasi-transformational justifications included (a) a balancing conception (e.g., 5 groups of 7 is the same as 7 groups of 5 because with 5 groups, there are fewer groups and more in a group, while with 7 groups, there are more groups, but fewer in each group); (b) a justification based on equivalent partial products (e.g., $8\times13=13\times8$ because both are 80+24); and (c) a partition model (e.g., $9\times6=6\times9$ because 54 can be partitioned into 6 segments of 9, or into 9 segments of 6). Transformational justifications included array-based justifications and justifications based on a rectangular area model. A significant relationship was noted between students' ability to articulate why it makes sense to multiply to enumerate the number of objects in an array, and the production of an array-based justification of the CPM. If students were not able to see the rows and columns of the array as iterable, composite units, they were not able to articulate how an array could represent both $a\times b$ and $b\times a$.

Discussion

Based on students' justifications of the CPM, there appear to be two types of conceptions of the CPM reflected in students' uses and justifications of the CPM: *syntactic* and *structural*. Students holding a syntactic conception of the CPM offered authoritarian and empirical justifications of the CPM. For these students, the property is a rule dictating how the symbols in an expression can be manipulated while still maintaining equivalence. There are two parts to the syntax: you can switch the order of the factors, and you get the same answer either way. This conception can sound like just restating the CPM in students' own words. But for some students, it is an explanation as well. This may be a symptom of the students' beliefs about the nature of mathematics. They may see mathematics simply as a collection of rules to be followed, which tell them what they can and cannot do when manipulating mathematical objects.

Structural conceptions of the CPM draw on mental imagery connected to students' conceptions of multiplication. Additionally, structural conceptions of the property incorporate the "logical necessity" (Simon, 2011) of the numerical equivalence of the two products. Students who produced array-based justifications of the commutative property clearly hold a structural conception of the property. Justifications based on an area model are also evidence of a structural understanding of the property, provided that the relationship between multiplication and area is well understood. Though no students in this study articulated a rearrangement justification of the property, this would be another example of a structural conception of the property, based in this case on equal groups imagery. Ethan (6), who used a partition model to justify the commutative property, seems to have a somewhat structural conception of the property. His justification draws on imagery connected to his conception of multiplication, but does not include the logical necessity that two products are equivalent. Justifications based on a balancing idea, though not entirely structural because of their qualitative nature, may be initial steps toward a structural understanding of the property, as they are based on equal groups imagery. With appropriate experiences, students who produced a balancing justification of the commutative property might be able to construct a rearrangement conception of the property.

A COGNITIVE SCHEME THAT EMERGED FROM AN ALGEBRA CLASSROOM TEACHING EXPERIMENT

Diana L. Moss
Appalachian State University
mossdl@appstate.edu

Teruni Lamberg
University of Nevada, Reno
terunil@unr.edu

This study investigated the realized learning trajectory that emerged as sixth-grade students participated in an algebra whole class teaching experiment. A learning trajectory evolved based on the students' changing interpretations of a variable. Cognitive schemes emerged as students' understanding of expressions and equations became more sophisticated. The first phase of the learning trajectory that transpired is explored. This phase, involving a Variable-as-Label Scheme, is described. Specifically, students' initial misconception of a variable is discussed, including conditions, the focus of the classroom activity, forms of reasoning, key mechanisms that shifted student thinking, and type of thinking.

Keywords: Algebra and Algebraic Thinking; Design Experiments; Learning Trajectories

Theoretical Framework

A hypothetical learning trajectory (HLT) (Simon, 1995) is a model of student learning that consists of the goal for students' learning, the tasks that will be used to promote students' learning, and hypotheses about the process of this learning. Reconceptualizing a mathematics concept to lead to student learning and understanding is challenging (Simon & Tzur, 2004). For instance, development of an HLT requires the teacher to have a solid understanding of the mathematics content and the current knowledge of the students in order to make hypotheses about the process of student learning and to select learning tasks based on these hypotheses.

An HLT must be developed, tested, and refined to produce a realized learning trajectory (RLT) (Lamberg & Middleton, 2009). The RLT results from the HLT and shows the actual learning/thinking that took place in the classroom as the lessons were implemented. The RLT explains what happened, in other words, describes the sense making that took place. In addition, it documents "why and how" it happened. Once an RLT is established, it can then become the HLT and be retested and redeveloped to find a new and improved RLT.

The actual path that students take might differ from the HLT and can be described by schemes used to designate students' cognitive structures (Norton & McCloskey, 2008; Steffe, 2004; Steffe, Cobb, & von Glasersfeld, 1988). These schemes are constructed to explain and document *mechanisms* for supporting shifts in student thinking (Lamberg & Middleton, 2009). This paper reports on the first phase of the RLT that emerged.

Learning Algebra

Research on algebra shows that students have difficulty interpreting letters as variables and studies have focused on how students learn to represent values using variables (Knuth, Alibali, McNeil, Weinberg, & Stephens, 2005; NRC, 2001). Students learning algebra must move from arithmetic problems to symbolic representations of relationships with variables (Moseley & Brenner, 2009), requiring students to adapt their prior knowledge to new experiences. This requires the integration of symbols used in arithmetic (e.g., +, -, x, •, ÷, and =) to be used in the transition to algebra with variable expressions. Once students learn to work with variables without thinking about the numbers that the variable might represent, they have achieved manipulation of "opaque formalisms" (Kaput, 1995, p. 8).

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

Variables can represent different situations and therefore can be interpreted by students in different ways. For example, a variable can be interpreted as a *changing quantity* such as varying prices of a specific item in different stores. Or, it can be interpreted as an *exact value* such as the price of a specific item in one store. With experience, it becomes clear to algebra learners that these two interpretations are actually representing the standard definition of a variable as an unknown quantity that can change; however, we found that this is not initially the case. Clearly, learning the meaning behind symbols and variables is essential for students to become proficient in algebra. Kaput (1995) found that many students view algebra as "little more than many different types of rules about how to write and rewrite strings of letters and numerals, rules that must be remembered for the next quiz or test" (p. 4). Thus, students must find meaning in algebra not only to understand why they are solving algebraic equations, but also to understand what situations these equations represent. Therefore, further research on how to support student learning in terms of using variables in algebra is needed. We investigated how students respond to algebra tasks and the cognitive schemes that emerged as part of a whole class teaching experiment (Lamberg & Middleton, 2009). The purpose in using a design research approach was to understand the means of supporting and organizing student learning of algebra through tasks presented in a teaching experiment. In this paper, we describe one cognitive scheme that emerged as part of an RLT as students solved problems involving adding different types of quantities.

Methods

Students from a sixth-grade classroom in an urban elementary school in a western state participated in the study. The sample included a total of 22 predominately Latino(a) students, ages 11 to 12. There were 11 female students and 11 male students. The majority of the students were from lower to middle socioeconomic backgrounds. A whole class teaching experiment using design research (Lamberg & Middleton, 2009) was conducted (Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003). The framework of design research allows researchers to observe as well as intervene throughout the study process. It involves engineering learning environments, systematically studying what takes place, and making adjustments to the curriculum (Cobb et al., 2003; Collins, Joseph, & Bielaczyc, 2004; Kelly, 2003). Design researchers develop theories about the learning process, as well as techniques designed to support learning (Cobb, et al., 2003). We used a variety of data sources in order to analyze this teaching experiment using design research. Any source that related to the broader phenomena being studied in the experiment was collected (Cobb et al., 2003). Multiple sources of data allowed for retrospective analysis once the study was complete, as well as iterative analysis throughout the study. Data sources included field notes (Maxwell, 2005), video recordings, and documentation of anything that occurred in the classroom such as students' work and researchers' reflections. We had regular and ongoing discussions with the teacher about the in-class interventions and interpretations of the data. These discussions were important because they enhanced the quality of the study and research process. Data collection and analysis was a parallel process with prospective analysis occurring throughout the teaching experiment and retrospective analysis occurring after the teaching experiment.

Results

The whole class realized learning trajectory emerged around schemes documenting the meaning of a variable in various contexts of expressions, equations, and functions. Within this sequence of three phases, students' mathematical thinking revealed five schemes: *Variable-as- Label, Variable-as-Changing Quantity, Variable-as-Known value, Variable-as-Unknown value, and Independent and Dependent variable.* This paper presents the first scheme in this learning trajectory: *Variable-as-Label.*

Variable-as-Label Scheme

Students developed a *Variable-as-Label* scheme when they encountered a problem where they had to keep a record of adding multiple quantities. This scheme progressed as students encountered two different units and represented the problem context as an expression. Students were exploring the context scenario of going to soccer game. The class concluded that each family was unique and a different combination of people from each family would go to the game. The teacher asked students to figure out how many boys and girls would go to the game so that they could determine how many colored t-shirts to order.

Students reasoned that a variable *B* represented boys and therefore, the *B* was a shortened form of writing the word "boys". Similarly *G* was a shortened form for writing the word "girls". Therefore, students reasoned about variables as representing a label for a category. This reasoning became further evident when they began using variables to label a category and not the quantity. Specifically, students were asked to find the total of two groups, boys and girls, by writing an algebraic expression or equation. For example, a student labeled the category of boys with *B* and the category of girls with *G.* A variable was used as a label for the specific category of boys and a different variable was used as a label for the specific category of girls.

In the next case, students used a variable as a label to keep track of their counting. Students in a small group were given M&Ms and were asked to figure out the total red M&Ms given to their small group. Students recorded each person's amount in the expression and were asked to write an equation that represented the total M&Ms. The purpose in doing this activity was to have students combine like terms. Students added the quantities together and indicated the total. When students added, they were indicating the total M&Ms and using the variable as a label for the color of M&M. Students added the quantities independently and then indicated a total. At this point, they were treating the variable *r* as a label for a category of "red M&M" and the 16 represented the total. They were not thinking about the variable *r* as representing *one* and, thus, were thinking additively as opposed to multiplicatively ($7r$ did not mean $7 \cdot r$). The misconception of variables in the previous examples is to label colors or certain shapes as opposed to quantities. For instance, $7r$ means "7 red" in which the variable *r* labels the color *red*. In the second case, the variable *T* is labeling the word "total" – $68T$ is 68 Total. In another activity, students recorded that a soccer ball has 20 hexagons, and wrote an *h* to label and replace the word *hexagon*.

The teacher challenged the children to think about the meaning of the numbers. For instance, $1h$ represents 1 hexagon and $20h$ represents 20 hexagons. When the students added the number of hexagons, they were thinking additively. In other words "16 plus 4 equals 20". At this point, they were combining like terms by adding quantities together. However, they were not thinking multiplicatively until the teacher challenged them to think about what 20 hexagons represents – that there are 20 times the amount of hexagons. These examples demonstrate that students were thinking both additively by finding a total, and also multiplicatively because they were beginning to grasp the concept of $20h$ as $20 \cdot h$ where *h* is one hexagon. The variable represented a label to refer to the hexagon.

Discussion

Students' initial understanding of variable was a letter that labeled a specific category. However, their thinking evolved to thinking about a variable as representing a single quantity and thinking of a coefficient as multiple units of that item, such as $5r$ represented five red M&Ms. Their thinking also shifted to thinking multiplicatively where the *5* represented five times as many M&Ms. The scheme of Variable-as-Label emerged as students abbreviated the name of a group with the first letter of the word or used a letter to represent one object or one group. This scheme developed out of a need to keep track of objects that represent a unit when counting.

Prior research identifies the importance of learning about the different meaning of variables (Kaput, 1995; Blanton, 2008; Carpenter, Franke, & Levi, 2003). However, the schemes in which students acquire different meanings and misconceptions for variables and the relationship between these schemes are not adequately addressed. This research provides a starting point for teachers and researchers to develop learning trajectories to promote student learning, keeping in mind that developing problem types and carefully sequencing them based on variables should be considered to support student learning of expressions and equations.

UNDERSTANDING STUDENTS' CHALLENGES WITH INTEGER ADDITION AND SUBTRACTION THROUGH ANALYSIS OF REPRESENTATIONS

Christy Pettis
University of Minnesota
cpettis@umn.edu

Aran W. Glancy
University of Minnesota
aran@umn.edu

This study investigates middle school students understanding of integer operations through basic computation problems and in their ability to generate story problems for certain number sentences. Consistent with other research, this study finds that students struggle more with certain types of subtraction problems than with others. Additionally, this study finds students conceptions of integers may make certain problem types more difficult to navigate. Student reasoning is compared to the typical classroom presentation of integer operations. Implications for instruction on integer operations are made.

Keywords: Middle School Education; Number Concepts and Operations

Student difficulties solving problems involving addition and subtraction of positive and negative values are well known to mathematics teachers and mathematics education researchers. Many studies have explored whether and how concrete models and/or real world contexts may be helpful in building student understanding about integers and integer operations (Ball, 1993; Stephan & Akyuz, 2012). Helpful models include using different colored chips, and number lines (Hayes & Stacey, 1998; Stephan & Akyuz, 2012; Tillema, 2012). Helpful contexts have included assets and debts, elevators going above and below ground, and stories about temperature changes, among others (Ball, 1993; Hayes & Stacey, 1998; Stephan & Akyuz, 2012). These studies show that while these models and contexts support student reasoning about integer operations, students consistently find subtraction more difficult than addition, even after instruction (Ball, 1993; Hayes & Stacey, 1998; Stephan & Akyuz, 2012). Recent work focusing on the ways students reason about integer addition and subtraction has found that integer addition is not uniformly easier than integer subtraction, but rather that performance varies by problem type and prior knowledge (Bishop et al., 2014; Bofferding, 2014; Whitacre et al., 2012).

In partnership with three sixth grade teachers, we have worked over three years to develop, test, and refine an instructional sequence meant to support students' informal reasoning about integer addition and subtraction. As part of this work, we observed that while integer addition and some integer subtraction problems are fairly easy for students, other subtraction problems remain challenging even after instruction. Thus we sought to examine both performance and reasoning strategies when students were asked to provide a context for a given subtraction problem in order to improve the instructional sequence. The research questions guiding this study were: (1) Are there patterns of errors within simple integer computation problems?; (2) In what ways do students represent integers and subtraction?; and (3) How does student choice of representation of number and operation relate to success in computation?

Theoretical Framework

The ability to represent mathematical concepts in a variety of representations along with the ability to translate between those representations plays an important role in the development of mathematical understanding (NCTM, 2000). With that in mind, this study uses the Lesh Translation Model (Lesh & Doerr, 2003) as a framework for representational fluency. According to this model, conceptual understanding is marked by an ability to translate between and within modes of representation, and asking students to represent concepts in multiple ways and to translate between

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

those representations promotes conceptual understanding. For example, asking students to translate an equation (a symbolic representation) to a story problem (a real world representation) can both promote and reveal their understanding.

A key feature of the Lesh Translation Model is that the different representational forms are but one component to building student understanding. Students must also be able to make connections between the different representations and understand how the different representations each embody the deeper mathematical concept being taught. When students fail to see the connections between the different representations, they also fail to comprehend the deeper mathematical concept embodied by this connection (Cramer, 2003). Thus, when employing multiple representations for the purpose of deepening student understanding, we should intentionally incorporate opportunities for students to translate within and between the representational forms. This was emphasized in this study by asking students to model an equation with chips or to write a story that would match an equation, thus providing them with opportunities to translate between modes of representation.

Method

This study was conducted during the 2012-2013 and 2013-2014 school years with the approximately 300 sixth grade students at a suburban, Midwestern middle school where 24% of students are on free or reduced lunch. This study is part of a larger project that is following a design-based research approach (Clements, 2007), with the ultimate goal of designing an instructional sequence that develops and supports student conceptual understanding of integer addition and subtraction appropriate for use with middle school students. Based on site restrictions, the unit was very short in duration, typically about one week in length, and included introducing the concepts of negative integers and integer addition and subtraction.

This study took place during the third iteration of the design-based research cycle and included a game called *Floats and Anchors* that had shown promise in supporting student reasoning about integer addition and subtraction. In the game, students model integer addition and subtraction by moving a ship up and down a vertical number line (i.e. above or below sea level) by adding or removing floats or anchors from the ship. This iteration of the study was designed to investigate the particular features of integer addition and subtraction problems that students found most challenging so that the game and follow-up activities could be redesigned to better support student reasoning for the most difficult problem types.

In addition to playing the Floats and Anchors game, instruction in the classes included moving forward and backwards along a number line, real-world contexts including money and good/bad guys, and mnemonic devices for remembering rules. The researchers made recommendations for and against some of these models, but the classroom teachers ultimately made the final decisions on instruction. All three teachers introduced a variety of models, but classroom observations conducted by the researchers at the time of the intervention indicated that one teacher placed comparatively more emphasis on mnemonic devices than the others while another placed more emphasis on the number line model. The unit, including the intervention, lasted between five and six class periods for all teachers.

Study Design

In this study, a concurrent explanatory mixed methods design was used to explore the relationship between student understanding of number and operations and student performance on various forms of integer addition and subtraction problems both before and after instruction. This design involved collecting and analyzing both quantitative and qualitative data then using the qualitative data to explain the quantitative results

In the quantitative component of the study, pre- and post-test data were collected to assess student performance on nine different forms of integer addition and subtraction problems to measure students' basic computational abilities with integers. The pretest was administered prior to any instruction and the post-test was given the class period immediately following the completion of the unit. Time between tests was approximately one week.

Pre- and post-test items were matched across the two tests, with numbers differing but the structure of the problem remaining the same across time. All problems involved only integers between $^{-}9$ and 9, excluding 0. Twelve different categories of problem types were created based upon the possible combinations of the sign of the subtrahend, minuend, and answer (+ or -) and the operation (addition or subtraction). Magnitude of the numbers was not considered except as necessary to generate an answer of an appropriate sign, i.e. $^{-}3 – 5$ and $^{-}5 – 3$ were considered the same problem type while $^{-}3 – ^{-}5$ and $^{-}5 – ^{-}3$ were not because of the differing sign of the answer. Of the twelve possible problem types, three were not included, specifically (+) + (+) = (+), (+) + -) = (+), and (+) - (+) = (+). The problem types not tested were excluded because nearly all students in a pilot study answered these problems correctly on both the pre- and post-test.

For the qualitative component of the study, students were asked to translate an open number sentence of the form (+) – (-) = (+) into a story problem at two different times during the unit. This problem type was chosen in part because it was a subtraction problem type that was most difficult for students on the pretest. The student generated stories were coded to determine the way they represented both positive and negative numbers and the operation of subtraction. In particular, we were interested in the ways students tried to make connections between real world contexts and symbolic representations.

Results and Discussion

Similar to previous work, integer subtraction was more difficult for students than addition. However, when we looked at student responses based upon the type of subtraction problem, we found that students performed only slightly worse on subtraction problems positive minuend and subtrahend (e.g. 3 - 5) than they did on the addition problems. Prior to instruction, students performed far worse on subtraction problems with a negative subtrahend or in which the signs differed between the subtrahend and minuend. Of these, problems like 3 - (-5) were the most difficult on the pretest, with fewer than 5% of students answering these problems correctly, while after instruction, student performance on this problem type improved to nearly the same success rate as addition problems. However, most of the other subtraction problems remained very difficult for students even after instruction. For example, problems like 5 – -2 = 7, -3 – (-5)=2 and (-3) – 5 = -8 had a very low success rate on both the pre- and post-test.

One result from the quantitative component of this study is that integer subtraction is not uniformly difficult for students but rather varies in difficulty depending on other features of the problem. This validates other research that has suggested that the sign and magnitude of the subtrahend and minuend both influence student success in solving such problems (Bofferding, 2014). Moreover, the students showed no or very little gain in their ability to solve these most difficult problem types even after instruction. Only problems such as 3 - (-5) showed considerable improvement, suggesting that the instructional sequence as implemented was not doing enough to support student reasoning about these difficult problems. Additionally, students were highly successful on addition problems of any type before and after instruction.

Qualitative analysis of the stories students generated for the open number sentences showed that nearly all the students modeled subtraction as take-away and used contexts that involved either discrete objects or money on both the pre- and post-tests. Students who used money as a context typically referred to "dollar bills." For both dollar bills and discrete objects, negative numbers were typically represented as those dollars/object being "borrowed" or "owed." Such representations were supportive for reasoning about subtraction problems involving a positive minuend and subtrahend but negative difference (e.g. 3-5), but were not supportive for cases involving a negative subtrahend (e.g. 3 - (-5)). Students who tried to create stories that involved taking-away owed objects were unilaterally unsuccessful in creating meaningful stories.

Together, these results suggest that instructional sequences must include explicit opportunities for students to learn how to model subtraction involving both positive and negative quantities. Instruction that works with discrete models and subtraction as take-away will connect with students' prior knowledge, but attention must be paid to helping students understand the need to use contexts that involve opposites (such as floats and anchors or credits and debts) as they are unlikely to note the importance of this on their own. Finally, a significant portion of instructional time should be spent developing students' understanding of integer subtraction when the subtrahend and/or minuend are negative, while relatively less time needs to be spent developing integer addition concepts.

STUDENT SUCCESS AND STRATEGY USE ON MISSING-VALUE PROPORTION PROBLEMS WITH DIFFERENT NUMBER STRUCTURES

Suzanne M. Riehl
University of Northern Iowa
riehl@uni.edu

Olof B. Steinthorsdottir
University of Northern Iowa
olly.steintho@uni.edu

As students develop proportional reasoning, they employ a variety of solution strategies with problems of different complexity. The solution strategy they choose gives insight to their thinking. In this report, we vary three characteristics of the number structure of missing-value proportion problems and compare both the success rate and types of strategies employed by middle school students. Findings indicate student thinking is more influenced by the character of the scale factor than the unit rate. Also, a hierarchy of difficulty in problem types is suggested.

Keywords: Rational Numbers; Middle School Education

Purpose of the Study

In school settings, the common way to develop students' proportional reasoning is to engage them in solving proportion-related problems. Since these problems are an important part of the curriculum, we need to understand how grappling with them advances the development of proportional reasoning. In our research, we focus on missing-value proportion problems and vary number structure characteristics. We seek to identify milestones of understanding, that is, essential understandings students require to reason through increasingly more difficult problems. Which variations in number structure provoke changes in students' success rate and strategy use? Which aspects of proportional reasoning are required for students to solve subsequent problems? This report is based on a preliminary analysis of eight problems in which three number structure characteristics vary. We compare student success rates and strategy use to establish a hierarchy of problem difficulty and aim to identify number structure characteristics that are most influential on student thinking.

Theoretical Framework and Methods

Our research is based on the idea there is a sequence of recognizable developmental stages achieved by students as their proportional reasoning matures. We use a learning progression for missing-value proportion problems proposed by Carpenter et al. (1999) and refined by Steinthorsdottir and Sriraman (2009) as our starting point. Associated with this learning progression is an implied hierarchy of problems. Students who have attained a particular developmental stage are predicted to be able to solve certain problems, but fail on problems that require more advanced reasoning. A premise of our investigation is we can infer the developmental stage of a student based on his/her work on a set of problems. Research, such as that involving cognitively guided instruction, has used this approach (Carpenter, Fennema, Franke, Levi, & Empson, 1999). In this study, instead of following individual students over several years, we are investigating the written work of many students of different ages for patterns of success and strategy use on a range of problems. As problems increase in difficulty, we expect to see both lower rates of success as well as decreased use of efficient strategies. We aim to identify what additional knowledge students employ at different levels of problem difficulty.

Prior research indicates many task features affect students' ability to solve missing-value proportion problems. Key among these are semantic type and number structure (Heller, Post, Behr & Lesh, 1990; Lamon, 1993; Tourniaire & Pulos, 1985; Vergnaud, 1983), though many others have been identified (Harel& Behr, 1989). We designed our instrument paying most attention to features related to number structure since a comparison of the impact of semantic type and the presence or absence of integer ratios indicated students were more influenced by the number structures of problems (Steinthorsdottir, 2006). We considered tasks in which the within measure space ratio was either an integer or non-integer, the between measure space ratio was either an integer or non-integer, and the given proportion was either to be enlarged or decreased in the target. The term *within measure space ratio* refers to the ratio of the given quantities with identical units; it is the scale factor needed to transform the given into the target quantity. *Between measure space ratio* refers to the ratio between the given quantities with different units. This ratio is a unit rate.

For our study, a pencil and paper instrument was administered to 409 middle school students (5th – 8th grades) in a small Midwestern city. Since the instrument is long (26 questions), three class periods were used over a two week period at the beginning of the school year. There was no instruction given in conjunction with data collection, therefore we consider the students' work to represent their natural approach, built on both informal and formal prior experiences. Students showed their work and did not have access to calculators.

The problems in this study, categorized by their number structure, are presented in Table 1. Each was given as a story problem, such as Q18: "Kris works at the stable and it is feeding time. If 24 horses eat 40 bales of hay each day, how many bales would 6 horses eat?" Prior research suggests that problems with an integer scale factor (Cells A and B) are easier than those with a non-integer scale factor (Cells C and D). Further, the ability to scale down by an integer, as in a Cell B shrink problem, is predicted to prepare students to succeed on problems in which the scale factor is a non-integer (Carpenter et al., 1999; Steinthorsdottir & Sriraman, 2009).

Table 1: Number Structures of Problems Analyzed

	Integer Scale Factor	Non-integer Scale Factor
Integer Unit Rate	Cell A Q23 4:16 = ?:48	Cell C Q19 60:20 = ?:45 Q03 3:9 = 11:?
Non-integer Unit Rate	Cell B Q02 5:7 = 40:? Q18 24:40 = 6:? (shrink) Q06 36:24 = ?:8 (shrink)	Cell D Q11 18:16 = 45:? Q12 42:35 = ?:10 (shrink)

Many researchers discuss common student strategies, both correct and error (Bezuk, 1988; Misailidou & Williams, 2003; Tourniaire & Pulos, 1985). We used a detailed rubric to code strategies. Broad categories of error strategies included haphazard calculations, additive comparisons, and incomplete multiplicative comparisons. Broad categories of correct strategies included build-up and multiplicative proportional reasoning strategies. We also coded a variety of errors students made after beginning a problem using proportional reasoning. These partially correct strategies had errors that included either calculation or conceptual errors. In all categories, we captured details of the students' work. Each strategy was coded by two people, and any disagreements were discussed and resolved. For this report, codes were then collapsed into the following categories. *Essentially correct* solutions are those with answers achieved using any proportional reasoning strategy with at most a minor calculation error. *Partially correct* are those that begin with proportional reasoning but finish with incorrect reasoning or contain a major (conceptual) calculation error. These typically arise from mishandling non-integer factors. *Incorrect* solutions are those in which students do not apply proportional reasoning.

Essentially correct solutions are further categorized as representing *efficient* or *less efficient* strategies. An efficient strategy is multiplicative in nature and uses two calculations; for example, a factor (either the scale factor or unit rate) is computed, then applied. Less efficient strategies are build up strategies (e. g. 5:7 = 10:14 = 20:28 = 40:?, answer 56) which take more than two steps. This labeling is subjective but indicates the sophistication of the strategy chosen by the student.

Results and Discussion

Results are presented in Table 2 with questions arranged from easiest to hardest based on the number of essentially correct solutions observed.

Table 2: Categorization of Strategies, Percent of 409 Students

		Q23 Cell A	Q02 Cell B	Q18 Cell B shrink	Q06 Cell B shrink	Q19 Cell C	Q03 Cell C	Q11 Cell D	Q12 Cell D shrink
Essentially Correct Strategies	Efficient	52%	44%	47%	40%	23%	24%	21%	24%
	Less Efficient	16%	21%	9%	8%	19%	17%	11%	2%
Essentially Correct		67%	65%	56%	48%	41%	41%	32%	26%
Partially Correct		1%	2%	3%	2%	19%	20%	19%	10%
Incorrect		32%	33%	41%	49%	39%	39%	49%	64%

McNemar's test is appropriate for comparing two paired proportions. Using this test, the proportion of essentially correct responses in all but two question pairs (Q23 and Q02; Q19 and Q03) were significantly different at the 5% level. As predicted by the learning progression, the enlarge problems with integer scale factors were the easiest, followed by the shrink problems with integer scale factors. The enlarge problems with a non-integer scale factor but integer unit rate are next, followed by the enlarge problem with two non-integer factors. The shrink problem with two non-integer factors is the hardest problem.

The amount of change between problems in different cells strongly suggests the complexity of the scale factor plays a larger role in student thinking than the complexity of the unit rate. Compare the enlarge problems from cells A and B in Table 2, in which the unit rate is integer and non-integer, respectively. The difference in the proportion of essentially correct solutions for Q23 and Q02 is negligible. On the other hand, when the scale factor changes from integer to non-integer, Cell A to Cell C, the success rate drops from 67% to 41% (Table 2, Q23, Q19 and Q03). We hypothesize students more easily notice the multiplicative relationship for quantities with identical units rather than for those with different units.

The ability to correctly partition a given ratio appears to represent a developmental milestone. Shrink problems have lower success rates than enlarge problems with a similar number structure. Compare results in Table 2 for Q02, Q18 and Q06, all cell B questions. The striking difference is the drop in less efficient strategies. This drop also occurs in Cell D, Q11 (enlarge) and Q12 (shrink). Most students who correctly solve a shrink problem do so with an efficient strategy. The ratio of efficient to inefficient solutions is about 2:1 on the enlarge problem and about 5:1 on the shrink problems in Cell B. Perhaps less advanced students have more entry points into an enlarge problem, allowing them to figure out a correct answer. Not seeing an entry point in a shrink problem, these students have a greater tendency to immediately use non-proportional reasoning. In fact, if our questions are ordered by increasing percentage of incorrect responses, the Cell C enlarge problems precede the Cell B shrink problems.

The ability to scale up and down by an integer should enable students to solve problems with non-integer scale factors (Cell C and D problems) equally well. We observed, however, students were more successful on Cell C problems (Q19 and Q03) than on Cell D problems (Q11 and Q12). We conclude the presence of an integer unit rate is beneficial, even though the explicit use of the unit rate strategy does not explain the differences in success. Rather, the integer unit rate appears to enable students to correctly finish a build-up strategy. It also may be that the "nice" unit rate provides an entry to the problem and so prevents students from turning immediately to non-proportional strategies.

Data from additional questions and deeper analysis should clarify our findings regarding the relative importance of number structure task characteristics.

ALGEBRA NOTATION FOR FUNCTIONS IN GRADES 5 THROUGH 9

Sheree T. Sharpe
Tufts University
sheree.sharpe@tufts.edu

Analúcia D. Schliemann
Tufts University
aschliemann@mac.com

We examine how 1343 students in grades 5 to 9 solved an arithmetic problem and attempted to provide a general representation for a function described in the problem. We found that use of letters appears from grade 5 and continuously increases through grade 9 and that students who solved the arithmetic part of the problem were more likely to use letters as variables.

Keywords: Algebra and Algebraic Thinking; Assessment and Evaluation

Research shows that middle and high school students often fail to solve algebra problems (Knuth et al, 2011), have trouble generating equations from word problems (Kieran, 2007), and do not use letters to solve them (Booth, 1984; Küchemann, 1981). Difficulties with algebra have been attributed to the inherent abstractness of algebra (Collis, 1975, Kuchemann, 1981) or to teaching that emphasizes the "meaningless manipulation" of variables (Chazan, 2000).

More recently, a different approach to high school algebra (see Schwartz and Yerushalmy, 1992), which emphasizes the relationship between quantities and focuses on functions and their multiple representations (e.g., tables, symbolic expressions, and Cartesian graphs) have shown to promote a deeper understanding of algebra (Chazan, 2000). In fact, even in elementary school, a functions approach to algebra can promote students' understanding of algebraic principles and representations and use of variables to represent verbal statements (Carraher & Schliemann, 2007; Kaput, Carraher, & Blanton, 2008). These results support the proposal for a different curriculum, aimed at integrating algebraic reasoning across all grades (Kaput, 1998). To design such curriculum, we need to better understand students' intuitive and conventional ways of attempting to use letters as variables across grades and to identify their typical mistakes. This study contributes to this goal by examining the evolving use of letters as a variable by students in grades 5 to 9, as they attempted to represent a function described in a verbal problem, after they had solved a specific instance of the problem using arithmetic.

Method

A total of 1343 students from New England (U.S.A.) completed a mathematics written assessment at the start of the 2012-2013 school year; 233 students were in grade 5 (17.3%), 465 in grade 6 (34.6%), 378 in grade 7 (28.1%), 131 in grade 8 (9.8%), and 136 in grade 9 (10.1%). We analyzed students' answers to parts (a) and (b) of a five-part problem taken from a grade 10 State Assessment test. Part (a) relates to grade 6 Common Core State Standards (on expressions and equations) and part (b) relates to grade 8 standards (on functions). The problem situation and the two questions examined were:

> Liam and Tobet are going to walk in a fund-raising event to raise money for their school. Liam's mother promised to donate to the school $4 per mile that Liam walks, plus an additional $30. Tobet's father promised to donate to the school $6 per mile that Tobet walks, plus an additional $20. (a) If Liam walks 15 miles during the event, what is the total amount of money his mother will donate? Show or explain how you got your answer. (b) Write an equation that represents y, the total amount of money Liam's mother will donate if Liam walks x miles during the event.

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

Results

Missing or incorrect answers were scored as 0 and correct answers as 1. Then, part (a) answers were coded into no response (blank answer or I don't know), incorrect answer, and correct answer; and part (b) into no response, do not use letters (e.g., 90, $60+$30=$90; $50=5 mi; 60, 15*4 = 60 or 20*4 = 80, 1120; 30 by 7.50 miles; if he walks 40 miles then his mom will donate $110), and use letters. Answers to part (b) that used letters were also coded into the six categories in Figure 1.

Use of Letters

a. **Conventional Correct Notation**: (e.g., y=4x +30)

b. **Different Correct Notation**: uses different letters to represent x (number of miles walked) and y (total donated) (e.g., d=4m+30 or 4y+30=x)

c. **Reverse Notation**: reverses order of number and letter
   - **i. Correct Answers** (e.g., x4+30 = y)
   - **ii. Incorrect Answers** (e.g., y = x6+20)

d. **Incomplete Notation**: provides an incomplete equation
   - **i. Correct Answers** (e.g., 4x+30)
   - **ii. Incorrect Answers** (e.g., y = x + 30 or y=4x)

e. **Wrong Information** (uses wrong number information in a complete, incomplete, or incorrect set-up; e.g., 30 + (x*5)=y; y = 4x + 40; y = 15x + 20; y = 6x, y = x + 20; y *x = 450; y=90)

f. **Unidentified Use of Letters** (Randomly combines letters given/not given in problem; e.g., x + y = m; (x*y)+20=90; y/x+30=60; 16xy; 15xy=y; 4x=y+30=y; y=x)

Figure 1: Categories for Use of Letters as a Variable in Part (b) of the Problem

Representing and solving the arithmetic part of the problem seems to have been easier than providing a general algebraic representation of the situation. Here, the percentage of correct arithmetic answers (part a) ranged from 38.2% in grade 5 to 77.9% in grade 9, with no significant differences (analyzed with an ANOVA) between grades 7 to 9, but significant differences between the other grades. Correct algebra representations (part b) ranged from 4.7% in grade 5 to 70.6% in grade 9; differences across all grades were significant.

The arithmetic part of the problem was significantly more difficult for 5th graders, with 38.2% correctly solving the problem, than for 7th through 9th graders, where more than 70% did so.

The algebraic representation of the problem was difficult for 5th, 6th, and 7th graders, with from 4.7% to 36.5% of the students correctly using letters. These percentages increased to 57.3 in grade 8 (the grade where variables are introduced) and to 70.6 in grade 9.

Table 1 shows, for students in each grade, how the percentage of no response, incorrect, or correct responses to part (a) relates to no response, did not use letters, and used letters in part (b). Percentages in the cells for each grade level add up to 100%.

The last column in the table shows the total number of responses to part (a), for each category and grade level. Here, 5th graders show almost equal percentages for each of the three categories. Among 6th graders, there was a slight improvement in results. For the three higher grades over 70% of students provided a correct response to part (a).

Overall, in response to part (b), 33.6% of students in all grades gave no response, 5.3% did not use letters, and 61.1% used letters as a variable.

Even though a high percentage (33.9%) of 5th graders provided no response for both parts (a) and (b), as many as 21.9% correctly solved part (a) and used variable(s) in their solution to part (b). From grades 6th through 9th, the percentage of students who correctly solved part (a) and used variables in part (b) increased from 42.4% to 75%.

As expected, across all grades, a high percentage of students who provided no response to part (a) also provided no response to part (b), while those who correctly solved part (a) had a higher percentage of use of variables in part (b). This suggests that students who understand the arithmetic relations in the problem are more likely to use variables in part (b), at any grade level. Also, the

Table 1: Percentage of Each response by Grade

Grade	Part (a) Response	Part (b) Response			Total
		No Response	Didn't use letters	Used Letters	
5 (N=233)	No Response	33.9%	0.9%	0	34.8%
	Incorrect	10.7%	9.0%	7.3%	27.0%
	Correct	12.0%	4.3%	21.9%	38.2%
6 (N=465)	No Response	21.7%	0	0.9%	22.6%
	Incorrect	9.5%	2.4%	9.5%	21.4%
	Correct	10.8%	3.0%	42.4%	56.2%
7 (N=378)	No Response	12.2%	0	0	12.2%
	Incorrect	3.7%	0.8%	13.0%	17.5%
	Correct	7.9%	1.6%	60.8%	70.3%
8 (N=131)	No Response	10.7%	0	0.8%	11.5%
	Incorrect	0.8%	0	14.5%	15.3%
	Correct	0.8%	2.3%	70.2%	73.3%
9 (N=136)	No Response	10.3%	0	0.7%	11.0%
	Incorrect	0	0.7%	10.3%	11.0%
	Correct	2.9%	0	75.0%	77.9%
All Grades (N=1343)	No Response	18.9%	0.1%	0.4%	19.4%
	Incorrect	6.3%	2.7%	10.6%	19.6%
	Correct	8.4%	2.5%	50.0%	60.9%

percentage of students who correctly answered part (a) and used variables in part (b) positively correlates with grade level.

A total of 672 (50%) of the 1343 students were able to correctly solve part (a) and then use letters as a variable in part (b). These were 51 students in grade 5 (21.9% of 5th graders), 197 in grade 6 (42.4% of 6th graders), 230 in grade 7 (60.8% of 7th graders), 92 in grade 8 (70.2% of 8th graders), and 102 in grade 9 (75.0% of 9th graders).

The percentage of students correctly using letters as a variable increases with grade level as does the percentage of those using the conventional notation. Accordingly, the percentages of most types of incomplete, wrong, and unidentified use of letters decreased with increasing grade levels but was still found among 27.3% and 12.8% of 8th and 9th graders, respectively. Only 9th graders used the correct conventional notation in more than 50% of responses, with 71.6% of them in this category. However, 5th to 8th graders would also use correct notation but reversing the order of variables and constants. Total percentages for correct use of variables, including cases of inversion and incomplete answers, show that 17.6% of the 5th graders, 49.2% of the 6th graders, and 56.5% of the 7th graders who used variables did so correctly, even though this is an 8th grade standard.

Discussion

In keeping with previous research on high school students' difficulties with algebra, our results show that generalized use of letters as a variable, although more frequent in later grades, is still problematic for more than half of 7th graders, more than 40% of 8th graders, and nearly 30% of 9th graders. However, among students who could solve the arithmetic part of the problem and used variables in its algebraic part, use of letters in the correct conventional notation or reverse correct notation start to appear from grade 5 and continuously increase through grade 9.

In terms of solving the arithmetic part of the problem, even though 7th to 9th graders results were better than those for earlier grades, as many as 38.2% of 5th graders and 56.1% of 6th graders understood what the problem was asking them to do. This is noteworthy because this study's data were collected at the beginning of the school year, before 5th and 6th graders were taught the content of part (a).

Our results show that even 5th graders are capable of using letters to represent variables described in verbal statements and suggest that instruction about variables can start much earlier in the K-12 curriculum. The results also suggest that the ability to understand and solve arithmetic problems is a basis for considering variables and using letters for representing them.

Concerning students mistakes, reversing the conventional order for representing variables and constants was present at all grade levels. This could be easily addressed with practice. Other mistakes such as incomplete, wrong, and unidentified use of letters, present even in 8th and 9th grades, call for introducing algebra and functions through activities that promote a clear understanding of variables and of how algebra notation relates to verbal statements.

This study's results and previous findings on young students' use of letters as a variable, suggest that the integrated teaching and learning of arithmetic and algebra may successfully start in elementary school to promote a deep understanding of mathematics across the curriculum.

LOST IN TRANSITION: DIFFICULTIES IN ADAPTING RELATIONAL VIEW OF EQUALS SIGN

Rashmi Singh
Kent State University
rsingh9@kent.edu

Karl W. Kosko
Kent State University
kkosko1@kent.edu

The concept of equivalence is one of the first algebraic notions introduced to students in early childhood. The future success of students in mathematics, and related subjects, is believed to rely significantly on their understanding of this basic algebraic concept. However studies have found that the operational view of the equals sign is a major obstacle in students' proper understanding of equivalence, and hinders their mathematical abilities. In this paper we report findings from part of a teaching experiment involving second-graders where students were observed developing their conceptions of equivalence. We describe the overlap of the operational view of equivalence and the relational view in two students.

Keywords: Algebra and Algebraic Thinking; Classroom Discourse; Reasoning and Proof

Background and Objectives

Numerous research studies have found that students' misconception of equivalence surfaces in the form of an operator conception the of equals sign (Carpenter et al., 2003; McNeil & Alibali, 2005). Students with such an operational view treat the equals sign as an operator to produce the result of the operation performed on the numbers on one side of the sign. Thus, equals is conveyed as "makes" or "produces" instead of "the same as." These effects have been observed to be long lasting and hinder students' success in their mathematics learning in later grades (McNeil & Alibali, 2005). Research spanning over 40 years has reported various reasons for this misconception and suggest that many students retain this misconception in some form or other even in higher grade levels (Kieran, 1981; Knuth et al. 2006). The present study extends this large body of literature by focusing on how children's conceptions of equivalence changed and varied across several weeks. Therefore, the purpose of this study is to examine the interaction of children's conception of the equals sign as an operator with their ability to grasp of a relational view.

Theoretical Framework

Children with an operational view of the equals sign generally give significance only to the number immediately following the equals sign and usually ignore any operations thereafter. However, with a relational view, students consider expressions appearing on the either side of equals sign as equivalent/same (Baroody & Ginsburg, 1983). The particular focus of research on students' conception of equivalence has been on the nature of children's misconceptions. Such research has found that beyond the conventional arithmetic problems (e.g., $2+1=\square$), children demonstrate difficulty with alternate forms. These include equations in reverse-order such as $a=b-c$ (McNeil et al., 2006), equivalent expressions such as $a=a$ (Baroody & Ginsburg, 1983), or missing numbers in equivalent expressions such as $a+b= \square+d$ (Rittle-Johnson & Matthews 2011).

Our primary interest in this study is to look for any nonstandard difficulties faced by students in realizing the relational view of equals sign. We used the construct map for mathematical equivalence knowledge, suggested by (Rittle-Johnson & Matthews 2011) to determine students' demonstrated level in terms of an operational or relational view of equals sign.

Methods

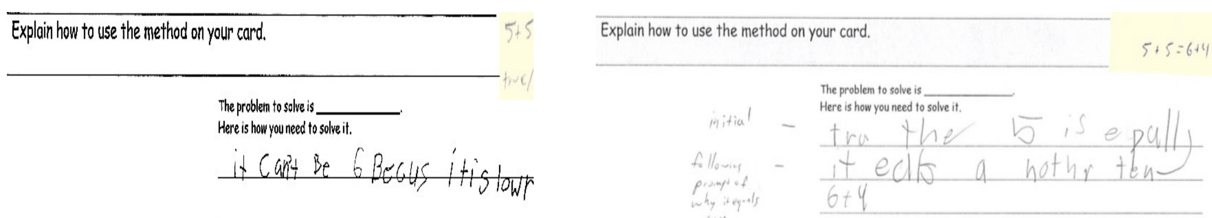
The data used in this paper focuses on the work of two students, Julia and Jacob, who were a part of a year-long teaching experiment with four second-grade students from a public school in a Midwestern U.S. state. For the sake of simplicity and space, we focus on six of these sessions (session 8 to 13). Based on Steffe & Thompson's (2000) description of teaching experiment, the first author served as the observer and the second author as the teacher-researcher. During the sessions of focus here, children were asked to consider different number sentences and their properties, including their association on number balances. The number sentences ranged from single expressions with single digit numbers (e.g., 5 + 7) to two expressions with multi-digit numbers in the equation (e.g., 15 + 10 = 18 + 7). All the sessions were video recorded and transcribed and written work of participants was digitally scanned. Field notes collected from the first author were also included.

Analysis

After each session, both authors used video, students' writing, and observer notes to examine students' understanding of equivalence. Transcripts were used along with other data following all sessions for further analysis. We used the construct map provided by Rittle-Johnson & Matthews (2011) to code students' demonstrated understanding. The concept map proposes four levels of mathematical equivalence knowledge; *rigid operational* ($a+b=c$); *flexible operational* ($c=a+b$, $a=a$); *basic relational* ($a+b=c+d$, $a+b–c=d+e$); and *comparative relational* (e.g., knowing that 85 + 14 = 80 + 19 without needing to find the sum of each expression). The findings were refined through continuous review of student data. After careful observation and independent analysis of data, both authors reached agreement on levels of the construct map for each student across different sessions.

Results and Discussions

In early sessions Julia demonstrates an operational view of the equal sign, as opposed to Jacob who consistently demonstrated the relational view. However, it should be noted that the very first problems involved equivalent expressions containing single digit number only (Figure. 1).



Julia: "It can't be 6 because it is lower" **Jacob:** "True the 5's equal...it equals another ten, 6+4"

***Figure 1*. Julia and Jacob's responses to whether 5+5=6+4 and why.**

Notice how, in Figure 1, Julia identifies only the 6 to the right of the equals sign, and does not identify the + 4 afterwards. Jacob, however, describes the whole equation in framing his response. Despite her rigid operational view in the beginning, Julia started to shift how she began describing the equals sign in using language resembling "same as" descriptions, but never reached a point where her descriptions of the arithmetic aligned with a *flexible operational* stage (Rittle-Johnson & Matthews 2011). Jacob's performance demonstrated a unique misconception hindering his advancement to the *basic relational* stage. For the sake of clarity, we discuss Julia and Jacob's performance separately for the remainder of the paper.

Julia's work

In view of (Rittle-Johnson & Matthews 2011) construct map, Julia would, at times, seemingly demonstrate a transition from the rigid operational view of equals sign to a flexible operational view, but this transition was not consistent. During one session, Julia responded to the question "Explain why 38 + 16 = 40 + 14" by stating "They did not show the same numbers but they are the same answers. So it is a different equation but it is the same answer.*"* Thus, Julia performs the operation of addition irrespective of the appearance of expression on the left or right of the equals sign, but does not demonstrate the equivalence of the expression. Rather, she talks about the answer of the addition operation separately on either side. We infer from this that she is, at this time, considering the two expressions either as $a+b=c$ or $c=a+b$.

Jacob's work

Jacob's responses for the equivalent expressions using single digit numbers suggest that his level of equivalence knowledge is beyond the *rigid operational* level (see figure. 1). When asked to consider the equivalent expressions involving two digit numbers, Jacob did not demonstrate an understanding of equivalence (see the Figure 2 below).

40+14=38+16: *"Because they are not the same patterns and the same numbers and the same equal"*
10+15=17+8: *"It doesn't work because it is not equal".*

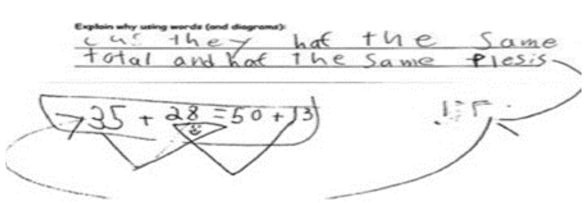
***Figure 2*. Jacob's failure to realize equivalence of expressions.**

Based on his work with equations with single-digit numbers, we initially considered that Jacob had an operational view, but we found disconfirmatory evidence in this regard. Jacob correctly identifies the equivalence in some other problems involving two digit numbers. For example consider his responses for the questions in Figure 3.This evidence seemingly contrasts an assumption of an operational view. To understand this discrepancy in Jacob's responses, we considered his work in response to various problems such as "*35+28=50+13*", as shown in Figure 3.

35+28=50+13: *"Because they have the same total and have the same places"*
21+36=50+7: *"Because they have the same total"*

***Figure 3*. Jacob's realization of equivalence of expressions.**

On careful observation, we found that Jacob's strategy with equivalent expressions involving two digit numbers relied primarily on adding the numbers in ones place on the left hand side of equals sign. He then looked for the same number (the sum of numbers in the ones place) on the right hand side of the equals sign. If the equation had the same number on the right hand side of equals sign, Jacob would conclude that the expressions are equivalent, and are not equivalent otherwise.



35+28=50+13; *"Because they have the same total and have the same places"*

***Figure 4*. Jacob's responses to equivalent expressions with two digit numbers.**

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

Confirmatory evidence for Jacob's adding strategy is presented in Figure 4. Jacob demonstrates adding the numbers in the ones place on left hand side of equals sign, but then looks for the resulting number on the right hand side. Thus, he adds 8+5 to get 13. He then checks to see 13 on the right hand side of equals. Finally he adds the numbers in tens place on the left hand side of the equals sign to get 30+20. He then verifies 50 to appear on the left hand side again and concludes that the expressions are equal. He does the same for 21+36 = 50 +7 and declares it to be correct (see Figure 3). Using the same method, he concludes that the two examples in Figure 2 are not equivalent. Based on the discussion above, we conclude that Jacob's level of equivalence knowledge can be placed somewhere between flexible operational and basic relational. His exhibition of a "pseudo-relational" view of the equals sign might be considered as his preliminary advent to the basic relational level of equivalence knowledge. Rather, at times he is able to demonstrate what appears to be a relational view, and provide what appear to be relational definitions, but disconfirmatory evidence suggests that such a view is too ill defined by Jacob for him to show consistency in his responses.

Conclusion

In this report, we have shown that children's relational and operational views of the equals sign may be mutually exclusive, but there is not as clear a line between these views as much prior research has suggested (Rittle-Johnson & Matthews 2011). We observed that Jacob's pseudo-relational understanding of the equals sign prevented him from consistently demonstrating a basic relational understanding. Such a view may signal false indicators of a basic relational view and thus be misleading for teachers (and also researchers).

Penn State Harrisburg
jmw41@psu.edu

Across the professional spectrum, teachers' mathematical knowledge for teaching impacts their teaching practice and students' learning opportunities. This brief research report details an ongoing study focused on the conceptions of place value and whole number operations among preservice (n=26) and inservice (n=8) teachers engaged in a multi-week teaching intervention involving an unfamiliar number system in base six. Using mixed methods, analysis of pre- and post-Assessment of Place Value data, participant reflections, and pre- and post-surveys of productive and unproductive beliefs about teaching and learning mathematics, yields insights about teachers' conceptions of place value and whole number operations, specifically noting differences across preservice and inservice teachers. Supporting literature and pilot data indicate the potential for positive impact on participants' mathematical knowledge for teaching.

Keywords: Number Concepts and Operations; Teacher Education-Preservice; Teacher Education-Inservice (Professional Development); Teacher Knowledge

Number and operations are a consistent component of the K-12 mathematics curriculum, and supporting teaching and learning of these concepts remains an enduring challenge in mathematics education. In U.S. states that have adopted the *Common Core State Standards for Mathematics* (*CCSSM*), teachers are expected to build upon concepts of number, operations, and place value, applying those concepts with increasing sophistication from natural and whole numbers, to fractions, integers, rational, irrational, and complex numbers. Similar progressions can be found in alternative curriculum standards. Here we report on an ongoing study of preservice and inservice teachers' conceptions of place value and whole number operations throughout an intervention designed to deepen teachers' understanding of these foundational concepts.

Purpose of Study

Preservice and inservice teachers' conceptual understanding of numeration systems, place value, and mathematical properties can influence how they teach the concepts and help students make meaning of them (Ma, 1999). Teachers must possess a deep conceptual understanding of numeration and place value in order to select the appropriate order of tasks to engage students in knowledge construction, choose appropriate manipulatives and representations to support those constructions (Morin & Samelson, 2015), analyze students' reasoning, facilitate productive mathematical discourse, and anticipate possible alternative solutions and strategies. The purpose of this study is to explore teachers' conceptions of place value and whole number operations through an intervention involving a base-six number system and alternative numerals. We also explore howthese conceptions differ among and between preservice and inservice teachers.

Theoretical Perspective

Building on Shulman's (1987) concept of pedagogical content knowledge, *mathematical knowledge for teaching* (Hill, Rowan, & Ball, 2005; Ball, Thames, & Phelps, 2008) is now a well-established construct in mathematics education. We draw from this construct as we consider conceptions of place value and operations among elementary preservice teachers (PSTs) enrolled in an undergraduate mathematics methods course and inservice teachers enrolled in a graduate mathematics education course. The study described in this paper engages teachers as mathematical learners of place value and operations concepts in an unfamiliar number system, providing them with opportunities to construct deeper understanding of mathematics and pedagogy through exploration and productive struggle with cognitively demanding mathematical tasks in base-six (Stein, Smith, Henningsen, & Silver, 2009).

There exists a robust research literature relating to teaching and learning elementary number concepts, with much attention directed toward progressions and characteristics of teaching and learning about place value and multi-digit addition and subtraction concepts (see, for instance, Fuson, 1990; Baroody, 1990; Fuson et al., 1997; Clements, et al., 2011). In order to facilitate student learning that focuses on such concepts, teachers must possess deep conceptual understanding (CBMS, 2001; Sowder, Philipp, Armstrong, & Schappelle, 1998). Yet, deep conceptual understanding cannot simply be assumed. For example, Thanheiser (2009) examined elementary pre-service teachers' (PSTs') conceptions of multi-digit whole numbers in a variety of contexts and found that the majority of PSTs experienced some gaps in their conceptions of whole numbers and place value. Variation in teachers' understanding of place value concepts has also been documented among practicing teachers (Tanase, 2011; Tanase & Wang, 2013).

One approach to developing teachers' knowledge and conceptual understanding of place value and operations has been to engage teachers as learners in a non-base ten number system (Andreason, 2006; McClain, 2003; Roy, 2008). Hopkins and Cady (2007) describe how learning experiences with the Orpda system, a base five number system that used symbols other than Hindu-Arabic numerals, provided preservice and inservice teachers with insight about student thinking and manipulative use, while developing a deeper understanding of place value concepts. In her dissertation study involving the Orpda system, Price (2011) also documents positive changes in teachers' conceptual understanding of place value and operations. Likewise, dissertation studies by Rusch (1997) and Radin (2007) emphasized a variety of number bases in coursework for pre-service elementary teachers. Positioning preservice and inservice teachers as learners of familiar mathematics in unfamiliar number systems can facilitate the construction of conceptual understanding, while providing authentic experiences with pedagogical approaches, potentially impacting teachers' mathematical knowledge for teaching.

Methods

The specific teaching intervention used in this study engages participants in place value and whole number operations tasks that parallel the progression of Number and Operations in Base Ten from the *CCSSM* (CCSSI, 2010). Throughout the multi-week unit, participants create, represent, and solve tasks in a base-six numeration system, termed the Sloth System, that uses the symbols **O**, •, ♥, ▽, □, ★, to represent the Hindu-Arabic numerals 0, 1, 2, 3, 4, 5, respectively. As instructors for these two courses, the authors pose tasks that include bundling objects in groups of six; representing and comparing quantities; manipulatives and representations of base-six blocks and six frames; composing and decomposing numbers; and adding, subtracting, multiplying, and dividing, all in the Sloth System. The intervention models many of the base ten concepts across elementary mathematics using the Sloth System with the goal of improving participants' mathematical knowledge for teaching place value and operations.

A mixed-methods approach is used throughout the study involving 26 preservice teachers in two sections of an undergraduate elementary mathematics methods course and eight inservice teachers in a graduate course on Numbers & Operations. Each participant is asked to complete a pre- and post-Assessment of Place Value, adapted from Rusch (1997), at the beginning and end of the semester. Additional data sources include teachers' written reflections on their learning related to the teaching intervention, and results of a four-point Likert-type beliefs survey adapted from productive and unproductive teaching beliefs as described in *Principles to Action: Ensuring Mathematical Success for All* (National Council of Teachers of Mathematics, 2014), administered at the beginning and end of the semester.

Using the constant comparative method (Strauss & Corbin, 1998), participants' reflections will be coded and examined for themes. The unit of analysis is the individual teacher. Additionally, reflections and the responses to open-ended items on the pre- and post-assessments will be analyzed using the *conceptions of multi-digit whole numbers framework* (Thanheiser, 2009). Results from qualitative analyses will be mapped to the findings from the quantitative results for each participant. Analysis of data from the subset of preservice participants will be compared with the subset of inservice participants, as well as among individuals in each group.

Preliminary Findings

We report on preliminary findings from this study in progress. Two prior iterations of the base-six teaching intervention yielded pilot data from elementary preservice teachers' reflections. Three themes emerged from the qualitative pilot data: preservice teachers reported increased understanding of student thinking and misconceptions about place value and operations; acknowledged that discussion of multiple strategies fostered their own understanding of place value and operations; and, gained appreciation for the manipulatives and representations. Preservice teachers described their initial frustration with representing and operating on numbers in an alternative numeration system, but were cognizant that their struggle was likely similar to that of many of their future students learning the same concepts in base ten. Because the teaching intervention in this study builds upon prior iterations, these findings suggest that teachers' understanding of both mathematical content and pedagogy, or perceptions thereof, may be impacted. Yet the extent to which that impact differs among students and between preservice and inservice teachers cannot yet be determined. Additionally, preliminary analysis of preservice teachers' pre-tests for this study indicates lack of familiarity with non-decimal number bases prior to the teaching intervention. Thus, participants' facility with alternative number bases, builds from a rudimentary baseline understanding of place value and operations that are not in base ten.

Discussion

Prior research has indicated positive results when preservice teachers' learn in non-base-ten numeration systems (Rusch, 1997; McClain, 2003; Andreason, 2006; Hopkins & Cady, 2007; Radin, 2007; Roy, 2008; Price, 2011). To this body of literature, the study described here will add results about inservice teachers' conceptions of number and operation concepts. Increased understanding of preservice and inservice teachers' conceptions of place value and whole number operations will support researchers and mathematics teacher educators to better target teachers' preparation and professional development needs, in turn potentially impacting teachers' mathematical knowledge for teaching (Ball et al., 2008) and students' learning of foundational number and operations concepts (Hill et al., 2005).

ALICE'S DRAWINGS FOR INTEGER ADDITION AND SUBTRACTION OPEN NUMBER SENTENCES

Nicole M. Wessman-Enzinger
George Fox University
nmenzinger@gmail.com

Alice, a fifth grader who participated in twelve weeks of a teaching experiment on integer addition and subtraction, produced drawings as part of her strategy for solving integer addition and subtraction open number sentences. The drawings she created during the twelve weeks of the teaching experiment were analyzed and grouped into the following categories: Single Set of Objects, Double Set of Objects, Number Paths & Number Lines, and Number Sentences. These drawings provide insight into how children may directly model or count when solving integer addition and subtraction problems.

Keywords: Number Concepts and Operation; Elementary School Education; Cognition

For solving addition and subtraction problem with positive integers we know that children often use strategies that incorporate drawings that include direct modeling, counting, or derived facts (Carpenter, Fennema, Franke, Levi, & Empson, 2015). Children often use drawings paired with direct modeling or counting strategies as they begin to invent strategies for solving addition and subtractions problems. We also know that children often draw upon direct modeling strategies, which may incorporate drawings, when the number size changes. However, as a field, we know little about the drawings that children employ as they transition from using positive integers to negative integers. Bofferding (2010) demonstrated that children often use a number path when solving integer problems. Other researchers have shown that children will use a variety of ways to reason about the integers which include order-based or number line reasoning (e.g., Bishop et al., 2014). Despite the insurgence of research on the ways that student think about integers (e.g., Bofferding, 2014; Bishop et al., 2014; Wessman-Enzinger & Mooney, 2014), we need to know more about the ways that children reason about integers in relationship to they ways that children employ direct modeling or counting. One way to identify more of these direct modeling and counting strategies from children is to look at the drawings that they produce and create. Vig, Murray, Star (2014) highlight that understanding the productive aspects of models, as well as their breaking points, is an important component to integer addition and subtraction. Understanding ways that children use these drawings productively and unproductively could help provide insight into affordances and hindrances of models.

Theoretical Perspective

Word use, visual mediators, narratives, and routines are the central tenets of discourse in commognitve theory (Sfard, 2008). Although all of the tenets of commognitive theory work together synergistically, the visual mediators are the focus of this paper. Visual mediators include recognizing artifacts such as gestures or drawings as part of a students' discourse. Drawings that children produce while solving integer addition and subtraction open number sentences represent a component of their discourse that is just as important as their verbal reasoning. For students, drawings can be as communicative as their verbal expressions and investigations into their drawings for negative integers can be illuminative. During the time with the Grade 5 students, they often used drawings to help them make sense of the negative integers. This research brief highlights one of these three students, Alice, and her drawings. Specifically, this research brief addresses the research question:

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

What types of drawings does Alice produce as she solves integer addition and subtraction open number sentences?

Methodology

Three Grade 5 students from a rural Midwest school participated in a 12-week teaching experiment (Steffe& Thompson, 2000) centered on integer addition and subtraction, using both contextual problems and open number sentences. The students met in both individual and group sessions during the teaching experiment and all sessions were videotaped. The students primarily solved problems in contexts during both the individual and group sessions; however, there were four individual sessions where students solved open number sentences.

Integer addition and subtraction open number sentences were solved during four individual sessions across the 12-weeks. During these sessions the open number sentences were provided on paper, with no manipulatives and only a box of markers available. The students were asked to explain their reasoning for solving the open number sentences. Alice was chosen as the participant to report on in this research brief because of the three participants Alice used drawings the most. Alice's drawings from the individual sessions with open number sentences represent the unit of analysis. A grounded theory approach (Glaser & Strauss, 1967) was utilized for categorizing the different types of Alice's drawings. Both the verbal interactions from Alice and the teacher-researcher, as well as, the process of her drawings were transcribed. Each of the drawings, paired with these descriptions and transcripts, was examined and sorted for common themes.

Results & Discussion

Single Set of Objects

Alice often drew a Single Set of Objects to solve the open number sentences. The Single Set of Objects were utilized in two different ways, by either crossing off objects or adding objects on. For crossing off a Single Set of Objects, Alice began by drawing an initial set of objects (e.g., boxes or tallies), which represented either a positive or negative integer. She then crossed some of the objects off (see Figure 1). The objects crossed off represented either the addition or subtraction of a positive or negative integer. Alice's objects that she drew included either boxes or tallies for the Single Set of Objects.

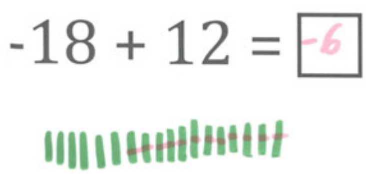

Figure 1: Single Set of Objects for Solving -18 + 12 = □

In Figure 1, Alice used 18 tallies to represent the negative integer, -18. Then, Alice crossed off 12 tallies, representing the positive integer being added.

Double Set of Objects

Other drawings that Alice produced frequently included two layers or two separated groups of objects. The drawings that included these layered or separated objects were considered a Double Set of Objects (see Figure 2). For example, Alice used the Double Set of Objects drawings with when solving □+ -4 = 13. In Figure 2, the pink tallies represent negative four and the green tallies represent 17. Alice added tallies until the leftover tallies totaled 13. Then, she counted all of the green tallies to determine the solution of 17.

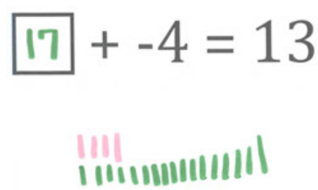

Figure 2: Double Set of Objects for Solving□ + -4 = 13

Although Alice would use objects that were layered on top of each other, Alice also represented the addition and subtraction with segregated layers. For example, in Figure 3, Alice represented the -4 with boxes and then segregated the second set of boxes, but this layer of boxes was not stacked on top of the other boxes like in Figure 2. She then added up all of the boxes to get 14. Alice described her drawing, "I did four for negative four (motions across four boxes), then I did how many I was adding a box for how many it would take to get me up to ten." Although this type of drawing is reminiscent of a Number Path (see, e.g., Bofferding, 2010; Wessman-Enzinger & Bofferding, 2014), Alice did not recognize these boxes as orderings of numbers. Instead, she described the quantities -4 and 10 without order.

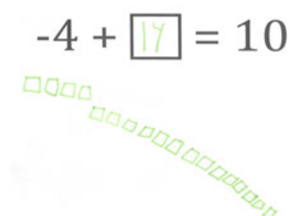

Figure 3: Double Set of Objects for Solving -4 + □= 10

Number Sentences

Alice often drew horizontal or vertical number sentences to solve the open number sentences. Sometimes the horizontal or vertical number sentences used only positive integers, while sometimes the horizontal or vertical number sentences incorporated negative integers. For example, to solve -12 – -11 = □, Alice drew a vertical number sentence involving negative integers. She vertically wrote, -11 – -12. Yet, Alice still obtained -1 as a solution. This is consistent to findings that children often incorrectly apply the commutative property when subtracting negative integers (Bofferding, 2010).

Number Path & Number Lines

Alice only drew a Number Path with negative integers once during all of the individual sessions (see Figure 4). Alice did not draw a conventional Number Line; rather, she drew a Number Path (see, e.g., Bofferding, 2010; Wessman-Enzinger & Bofferding, 2014).

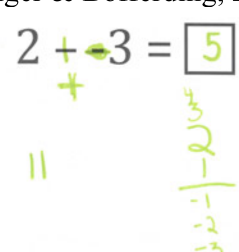

Figure 4: Number Path for Solving 2 – -3 = □

Her drawing in Figure 4 included the ordering of a Number Line and has a close relationship to the formal Number Line, yet is not a Number Line. She drew this Number Path after solving the open number sentences 2 – -3 = □ during the last individual session of the twelve weeks. To solve 2 – -3 =

□, Alice first solved it by recalling a rule that the student developed during the group sessions, “Because it's just like the last one. You do plus (changes minus sign to plus sign) and take that off (scratches off the negative symbol of -3). And, it just be like two plus three.” When asked why it worked, she drew both a Single Set of Objects (e.g., tallies) and then a Number Path to try to justify her reasoning. Although she drew a Number Path, she didn’t utilize it to solve or justify her solution. In fact, Alice shared that she didn’t know how to use either of her drawings (Single Set of Objects or Number Path) to explain her answer.

Conclusion

Alice used a variety of drawings that were productive for solving integer addition and subtraction number sentences. Despite the different types of drawings she drew, she did not draw very many Number Paths or any Number Lines during the individual sessions. Instead, Alice drew the quantities of objects that seem to be related to direct modeling strategies (Carpenter et al., 2015). Towards the end of the teaching experiment Alice began to utilize a Number Path, which may highlight that the development of drawing Number Lines takes extended time for some children. This may point that the development of using Number Paths and Number Lines takes significant for some students. These different types of drawings (e.g., Single Set of Objects, Double Set of Objects) provide further insight into the ways we understand student thinking about addition and subtraction with integers.

What strategies can secondary precalculus and calculus students use to identify whether representations correspond to the same function, and how do the coordination strategies a student uses correspond with his/her success in identifying matching representations? We analyzed 64 think aloud protocols in which high school students were asked to identify whether a given pair of representations (graph, table, equation) corresponded to the same function to answer these questions. Results indicated that two clusters of students using distinct strategies were identifiable on tasks that required matching equations and graphs and equations and tables. However, we were not able to identify clusters by strategy for graph-table representations. We discuss how task demands might explain this pattern of results and consider implications for teaching that are responsive to students' conceptions of mathematics.

Keywords: Algebra and Algebraic Thinking; High School Education; Cognition

Objectives

A critical ongoing challenge for mathematics educators is helping more students achieve success in advanced mathematics courses such as calculus where flexibly using multiple representations is a critical skill. This study seeks to extend the field's understanding of how secondary calculus and precalculus students identify whether pairs of equations, graphs, and tables corresponded to the same function. In secondary mathematics and especially in reform approaches to calculus (e.g. Hughes-Hallet et al., 2012), students are often required to identify whether two graphs, tables, or equations are equivalent (Leinhardt, Zaslavsky, & Stein, 1990). This identification is part of a more complex set of skills related to coordinating multiple representations (CMR). This study builds on our past work (Zahner, 2012, Chang, Cromley, & Tran, in press) through incorporating mixed methods to more fully describe how 64 secondary students approached CMR tasks.

Consider the CMR identification task in Figure 1. A student has multiple options when deciding whether these two representations correspond to the same function. Since the y-intercept and constant term match, these two representations might correspond to the same function. How could a student check? She could use the equation to evaluate $f(x)$ for a set of inputs (e.g., let $x = \{1, 2, 3\}$). This point-testing strategy would solve this mismatch problem (e.g. since $f(3) = 7$ but (3,7) is not on the graph, the graph and equation are not the same function). However, with some background knowledge another strategy is possible. Knowing that degree two (quadratic) functions have a U-shaped graph, a student could coordinate the shape of the graph and the equation and conclude these cannot be the same function. These two hypothetical solutions represent different strategies for solving CMR problems.

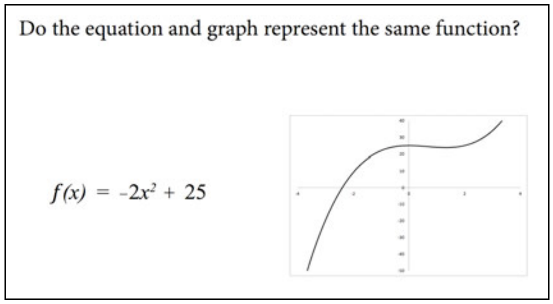

Figure 1: Sample Equation Graph Item

This study was designed to investigate the strategies used by precalculus and calculus students to coordinate representations of polynomials. Our main research questions were 1) What are the strategies students use to solve CMR identification tasks such as this? 2) Is it possible to identify distinct groups of students based on strategies used? 3) If it is possible to identify distinct groups, are there data to show that one group is more or less successful than the other?

Theoretical Perspectives

We draw on theoretical models and analytical methods from Siegler's overlapping waves theory (Siegler, 2005). This theory describes children's development and use of problem solving strategies as probabilistic. Rather than developing expertise in strategy use along a linear progression, problem solvers often mix more and less sophisticated strategies, and the problem prompt is an important mediator of strategy choice. This latter insight from Siegler's cognitive work brings to mind Wertsch's (1998) cultural historical and semiotic analysis of the affordances of representational tools that make particular problem solving strategies more or less viable. Thus in our discussion we tie together these two distinct branches of research.

Methods & Analysis

The participants were 64 secondary students enrolled in precalculus and calculus in suburban high schools in the Northeast. The sample consisted of 60% female and 79% White students. As a proxy for socio-economic status, we measured maximum parental education; 80% of families had at least one parent with a Bachelor's degree or above.

The students were presented with a set of 12 questions similar to the question in Figure 1 and they were asked to follow a think-aloud protocol (Ericsson & Simon, 1984) while solving the problems. The questions were presented on a computer screen that included eye-tracking tools. The 12 prompts included four items with each of the possible combinations of equation ↔ graph, equation ↔ table, and graph ↔ table. The functions were distributed among linear, quadratic, and cubic functions with integer coefficients. Half of the items showed a match.

The think aloud data were transcribed and divided into utterances roughly corresponding to a phrase containing a subject and a verb such as "the negative x squared matches the parabola." Codes were created to identify CMR strategies including matching ordered pairs (MOP for non-intercepts and MOPX or MOPY for matching an intercept without naming the intercept as such), explicitly matching the x- and y- intercepts (MINTX and MINTY), evaluating the degree of a function (DEG), and evaluating the direction (DIR) or magnitude of the leading coefficient (MAGC). A total of 2889 utterances were coded. After the initial coding by strategy, two overarching strategies were identified: evaluating global characteristics of the function (DEG, DIR, and MAGC), and evaluating on a point-by-point basis (MOP, MOPX, MOPY, MINTX, and MINTY).

In the process of coding we also noted that although some students tended to use global strategies while others used "point-by-point" comparisons, both groups of students who used different strategies had similar levels of accuracy on the CMR tasks (Zahner & Cromley, 2014). To further explore students' strategy-use profiles by representation pair, we employed a cluster analysis (Aldenderfer & Blashfield, 1984) on strategy use by representation pair. Cluster analysis is a person-centered approach that uncovers homogeneous groups underlying a set of data (DiStefano & Kamphaus, 2006). We used a hierarchical cluster analysis procedure based on squared Euclidian distances with the Ward's method on standardized ratios of strategy use (i.e., Z scores of [occurrences of a strategy/occurrences of all strategies per student]; Milligan, 1996). We then evaluated the validity of the obtained cluster solutions by comparing the subgroups with respect to accuracy in answering the CMR items, time used in answering the CMR items, and total number of strategies used.

Results

For the equation ↔ graph (EG) items, cluster analysis results indicated two distinct groups of students by strategy use: EG group 1 (n = 49) used significantly more EVAL and fewer MOP strategies, whereas EG group 2 (n = 16) applied significantly more MOP but fewer EVAL strategies. Comparing the two groups in accuracy and average time used, we found both groups were similar in accuracy but EG group 1 spent significantly less time than EG group 2 to complete the equation-graph items.

Table 1: Summary of cluster analysis for EG items

	Accuracy Rate	Time Used**	No. of Strategies Used
Group 1 (n=49)	85.0%	25.1	9.4
Group 2 (n=16)	87.5%	36.8	9.3

**p<.01

For the equation ↔ table (ET) items, cluster analysis results also indicated two distinct groups of students. However, the groups were only marginally different with respect to their use of EVAL. Instead the ET group 1 (n = 12) explicitly matched the y-intercept (MOPY) more often while ET group 2 (n = 52) matched order pairs without explicitly referencing the y-intercept as a salient point. Comparing these two groups in accuracy and time used, we found members of ET group 1 were significantly quicker but less accurate in responding to the equation-table items.

Table 2: Summary of cluster analysis for ET items

	Accuracy Rate**	Time Used***	EVAL~	MOP***	MOPY***
Group 1 (n=52)	86%	51.6	1.4%	68.7%	22.0%
Group 2 (n=12)	67%	23.2	9.6%	22.5%	66.3%

Note: ~ $p< .10$; * $p< .05$; ** $p< .01$; *** $p< .001$.

Finally, the graph ↔ table (GT) cluster analysis did not yield a solution we consider meaningful in practice due to the size difference in clusters.

Discussion & Conclusions

In summary, the cluster analysis confirmed one of the hypothesized relationships. For the items that presented an equation-graph pair of representations, one group of students tended to use strategies from the superordinate category "Evaluate" while the other group tended to use strategies under the superordinate category "Match Ordered Pairs." Interestingly there was no significant difference between the two groups in terms of accuracy on the task, but the students who used evaluate tended to complete the task faster than those who matched ordered pairs. It is notable that the accuracy of the respondents' answers was not significantly related to cluster identification. This indicates that there are multiple possible solution pathways on CMR identification items like the ones used in this study.

Looking ahead, we are currently testing whether modifications such as adding arrows and boxes to highlight particular features of the prompt will be associated with a shift in the strategy that students use while solving the problem.

Second, the cluster analysis revealed that clusters of students by overarching strategy were not readily identifiable on the table ↔ graph items. We relate this to the affordances of a table, which makes point-by-point comparison easy and global comparisons relatively difficult. In future research where we attempt interventions, it may be worthwhile to build on Lobato's focusing perspective (Lobato et al., 2003) and investigate how modifications to table items (e.g. adding a difference or ration column) can prompt students to use more sophisticated strategies.

EXPLORING A ‘NOT-SO-COMMON’ COMMON FRACTION REPRESENTATION

Ryan Ziols

ziols@wisc.edu

Percival Matthews
University of Wisconsin-Madison
pmatthews@wisc.edu

This study examines undergraduate responses to a fraction task designed to investigate how different individuals leverage a perceptually based “sense of proportion” with a continuous, nonsymbolic representation of fraction values. Participants were asked to double two parallel line segments used to represent the fraction 3/5, write an equation, and give explanations to show what they did mathematically. The representation elicited a diversity of symbolic operations and explanations of reasoning among participants. This may provide further insight into the complex psychological foundations involved with learning fractions.

Keywords: Rational Numbers; Elementary School Education; Reasoning and Proof

Developing a strong understanding of fractions is one of the main goals of K-8 mathematics education (e.g., CCSSM, 2010).Yet children often experience considerable difficulties developing an understanding of fractions. Indeed, the National Math Advisory Panel (2008) declared fraction knowledge to be the most important foundational skill that is not presently developed in the school-aged population. Additionally, fractions are also considered a topic not adequately developed in primary education (NMAP, 2008)

One potential source of these difficulties may be located in foundational assumptions about how fractions are learned. For example, fraction knowledge is often approached from the assumption that fractions knowledge must be rooted somehow in whole number knowledge (e.g., Steffe & Olive, 2010). However, some research suggests that we should re-evaluate this widely held assumption. Notably, evidence strongly suggests that humans (and even non-human primates) easily compare visuo-spatial ratios in multiple types of representations such as line segments, dots, and areas (e.g., Jacob, Vallentin & Nieder, 2012; Lewis, Matthews, Hubbard, 2014; Matthews & Chesney, 2015). This perspective accords well with Carraher’s (1996) distinction between a *ratio of quantities* and a *ratio of numbers*. A ratio of quantities concerns two magnitudes such as the ratio of two lengths (e.g., one half instantiated as , or even the ratio between a circle’s circumference and its diameter). If we take seriously the proposition that number knowledge is “developed through acting and reflecting upon physical quantities” (Carraher, p. 241), then we should pay due attention to research suggesting fractions qua ratios might be accessed by the perceptual system – even in approximate form. The implication is that this type of representation may provide a valuable foundation for understanding fraction magnitudes in ways that may be elusive to current research paradigms.

Although some research does suggest that humans have an early ability to identify and reason with visuo-spatial ratios, little research has investigated how such nonsymbolic ratio abilities interact explicitly with mathematical reasoning. With this research, we sought to investigate this question using a sample of undergraduate students from a selective Midwestern university. This study was undertaken as part of a larger study of undergraduates’ understanding of fractions which has shown a) that fractions knowledge is often fragile - even at a selective university, and b) that undergraduates’ nonsymbolic ratio processing abilities are predictive of standardized math achievement test scores (Lewis, Matthews & Hubbard, 2014).

Theoretical Question

Ratios as Units?

It is not clear that research in mathematics education has sufficiently explored whether a continuous visuospatial ratio can be taken as a mathematical unit. To clarify, can the relationship between two line segments deemed to be *perceptual items* by Steffe & Olive (2010) in the plural sense potentially be conceived alternately as a *perceptual item* in the singular? Stated alternately, can perception of an *intensive* ratio between what are commonly understood as two *separate* items itself be taken as a mathematical unit? We explore this possibility in the discussion section by considering the construct of *unitizing*- which we take to mean "the mental act of forming unit items out of sensory experience (Olive & Lobato, 2008, p.5). For example, 3 equal slices of a pizza divided into 5 equal slices can be *unitized* as a 3/5-unit (such that two of these 3/5-units can then be understood to make 6/5). *Units-coordination* is necessary to *simultaneously* understand, for example, that 3/5 is three 1/5's, which is in turn 3/5 of a unit whole (e.g., Steffe& Olive, 2010). Our question examines how the unit may be identified in a continuous representation that is in some sense equivalent to 3:5 such as .

Methods

Participants and Task

27 undergraduate participants were given a pencil-and-paper assessment of aspects of their fractions knowledge that included a task adapted from Carraher (1996) shown below (Fig. 1).

5. The fraction shown by the line segments below represents $\frac{3}{5}$. If you double the length of **both** line segments, what did you do mathematically? (Write an equation and try to solve the problem. Then explain.)

a. Equation:

b. Explanation:

Figure 1: Selected task

Data Analysis

First, we considered any nonsymbolic drawings or markings made by participants on the representation. We categorized markings as one of five types: partitioning each segment separately, partitioning both segments, extending both segments, extending only one segment, and no markings/drawings. Second, we categorized equations as either showing the fraction as a ratio remained the same ("correct") or did not ("incorrect"). Subcategories were created for equations that were procedurally correct and those that were not, those that included idiosyncrasies such as the presence of algebraic symbols, and those treating the problem mathematically as either two separate equations or one equation. Finally, explanations were classified as either congruent with the procedure, in conflict with the procedure, or not present.

Results

Results were consistent with the extensive body of research demonstrating learner difficulties coordinating numerical and non-symbolic representations of fractions (e.g., Moss & Case, 1999).

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

Here, we focus on examples that help communicate the diversity of responses generated. The figures below show examples of a "correct" result with a procedurally correct equation where the verbal response is in agreement (Fig. 2), a "correct" result with algebraic symbols and an incorrect procedure that is in conflict with the explanation (Fig. 3), as well as examples of an "incorrect" result with an incorrect procedure (Fig. 4), and a "correct" result with a correct procedure that is approached in two separate equations (Fig. 5). It is of note that 15 participants verbally explained the result as an equivalent fraction – not including those participants who found the result to be 6/10 or 3/5. Finally, two participants *explicitly* identified the two segments as a single "whole" or unit (Fig. 2 & Fig. 3).

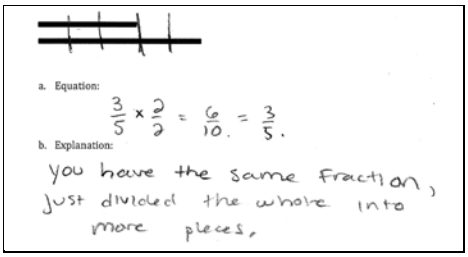

Figure 2: Partitioned "whole"

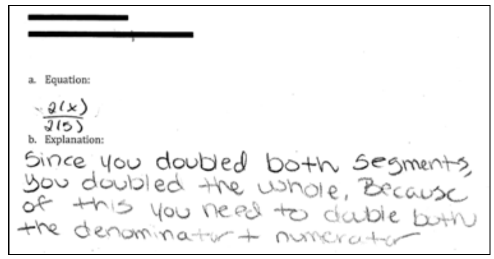

Figure 3: Algebraic symbol use with unit "whole"

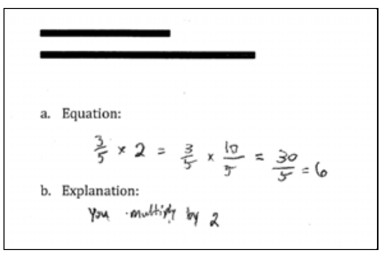

Figure 4: "Incorrect" response

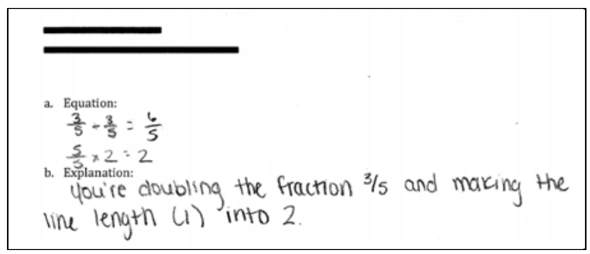

Figure 5: Separate equations (and operations)

Discussion

Although this study is clearly limited in scope (indeed, it only considers a singe task), we feel the wide variety of procedures brought to bear on identifying the "same fraction" as well as the explicit identification of two segments as a unit whole are notable. They demonstrate a marked need to continue the project of disentangling numerical, nonsymbolic, and verbal understandings of what might constitute a unit and under what circumstances. For example, it may simply have been the case that a numeric unit of 3/5 was identified and that the procedural knowledge necessary to multiply the numerator and the denominator was sufficient to recognize the resulting equivalent fraction. However, participants' drawings, explanations, and inscriptions of the nonsymbolic fraction as single or separate equations suggests different ways of interpreting the representation - from potentially a single perceptual item that can be "doubled" (Fig. 2 & Fig. 3) to separate unit items that are not integrated (Fig. 5). Similarly, it is difficult to determine what additional mathematical processes support idiosyncratic symbolic responses that recognize the preserved ratio (Fig. 3) or those that appear not to rely on perceptual supports at all (Fig. 4). Thus, further research is needed to delimit alternative ways in which units come to be understood– particularly insofar as basic perception may support certain intuitive conceptions which may help ground more formal knowledge. Ultimately, if unit ratios can in fact be both perceptually *and* mathematically identified, this may have implications for early fractions pedagogy by leveraging a more intuitive “sense” of proportional and multiplicative reasoning.

Introduction/Purpose/Methods

Researchers have identified a shared cognitive necessity for understanding fractions as numbers and for conceptualizing multiplication (and division) – an ability to *coordinate multiple levels of units* (Hackenberg & Tillema, 2009; Steffe, 1992). We describe how a teacher's alternating tasks with fractions and tasks with whole numbers in multiple contexts contributed to growth in a sixth-grade student's (Dylan) ability to coordinate units during an 11-session constructivist teaching experiment (Steffe & Thompson, 2000).

Results/Conclusions/Implications

Dylan had interiorized two levels of (whole number) units and could coordinate a third level of whole number unit in activity at the onset of the teaching experiment. Introducing tasks where the units coordination demands varied helped Dylan begin to anticipate coordination of three levels of units in activity with fractions. Dylan thus made progress toward interiorizing three levels of units, a developmental precursor to understanding improper fractions as numbers (Steffe & Olive, 2010).

Within-session task sequencing generally involved whole numbers tasks preceding fractions, but the random sequencing of tasks in some contexts, including engagement with the iOS app *CandyDepot* (LTRG, 2013)meant that any task could potentially involve improper fractions or whole numbers. This seemed to help prolong productive interaction in Dylan's zone of potential construction (Norton & d'Ambrosio, 2008). Future plans include further investigations of this conjecture and its generalizability.

Keywords: Algebra and Algebraic Thinking; Instructional Activities and Practices; Elementary School Education; Teacher Knowledge

This poster reports the evaluation findings of a sustained early algebra professional and curriculum development project; Conceptual Algebra Readiness for Everyone, (CARE) in fourth and fifth grade for both students and teachers. CARE is designed to prepare students conceptually for algebra-conceptual algebra readiness. Through a state Mathematics Science Partnership grant with a local school system we developed weekly problem solving activities for students in grades 3-7 to improve their conceptual algebra readiness. Our guiding rationale is that helping students understand certain underlying, foundational concepts of algebra will prepare them for future success in formal algebra.

Three parts of the evaluation are presented. First, treatment/control test results of algebra readiness test given to fourth and fifth grade students are provided. Second, graphs of the mathematics standardized test results over a five year period for grades 4 and 5 are given. Finally, results from the Diagnostic Teacher Assessments in Mathematics and Science (DTAMS) Exam from the University of Louisville was utilized to determine if professional development impacted teachers' mathematical content knowledge. The methodology and participants differed for each part of the evaluation. The project and evaluation occurred in a Midwestern, high-needs, urban school (free and reduced lunch rate of 75% and a minority population of 51%). The results provided were collected in different years and involve different cohorts of teachers and students.

Results from the evaluation indicate that children using the CARE materials are engaged in deep mathematical thinking. Not only are they problem solving, but they are able to model mathematical situations and describe their own thinking in mathematical language. In almost every case, there are indicators that they are engaged in mathematical practices consistent with the Common Core State Standards for Mathematical Practice. Classroom observations of students engaged in these activities indicated that students enjoy solving the activities and that many teachers are developing problem based learning approaches to instruction. Students are frequently engaged in rich mathematical discussions. Many of the teachers and students are realizing the type of instructional practice advocated by the CCSS. These results indicate that students are developing algebraic reasoning through their participation in the project.

Our study supports current research that early algebra interventions can impact algebra readiness (Blanton, Stephens, Knuth, Gardiner, Isler, & Kim, 2015) and provides evidence that teachers can successfully provide algebra readiness interventions. Teachers, when provided with the appropriate professional development, can be agents of change for algebra readiness.

The National Research Council (2010) review noted the dearth of detailed studies of mathematics teacher education programs. As algebra is a gatekeeper for advanced mathematics and science studies and career opportunities (Kilpatrick & Izsàk, 2008), it is important to investigate the opportunities that preservice teachers (PSTs) have to prepare to teach algebra to diverse student populations at a program level. The Conference Board of the Mathematical Sciences (2012) recommends that PSTs should have opportunities to learn advanced algebraic knowledge and connections between advanced algebra and school algebra in five dimensions: (1) applications, (2) algebraic structures, (3) connections between geometry and algebra, (4) reasoning and proofs, and (5) technology. This poster will describe the nature of opportunities provided by three secondary mathematics teacher education programs (Beta, Gamma, and Kappa Universities) according to these five dimensions.

For this poster we draw on case study data from a larger project, but we only analyzed interviews with instructors of Linear Algebra and Abstract Algebra. Here we preview results from Linear Algebra, but the poster will also include results from Abstract Algebra.

Instructors of Linear Algebra at Beta reported opportunities to learn [OTL] advanced algebra across all five dimensions, whereas Gamma offered OTL across the four dimensions other than technology, and Kappa offered OTL across the four dimensions other than applications. Across the three programs instructors reported fewer opportunities to learn connections between advanced algebra and school algebra than opportunities to learn advanced algebraic ideas. Beta stood out by offering opportunities to learn connections across all dimensions. Gamma provided opportunities to learn connections only in the dimensions of applications and reasoning and proof. Kappa offered no opportunities to learn connections at all. In addition to quantitative differences, universities provided qualitatively different experiences to learn in each dimension. For instance, for the dimension of technology, Kappa only used TI-84 calculators, whereas Beta used Maple.

Keywords: Algebra and Algebraic Thinking; Middle School Education; Equity and Diversity

An enduring challenge in today's middle schools is the increasing need to understand students' diverse cognitive needs and organize mathematics instruction accordingly. Students enter middle school at different levels of reasoning about multiplicative relationships (Hackenberg & Tillema, 2009). These levels affect the way they understand quantitative relationships, thus affecting the way they work with and talk about fractions. One way schools have traditionally dealt with cognitive difference is to track students into different classes. Another way, which is relatively new, is differentiating instruction by creating tasks that are both accessible and challenging for different groups of students (Tomlinson, 2014). In order to differentiate instruction for cognitively different students in mathematics, it is necessary to create models of student thinking (Steffe, 1994). This requires attention not just to the products a student creates, but also to the meaning of those products.

Our study is part of a larger study that investigates how to differentiate mathematics instruction at middle school. The focus of our poster study is on models of middle school students' reasoning with quantitative relationships and the potential use of those models in differentiating instruction. In our analysis we use video/audio records of individual and group work of middle school students in addition to their written and computer works. Specifically, we look at their drawings, algebraic notation and explanations of fractional relationships between two unknown quantities.

Our preliminary analysis shows interesting differences in the models of thinking we have created for two students who are at the same level of multiplicative reasoning. For example, one student anchored his explanations of quantitative relationships in drawings and seemed to create equations based on those. The other student appeared to anchor her explanations in equations, struggling with visual representations of quantitative relationships. Given the persistence of this level of reasoning for students (Steffe, 2007), we would like to learn more about the models of reasoning for these students by researching the diversity of thinking within the group. We believe this will guide us in responding to our students' diverse cognitive needs through differentiated mathematics instruction.

Keywords: Algebra and Algebraic Thinking; Modeling; Teacher Education-Preservice; Teacher Knowledge

The U. S. Department of Education (2009) noted that teaching is becoming increasingly challenging as teachers seek to meet changing needs and requirements: Diversity of student populations is growing and state graduation requirements, especially with respect to algebra, are evolving. Algebra is a foundation for advanced mathematics and a gatekeeper for high school students to enter a college or university (e.g., Kilpatrick & Izsák, 2008). Given this context, teacher education programs play a vital role in supporting pre-service teachers (PSTs) to overcome these challenges and prepare their students to learn about algebra.

Modeling is an area that has been emphasized since *Common Core State Standards for Mathematics (CCSSM)* included modeling as a mathematical practice for all K-12 students (NGA & CCSSO, 2010). The processes of modeling described in *CCSSM* (e.g., identifying and selecting variables) is related to algebra learning because students choose variables and develop algebraic representations (e.g., graphs, equations) to solve realistic problems. The new expectations from *CCSSM* related to modeling raise questions about whether teachers are being prepared to teach algebraic modeling in secondary school mathematics classrooms.

As part of a larger project, *Preparing to Teach Algebra*, we gathered data at five universities to investigate PSTs' opportunities to learn about algebra. We interviewed instructors of required mathematics and mathematics education courses for PSTs and collected corresponding instructional materials. We also interviewed two groups of PSTs from each institution. With these data sets, we aim to answer the question, "What opportunities do secondary mathematics teacher preparation programs provide to learn about algebra related to the modeling standards described in *CCSSM*? For data analysis, we coded our data according to each modeling process described in *CCSSM* and compared different types of opportunities.

We will present concentrations of opportunities provided to PSTs to learn about and learn to teach algebra related to each modeling process within and across mathematics and mathematics education courses in five institutions. For example, at Gamma University, both instructors and PSTs describe diverse opportunities to learn about creating algebraic representations and few opportunities to reason behind their solutions to modeling problems. Teacher educators can look across opportunities provided from these exemplar teacher education programs to find gaps in their programs and refine their instructions about algebraic modeling.

MATHEMATICAL EQUIVALENCE AND ALGEBRA: FUNCTIONS, VARIABLES, AND EXPRESSIONS

Tamika A. McLean

kmix@msu.edu

Keywords: Algebra and Algebraic Thinking; Middle School Education

Mathematics educators and researchers agree that algebra is pivotal in students' mathematical development (National Research Council [NRC], 1998; RAND Mathematics Study Panel, 2003). However, children encounter many obstacles as they acquire algebra (National Council of Teachers of Mathematics, 1988). Because of its importance and the challenges children have learning it, experts have recommended introducing algebra as early as kindergarten (NRC, 1998; RAND, 2003). This recommendation raises questions about how algebraic thinking develops over the longer term, and what prerequisite knowledge is needed for success. The current study investigated students' understanding of mathematical equivalence as it relates to performance on a range of algebraic tasks.

Some students have an operational understanding of the equal sign and view it as a signal to supply an answer or apply the operation. Those students fare worse in algebra than those with a relational view of equivalence in which they view the equal sign as representing a balance between two quantities (Knuth, Stephens, Mcneil, & Alibali, 2006). This research, however, has focused solely on the effects of equivalence understanding on solving algebraic equations. Thus, it is unclear whether equivalence concepts also impact learning in other areas of algebra.

There is reason to think equivalence understanding is implicated throughout this system. For functions, students have to understand that any manipulations that they make to x will result in a particular value of y. The relational view of mathematical equivalence might help students perceive the functional relations among symbols rather than focusing on specific quantities. Similarly, variables are symbols that represent unknown quantities in an equation or expression. A relational understanding of equivalence might help students comprehend their many-to-one mapping to referents.

In the present study, 242 7th and 8th grade students completed a 22-item written assessment that included items about equivalence, equations and equation solving, expressions, functions, and variables. Students' level of equivalence understanding was coded according to the guidelines provided in Knuth et al. (2006). In a series of regressions, with level of algebra instruction controlled, there were significant relations between equivalence understanding and three algebra subskills (variables, functions, and equations). This finding suggests that differences in equivalence understanding can have far-reaching effects on algebra learning.

USING FRACTION MODELS WITH DEVELOPMENTAL ALGEBRA STUDENTS

Nicole A. Muckridge
Kent State University
nmuckrid@kent.edu

Keywords: Post-Secondary Education; Rational Numbers; Instructional Activities and Practices

The National Center for Education Statistics (NCES) reported that almost 30% of incoming freshman students entering a postsecondary institution in the fall of 2000 needed developmental coursework due to a lack of preparedness for standard credit-earning courses (Wirt, Choy, Rooney, Provasnik, Sen, & Tobin, 2004). The majority of these developmental courses were in the area of mathematics. Despite this remediation, developmental mathematics courses usually have the highest failure and incompletion rates among all developmental subjects (Bonham & Boylan, 2011). According to data from the National Educational Longitudinal Study, only 30% of students pass all of the developmental mathematics courses in which they enroll, as compared to 68% in writing and 71% in reading (Attewell, Lavin, Domina, & Levey, 2006). These developmental mathematics courses become a barrier to students' degree completion. Therefore it is necessary to examine the concepts with which students in these courses typically struggle. Fractions have been studied extensively across the middle and high school grades and have repeatedly been cited as a difficult concept for students of all ages (Moss & Case, 1999). Yet, fraction understanding is essential for further learning of mathematics. To date, little research has been done on adult developmental students' understandings and conceptions of fractions.

The purpose of this study was to examine adult developmental algebra students' knowledge of fraction addition with unlike denominators. Prior research has shown that two typical errors are made by students when adding fractions with unlike denominators: representing fractions with unequal whole units and not using a common denominator (Hui-Chuan, 2014). The present study conducted clinical interviews with two adult developmental algebra students. The first set of interviews revealed errors consistent with the aforementioned research, as well as the tendency to try to remember rules learned in prior mathematics courses. Additionally, participants' responses on fraction addition tasks did not rely upon a model (e.g., pie chart) to represent the fractions or upon rational number sense (e.g., magnitude and/or estimation of the fractions). A teaching activity using paper folding was designed and implemented during the second set of interviews. The activity helped both participants to understand *why* equal whole units and common denominators are necessary in fraction addition.

THE ROLE OF SLOPE IN CONCEPTUALIZING THE LINE OF BEST FIT

Courtney Nagle
Penn State Erie, The Behrend College
crt12@psu.edu

Stephanie Casey
Eastern Michigan University
scasey1@emich.edu

How students conceptualize slope and the extent to which they are able to consider functions as relations of covarying quantities impacts their understanding of linear functions as well as advanced topics that require a foundational understanding of linearity. In this case study, we consider how one student, Claire, leveraged her notions of slope when conceptualizing and placing the line of best fit (LOBF). In particular, we call on previous research to investigate the conceptualizations of slope (Moore-Russo, Connor, & Rugg, 2011) and the stages of covariational reasoning (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002) Claire used on four interview-based tasks which asked her to place a straight piece of wire to represent the LOBF on a scatterplot (see Casey, 2015).

The first two tasks involved scatter plots representing the relationship between the drop height and corresponding bounce height of a golf ball. Claire struggled with the notion of placing a straight line to represent non-collinear data points. Her responses showed that she was neither reasoning about slope nor the covariational relationship between drop height and bounce height. She placed inaccurate lines that were meant to show the range of values represented by the points. The second two tasks provided a context (ticket price vs. movie attendance) that seemed to resonate with Claire. She immediately described the relationship between the covarying quantities by describing the *Directional Change* (*L2*) between the quantities. This helped her place an accurate line using the *Behavior Indicator* conceptualization of slope. Despite her success on these tasks, Claire was not able to explain how she determined the line's steepness (*Physical Property*) using covariational language (i.e., *Amount of Change – L3*).

The findings suggest that covariational reasoning and the notion of slope are closely connected ideas and suggest the need to more carefully link the two bodies of research. Instruction that focuses on slope as indicating the increasing and decreasing behavior of a line is supported by, and in turn supports, students' ability to think covariationally about the direction of change of two quantities. More clearly describing how covariational reasoning can be developed when studying slope, one of students' earliest interactions with covarying quantities, could greatly improve the learning of slope and strengthen students' understanding of advanced mathematics and statistics.

BUILDING ALGEBRA CONNECTIONS IN TEACHER EDUCATION

Jill Newton	Hyunyi Jung	Eryn Stehr	Sharon Senk
Purdue University	Purdue University	Mich. State Univ.	Mich. State Univ.
janewton@purdue.edu	jung91@purdue.edu	stehrery@msu.edu	senk@msu.edu

Keywords: Algebra and Algebraic Thinking; Teacher Education-Preservice; Curriculum; Teacher Knowledge

Given the move toward algebra-for-all across the U.S., most mathematics teachers find themselves teaching algebra in their first position upon completion of their teacher preparation program; in addition, they are expected to teach algebra to a more diverse population of students than ever before (Stein, Kaufman, Sherman, & Hillen, 2011). Given this movement and algebra's role as a gatekeeper to college and career opportunities (e.g., Kilpatrik & Izsák, 2008; Moses & Cobb, 2001), it is imperative that we study how future teachers are prepared to teach algebra.

When future teachers learn algebra and learn to teach algebra, they need to make connections among mathematical topics and in relation to others, as they consider mathematics as a "whole fabric" (National Board for Professional Teaching Standards, 2010). In this poster, we report the findings from an investigation of future teachers' opportunities to learn about such connections. Specifically, our research question is "What opportunities do secondary mathematics teacher preparation programs provide to learn about connections related to algebra and algebra teaching? The algebraic connections of interest here include: (1) connections within algebra, (2) connections between algebra and other mathematical fields, (3) connections between algebra and non-mathematical fields, and (4) connections between college-level algebra and school algebra.

This study is being conducted as part of a larger mixed methods study (i.e., a national survey and five case studies of secondary teacher education programs) that investigated opportunities to learn about algebra, algebra teaching, equity issues related to algebra, and the algebra described in the *Common Core State Standards for Mathematics*. Data were collected from semi-structured instructor interviews, focus group interviews with pre-service teachers (PSTs), and course materials. To answer the research question of focus here, two members of the research team coded interview data for opportunities to learn related to the four types of algebra connections described above; connections that did not fit into these types were also noted.

Analysis of this data is ongoing; however, preliminary findings show that different types of opportunities to learn about algebra connections were found at all case study sites. Instructors and PSTs alike at Gamma University reported more attention to connections within algebra and between algebra and other mathematical field than to the other two types of connections. PSTs provided examples of such connections, along with how technology helped them connect algebra with geometry in the courses designed to link school and college mathematics.

It is only by investigating how PSTs are prepared to teach algebra that we can improve teacher education and effect the enduring challenge of students who are unprepared for the algebra required by college and career opportunities. This study is a step in that direction.

Inverse function, and more generally reversibility, is important for success in mathematics (Hackenberg, 2010). Researchers (Oehrtman, Carlson, & Thompson, 2008) have argued that college students, pre-service teachers, and in-service teachers construct unproductive inverse function meanings. For instance, Vidakovic (1997) identified that despite having success in determining analytical and graphical representations of inverse functions, students did not relate these representations to critical ideas of inverse function (e.g., function composition).

We used semi-structured task-based clinical interviews (Goldin, 2000) for the purpose of further understanding students' inverse meanings. Specifically, we interviewed 25 pre-service teachers using an interview protocol that consisted of decontextualized and contextualized tasks that included analytical (e.g., equation) or graphical representations. We characterize students' actions based on our perspective of the consistency of their strategies used within and among the various task types. Compatible with previous researchers' findings, we argue that students' meanings are often restricted to carrying out specific actions in analytic or graphing situations. We also illustrate that the students held compartmentalized meanings for inverse function dependent on the function and/or representation. For instance, although each of the 25 students used a consistent technique in analytic, decontextualized tasks, only five of these students were able to determine a viable interpretation of the inverse function they defined analytically in a contextual (e.g., temperature conversion) situation. An important finding is the extent that students focused on carrying out a particular activity (e.g., switching x and y); to most students, carrying out a particular activity dependent on representation and context *was* their meaning for inverse. We did not interpret these students to hold meanings for inverse function that enabled them to conceive connections across all task types. Future researchers may be interested in exploring ways that would support students in constructing productive meanings for function and inverse function in contextualized and decontextualized situations.

For many students, algebra continues to be a gatekeeper to future academic and employment opportunities. As a result, it is now widely accepted that algebra should be treated as a grades K–12 strand of thinking. In response, our project aims to examine the effectiveness of a longitudinal early algebra intervention on grade 3-5 students' algebra learning and algebra-readiness for middle school. The study described here compares understandings of the Commutative Property of Addition demonstrated by students who participated in an early algebra intervention in grades 3 and 4 to those of students who experienced more traditional elementary grades instruction.

Arithmetic properties provide students an opportunity to look at arithmetic expressions "in terms of their form rather than their value when computed," and can serve as a route into algebra (Kaput, 2008, p. 12). Based on the results of our study, we argue that traditional arithmetic approaches to properties do not provide sufficient opportunities for students to engage in the important algebraic thinking practices of generalizing, representing generalizations, justifying generalizations, and reasoning with generalizations (Kaput, 2008).

Participants included approximately 100 intervention students and 60 comparison students from two elementary schools in the same district in the Northeast. Written assessments administered at the beginning of grade 3, end of grade 3, and end of grade 4, were coded based on correctness as well as strategy use. On the grade 3 pre-test, there were no significant differences between the performances of intervention and comparison students. At the grade 3 and grade 4 post-tests, there were no significant differences between the proportions of students who invoked the Commutative Property of Addition when justifying the correctness of a specific numerical example ($23 + 15 = 15 + 23$). However, when students were asked to represent and justify this generalization, the groups' results differed significantly. Students who participated in the intervention were more successful representing the property using variables (e.g., $a + b = b + a$) and justifying why the property holds true for all numbers. Our findings suggest that arithmetic properties can serve as useful contexts to engage students in developing, representing, and justifying generalizations.

The inclusion of field properties in early grade mathematics instruction may provide teachers with the opportunity to use them as a springboard for engaging students in algebraic reasoning. The development of teachers' "algebra eyes and ears" and the use of supplemental "algebrafied" instructional materials are critical to teachers' ability to encourage such algebraic activity amongst elementary students (Blanton & Kaput, 2003).

RELATING ADDITIVE AND MULTIPLICATIVE REASONING: A TEACHING EXPERIMENT WITH SIXTH-GRADE STUDENTS

At the end of her chapter in the *Second Handbook of Research on Mathematical Teaching and Learning*, Susan Lamon (2007) lists outstanding questions for future research. The first of these is, "What are the links between additive and multiplicative structures?" (p. 662). Understanding the psychological operations that link additive and multiplicative reasoning remains relatively mysterious for researchers today. From December 2013 until May 2014 we conducted a constructivist teaching experiment (Steffe & Ulrich, 2014) with three pairs of sixth-grade students in order to investigate how the complexity of a student's additive reasoning was related to the complexity of their multiplicative reasoning. As part of this analysis, we compared the students' zones of potential construction (ZPCs) (Norton & D'Ambrosio, 2008) in coordinating multiple additive comparisons and their ZPCs in coordinating multiple multiplicative comparisons.

Using tasks and findings from previous research (Steffe & Olive, 2010), we selected students whose ZPCs included constructing multiplicative comparisons in activity but not using them to assimilate situations (Pair 1), students for whom a single multiplicative comparison could be assimilatory (Pair 2), and students who could coordinate multiple multiplicative comparisons in their assimilatory structures. These ZPCs were confirmed in various contexts throughout the teaching experiment. Multiple additive comparisons were engendered using tasks involving a second difference (a comparison of differences between quantities), such as the following:

> Team B beat Team A and Team D beat Team C. Team D won their game by 18 more points than Team B won their game by. Find the missing score. Team A: 89. Team B: ___. Team C: 54. Team D: 77.

We found that the additive complexity within each pair's ZPCs were either comparable to or greater than the multiplicative complexity in their ZPCs. In particular, these problems were not in the ZPC of Pair 1. Solving these problems was in the ZPC of Pair 2. However, constructing an assimilatory structure for the problem was surprisingly difficult: It took six teaching sessions for Pair 2 to stop regularly conflating quantities and eight teaching sessions until the underlying additive structure of these problems appeared to be assimilatory for both students in Pair 2. Finally, this problem was within the ZPC of Pair 3. One potential implication is that complex additive situations can sometimes be used to challenge a student to work with increasingly complex quantitative relationships when corresponding multiplicative complexity is outside the student's current ZPC.

LINEAR REPRESENTATIONS OF TWO-DIGIT NUMBERS PROMOTE FIRST GRADERS' ESTIMATION

Yu Zhang

Introduction. Previous studies indicated that it is not until about second grade that numerical estimations of two-digit number magnitudes show a linear correspondence between estimated and actual magnitudes (Siegler & Booth, 2004), consistent with the developmental progression depicted by Case and Okamoto (1996). The objective of the present study is to examine the effectiveness of three instructional strategies to promote first graders' acquisition of numerical magnitudes of two-digit numbers. We predicted that teaching children magnitudes of decades (e.g., 10, 20, and 30) in a linear fashion would be more effective than the alternative strategies.

Procedure. Thirty-one first graders participated in the study. The experimenter met with the participants individually for four 15-minute sessions (pretest, two training sessions, and posttest) over a 4-week period. The number estimation task (Siegler & Booth, 2004) was used as a pre and posttest measure. A blank number line (25 cm long) was drawn on a sheet of paper with "0" and "100" appearing below the left end and the right end of the number line, respectively. Each child worked on 26 estimation problems in a random order.

Training. The students were randomly assigned to one of the three training groups. In all three interventions, base-10 blocks were used. The interventions differed in the terms of which blocks were used: (1) multiple 10 blocks and unit blocks (M10U), (2) single-10 block and unit blocks (S10U), and (3) unit-blocks only (U). For the M10U group, the experimenter demonstrated how to construct two-digit numbers by using the precise combination of 10 and unit blocks. For example, 35 was constructed by placing three 10 blocks and five unit-blocks in a linear fashion. For the S10U group, the experimenter constructed 35 by placing one 10 block and 25 unit blocks in a linear fashion. For the U group, the experimenter constructed 35 by placing 35 unit blocks in a linear fashion.

Results. The students in the M10U group improved their PAE from pretest (41%) to posttest (16%) whereas the other two groups did not. All three groups at pretest showed estimation patterns best described as logarithmic but only the M10U group's estimation patterns changed to linear at the posttest ($R_{lin}^2 = 98\%$).

Discussion. The current study showed that use of base-10 blocks to show chunks of 10s in a linear fashion was effective in promoting first-graders' understanding of two-digit number magnitudes. This study showed that unstructured use or non-canonical base-10 use does not lead to improved understanding. It is the activity of placing 10 blocks in a linear fashion that helps students to build canonical base-10 representations.

CHILDREN'S REASONING WITH FRACTION REPRESENTATION SYSTEMS

Research suggests teachers should know how to selectively use multiple representations of fractions to teach for understanding (e.g., Cramer & Wyberg, 2009; National Mathematics Advisory Panel, 2008). Yet little is known about how children reason within and between elements of fraction representation systems. Drawing from Behr, Lesh, Post, & Silver's (1983) *representation systems* (i.e., pictures, manipulatives, spoken and written symbols, and "real-world" situations), we investigate this problem with the following research question: *How is children's reasoning related with their use of fraction representations?*

Part of a larger study, the data considered for this report focus on clinical interviews with four children (at the ends of 2nd, 3rd, or 4th grades) from a diverse group of 24 children in the Southeastern U.S. Children were given fraction tasks designed to probe their fraction understanding and encourage use of multiple fraction representations. Results from cycles of open coding that highlight nuances of reasoning types are presented in Table 1.

Table 1. Student Reasoning Types

Reasoning Type	Brief Description	Examples
Informal/Intuitive	"Real-world" prior knowledge is used to extend reasoning beyond the original problem context.	- Sadie introduces brownies that can be partitioned instead of candies in a discrete collection in order to reason about fraction sizes. - Ariel recognizes that 2 cakes can be cut and shared equally with 3 people after saying it was impossible to equally share 2 cookies with 3 people.
Formal and Disconnected	Knowledge within one representation is not extended to another.	- Kevin argues that 2/3 is larger than 5/8 when using an area model to compare fractions but that 5/8 comes after 2/3 on a number line.
Formal and Connected	Knowledge is extended from one representation to another.	- Paul identifies a unit fraction from a bar described as 2/5 and is able to find the length of the whole. He generalizes his knowledge when given 13/15 as a numeric symbol only.

Results both extend previous research (e.g., Cramer & Wyberg, 2009) and suggest a more nuanced approach is needed to understand student thinking with representation systems. Importantly, existing analytical frameworks for understanding how and when knowledge is connected (or not) with different representation types may be insufficient for both researchers and teachers to assess and support student thinking at fine-grained level of analysis.

TEACHERS' EXPECTATION ABOUT GEOMETRIC CALCULATIONS IN HIGH SCHOOL GEOMETRY

Nicolas Boileau
University of Michigan
nboilea@umich.edu

Patricio Herbst
University of Michigan
pgherbst@umich.edu

This paper reports on a study of the instructional situation in high school Geometry that Hsu (2010) called Geometric Calculation in Algebra (GCA). In particular, we conducted a virtual breaching experiment in order to examine the extent to which high school teachers recognized breaches of two norms that we conjectured to describe geometry teachers' expectations of this work context. The results of our analysis of the data (using z-tests and mixed effect regression models) provide evidence that, in the situation of GCA, (1) teachers appear not to take issue with giving students tasks that require them to set-up and solve equations whose solutions have no geometric meaning (e.g., the length of a side of the figure is zero), and (2) teachers do not appear to expect students to document the geometric theorem or property that justify the setup of those equations (highlighting the contrast between the situation GCA and that of doing proofs).

Keywords: Algebra and Algebraic Thinking; Geometry; Instructional Activities and Practices; Measurement

In an effort to describe the practice of teaching mathematics in schools, some mathematics educators have argued for the importance of understanding the factors that influence mathematics teachers' instructional decisions. Some researchers have described these decisions as motivated by the teacher's individual goals, beliefs, and knowledge (Schoenfeld, 2010). However, others have sought to complement this perspective by suggesting that decisions might also be understood as influenced by customary norms of the practice of teaching. In their account of the practical rationality of mathematics teaching, Herbst and Chazan (2012) suggest that students and teachers recognize some patterns of interaction as defaults for recurring classroom situations (e.g., when doing proofs in high school geometry class).

This study investigates norms of another instructional situation in high school geometry instruction: what Hsu (2010) has referred to as Geometric Calculation in Algebra. We use Herbst's (2006) definition of instructional situation to conceptualize geometric calculations in algebra (GCA): GCA enables an exchange between the work students do posing and solving an equation and the claim their teacher can make that they know properties about a geometric figure (to which the equation refers). As in the case of other instructional situations, we expect there are norms for what the teacher and the student are expected to do to enable them to do such work and operate such exchange. Figure 1 shows an example of a GCA task.

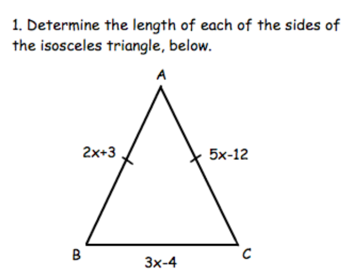

Figure 1: Sample GCA task

The example in Figure 1 illustrates some norms of GCA: Students are informed (often, through a diagram) that certain dimensions of a given geometric figure can be represented by given algebraic expressions and they are expected to use their knowledge of the properties of that figure to set up and solve algebraic equations using the given expressions in order to find one or more of the figure's dimensions. Their success in this work counts toward their understanding of the geometric properties of the figure as well as their retention of algebraic skill.

The work of investigating the norms of this instructional situation may be of interest to mathematics educators (both practitioners and researchers) for several reasons. For one, in terms of efforts to understand and describe the ways that mathematics is actually taught and learned in schools, norms provide interesting insights because they represent both expected actions and a rationale for teacher's instructional actions. Norms also provide a baseline in the process of improving instruction: Efforts to change instruction need to oppose existing norms and propose justifiable breaches of such norms. Along those lines, while this study explores GCA in particular, its methods are equally applicable to the study of norms of other situations in other courses of study beyond high school geometry. Second, for those particularly interested in geometry instruction, the situation of GCA is a common instructional situations in American high school geometry courses, and one that provides students with opportunities to engage in practices that have generally been supported by mathematics educators, such as engaging in algebraic and geometric reasoning as well as connecting multiple representations (NCTM, 2014). Further, Hsu (2010) argued that geometric calculation tasks offer students inroads to the types of reasoning needed for understanding and writing proofs in geometry.

Based on our observations of American high school geometry classrooms and informal analysis of geometry textbooks, we hypothesized that the following were norms of the instructional situation of GCA:

- When a GCA task is given to students the algebraic expressions associated to the dimensions of the figure are such that when an equation is set-up on the basis of one or more true geometric properties of the figure the numerical measures obtained from the solution of such equation will have interpretable geometric meanings (e.g., side lengths and angle measures will be positive).
- Although students may be asked to state orally the geometric property that they use to set-up one or more equations when solving GCA problems at the board, they are not expected to write that property.

For sake of brevity, we will refer to the first of these two norms as the GCA Figure (GCAF) norm and to the second as the GCA Theorem (GCAT) norm.

Similar to other mathematics educators who have endeavored to investigate instructional norms (e.g.,Dimmel, 2015; Herbst, Kosko, & Dimmel, 2013), we adopted a variation of a breaching experiment (Garfinkel, 1963) to determine whether two norms that we conjectured to exist actually describe how high school geometry teachers expect work on GCA problems will unfold, by examining the extent to which high school mathematics teachers recognize breaches of them. Accordingly, we posed the following two research questions:

- Do the GCAF and GCAT norms exist (i.e., represent how high school geometry teachers expect work on GCA problems will unfold)?
- How do participants react to breaches of the GCAF and GCAT norms?

Further, aware that in any instance of an instructional situation more than one norm might be breached, we also sought to investigate how breaches of a given norm at one point in a lesson might influence teacher's reactions to breaches of norms of that situation that occur later in the lesson. We therefore also posed a third research question:

- Is participants' recognition of breaches of the GCAT norm affected by whether the GCAF norm is breached or complied with?

In order to measure teachers' recognition of breaches of these hypothesized norms, we designed and implemented a research instrument, which we describe in the next section.

Methods

Data Collection

The present study represents a first attempt at answering our three research questions – by designing a research instrument and using it with a convenience sample of 40 high school mathematics teachers from a Midwestern state. The instrument designed sought to elicit mathematics teachers' reactions to storyboard representations of classroom scenarios, through online multimedia questionnaires, in order to determine whether hypothesized norms of the instructional situation of GCA exist, by measuring the extent to which participants recognize the breaches of those hypothesized norms (see Herbst, Kosko, and Dimmel, 2013) that occurred in some of those scenarios.

The instrument was comprised of twelve item sets. Each item set consisted of various questions referring to one storyboard. The scenario represented by each storyboard can be described as following one of three experimental conditions, which we refer to as the CFCT, the CFBT and the BFBT conditions (to denote which of the two norms are breached or complied with). The four CFCT scenarios were conjectured to be completely normative (both norms were complied with). The four CFBT scenarios breach the GCAT norm, but not the GCAF norm. The four BTBF scenarios breach both norms. We represented four scenarios of each condition to increase the "construct validity" (Shadish, Cook, & Campbell, 2002) of the instrument – only having one scenario of each condition would threaten the validity of our claim that participants' responses to the scenarios represent whether and how participants might react to breaches or compliance with the two norms (rather than the specific task or other incidental aspects of the scenario). One way of distinguishing the four scenarios in each experimental condition is by describing them as following one of four general storylines (i.e., plots), which differ in terms of how the task and student who solves it are selected, as well as how the correctness of the students' solution is discussed. The scenarios also differ in terms of the figure in the task – a feature that we use to title the storylines: the similar-triangles storyline, the trapezoid storyline, the isosceles-triangle storyline and the parallelogram storyline.

Each storyboard consists of 12 frames. During the first three frames, the class selects a GCA task to work on and the teacher either asks for a volunteer or selects a student to solve it, at the board. This occurs in one of four ways (depending on which storyline the given scenario follows), all of which were conjectured to be normative (e.g., the teacher in the scenario may accept a student's request to review a problem from the homework given the day before or may choose a problem that they conjecture might challenge the students; they may request that a particular student share their solution or ask for a volunteer). In the following three frames of each storyboard, the teacher puts the problem on the board and asks for the selected student to present their solution. In the CFCT and CFBT scenarios, the task complies with the GCAF norm, while in the BFBT scenarios, it breaches the GCAF norm by involving algebraic expressions that imply that the length of one of the sides of the figure is less than or equal to zero (and, therefore, that the figure does not exist). In the following three frames, the selected student writes a correct equation on the board, after which the teacher asks the student what theorem or property they used to set-up that equation. In all cases, the student identifies a correct theorem but, whereas in the CFCT and CFBT scenarios the teacher then affirms the student, in the BFBT scenarios the teacher breaches the GCAT norm by saying something that conveys that they expected the student to write the theorem or property on the board (e.g., the teacher says "Why was that not written on the board? Please always write down the properties you use to justify your work."). In the last three frames, the student finishes correctly solving the problem and asks the teacher to help them determine whether their solution is correct. This occurs in one of two ways, both of which were conjectured to be normative - the teacher either asks the class whether they think the solution is correct (which occurs in two of the storylines) or asks a specific student the same question (which occurs in the other two storylines). In the CFBT and BTBF scenarios, the theorem or property used to set up the first equation is also written on the board, in response to the teacher's request[1].

For each item set, and hence for each scenario, the questionnaire contained seven open-response and five closed-response questions. After being shown the first six frames of a storyboard, participants were asked, "what did you see happening in this first segment of the scenario?" and provided with an open box in which they could type their response. Asking this type of question (a prompt for participants to describe what they notice about a given scenario) permits one to observe what participants tacitly expect will occur in those situations. In line with the notion of breaching experiments, we would expect that most participants who saw a scenario where GCAF had been breached would remark that breach. After that open-ended question, participants were asked to rate the appropriateness ofthe teacher's actions in the first three frames of the storyboard, using a 6-point Likert scale, and asked to explain their rating in an open-response field. The same appropriateness questions were asked about the second group of three frames of the storyboard. From the explanations of their ratings, we also expected to see evidence of participants' recognition of the breaches of the GCAF norm as well as to learn why some teachers might disagree with certain breaches, while others might deem them justifiable.

Participants then saw the second half of the scenario (the third and fourth segments) and were asked the same three open-response and two closed-response questions about those segments. Last, they were asked to rate the appropriateness of the teacher's facilitation of the work on the problem throughout the scenario (again, using a 6-point Likert scale) and to explain their answer (in an open response field). This last question was posed, in particular, to provide participants with an opportunity to remark on breaches of the GCAF norm, in the chance that they had not realized that the task was not normative (if it was not) when it was first put on the board, but realized it once the student finished solving it.

Each participant was randomly assigned to one of three groups, each of which was assigned four item sets (two of one condition and two of another), as follows:

- Group 1 was assignedtwo CFCT item sets, one that followed the similar-triangles storyline and one that followed the trapezoid storyline, as well as two CFBT item sets, one that followed the isosceles-triangle storyline and one that followed the parallelogram storyline.
- Group 2 was assignedtwo CFBT item sets, one that followed the similar-triangles storyline and one that followed the trapezoid storyline, as well as two BFBT item sets, one that followed the isosceles-triangle storyline and one that followed the parallelogram storyline.
- Group 3 was assignedtwo BFBT item sets, one that followed the similar-triangles storyline and one that followed the trapezoid storyline, as well as two CTCF item sets, one that followed the isosceles-triangle storyline and one that followed the parallelogram storyline.

Data analysis

As each participant was assigned two item sets of the same condition, we used mixed effects regression models (Agresti & Finlay, 2009) to analyze the closed-response data, using MemberID (a variable used to keep track of which responses were associated with which participant) as the random effect. The outcome variable in each model was the set of responses to one of the five Likert-scale items that asked participants to rate the appropriateness of the teacher's action (in each of the four segments of the scenario, then overall). To be able to compare ratings of scenarios of different experimental conditions and scenarios of different storylines, we created two variables - Condition (with values CFCT, CFBT, BFBT) and Storyline (with values similar-triangles, trapezoid, isosceles-triangle, parallelogram) – applied these to code each of the closed-responses and, after dichotomizing each, used those dichotomous variables as dependent variables in each model. The CFCT condition was used as the reference group for the CFBT and BFBT conditions, because the CFCT scenarios were designed as control scenarios (i.e., neither norm was breached in them). The choice to have the similar-triangles storyline as the reference group was arbitrary, as all scenarios were designed to be normative except for whether or not they complied with either the GCAF or GCAT norms.

We hypothesized that, when controlling for the Condition variable, there would be no significant differences between the mean ratings of the scenarios of different storylines, in any of the models, as we conjectured that the teachers' actions in each were equally appropriate (as they were designed to be normative, outside of the moments when each of the norms were at issue). Similarly, we also conjectured that there would be no significant differences between the mean rating of segments 1 and 4 of the scenarios, when controlling for the Storyline variable. The only significant differences we expected to observe were in the mean ratings of segments 2 and 3 of the scenarios, because they each relate to part of the text where one of the norms was breached in some items, but not in others. Specifically, since the GCAF norm was only breached in segment 2 of the BFBT scenarios, we expected that it would be rated significantly lower than segment 2 in CFCT (the reference group) scenarios, on average. As the GCAT norm was breached in segment 3 of both the CFBT and BFBT scenarios, we expected that it would be rated significantly lower than segment 3 in the CFCT scenarios, on average.

Last, to evaluate our hypothesis that teachers would recognize the breaches of our two hypothesized norms, we created two dichotomous codes – one representing that there was evidence of recognition (versus non-recognition) of the breach of the GCAF norm and one representing that there was evidence of recognition (versus non-recognition) of the breach of the GCAT norm – and applied each to all open-response items. The following is an example of a response coded for recognition of a breach of the GCAT norm: "Kids solves it but doesn't write justification. Teacher tells kid (with different word choice) to write justifications. Kid does it and we move on."

Each participants was then given two scores – one indicating whether there was evidence of recognition of a breach the GCAF norm in any of their open responses and another indicating whether there was evidence of recognition of a breach of the GCAF norm in any of their open responses. A series of z-tests were then conducted to determine whether most participants who were assigned each item that contained a breach of one or both norms recognized those breaches.

Results

Results related to research question 1

In terms of the results of the twelve z-tests of the proportion of participants who recognized the breach of the GCAT norm in each open-response item (against the null hypothesis of 50% recognition), as predicted, no participants recognized a breach in any of the CFCT-condition items, as the norm was not breached in those scenarios. The proportion of participants who recognized the breach in each of the CFBT-condition and BFBT-condition items, except one, ranged from 0.45 to 0.73 (but none of those values were statistically significant at the level of 0.05).

Further, when coding the open-response data for recognition of the breaches of the GCAT norm, we noticed that there were several participants who noted that the teacher requested that the student state the theorem or property that they used to set-up the equation. Consequently, we also conducted a z-test of the proportion of participants that recognized this request in relation to each item. The results indicate more than 50% recognition in all the CFBT-condition and BFBT-condition items (in some cases, significantly more). In fact, even the proportion of participants that recognized this request in each of the four CFCT-condition items was 0.82, 0.43, 0.47 and 0.33.

One surprising result was that, although all BFBT scenarios contained a breach of the GCAF norm, there was only evidence that one participant recognized one of those breaches. Further, this evidence was in their response to the rating of the third segment of the scenario, when they wrote: "the teacher is allowing the student to discover that there is no solution to the problem". Therefore, there was no recognition of the breach of the GCAF norm when the problem was being written on the board (despite this being done over three frames). As we discuss in the next section, this result suggests the need for deeper exploration of the GCAF norm.

Results related to research questions 2 and 3

The results of the five mixed-effect regression analyses (one for each of the ratings of the four segments of the scenario and one for the rating of the teacher's facilitation of the work on the problem throughout the scenario) are summarized in table 1 and generally confirm most of our hypotheses.

As indicated in table 1, when controlling for the Condition variable, we see that all but two of the coefficients are not significant. This supports our earlier claim that, outside of the breach or compliance with one or both of the norms, participants rated the teachers' actions in the scenarios as being similarly appropriate. On the other hand, the two significant Storyline coefficients suggest that this might not be the case. We will discuss this point further in the next section.

When controlling for the Storyline variable, the coefficients for the Segment-3 ratings and the Overall ratings of the CFBT scenarios and BFBT scenarios are negative and significant. This indicates, as hypothesized, that ratings of the segment of the scenarios in which the GCAT norm was breached would be rated lower, on average, than the equivalent segments of scenarios in which that norm was not breached (CFCT scenarios), and that the same would consequently be true for the overall rating of the scenarios. However, neither the rating of segment 3 or the overall rating associated with BFBT scenarios was significantly different than those of the CFBT scenarios. Although this does not provide us with evidence to believe that participants' reactions to breaches of the GCAT norm are influenced by the reactions to breaches of the GCAF norm, as we also discuss in

Table 1: Summary of Mixed Effect Regression Analyses for Variables Predicting Ratings of Each Segment of the Scenarios and the Overall Rating

	Seg-1 rating B(SE)	Seg-2 rating B(SE)	Seg-3 rating B(SE)	Seg-4 rating B(SE)	Overall rating B(SE)

the next section, lack of recognition of the GCAF norm could be the explanation for this.

Also in line with our hypotheses, the mean ratings of segment 4 in all scenarios were similar, which was expected, as no norm was breached in that segment of any of the scenarios. In contrast, however, segment 1 and segment 2 of the CFBT scenarios were rated significantly higher, on average, when controlling for the Storyline variable, than those segments in the CFCT scenarios, which contrasted with our hypothesis that they would be rated similarly (as both of those segments in all of those scenarios were also designed to represent normative instruction).

Discussion: Potential Revisions to the Instrument

Although the results of the study are mixed, in the sense that the instrument provided us with evidence that the GCAT norm is, in fact, a norm of the instructional situation of GCA, but did not allow us to conclude the same about the GCAF norm, nor to detect any relationship between the way that participants reacted to the two norms, the results do provide us with ideas for future research. For one, we would argue that the general design of the instrument is promising. The "what did you see happening…" questions provided us with evidence that one of the hypothesized norms exists. Another affordance of the open-response questions was that they not only allowed us to collect evidence in support of our hypothesized norms, but also allowed us to consider whether and how to revise these hypotheses. Although the proportion of participants that recognized breaches of the GCAT norm in some of the scenarios was as high as we expected, there were scenarios for which the proportion was lower. Of course, this could be a consequence of the small sample size or the representativeness of the sample, but the proportions of participants that recognized the teachers request that the student state the theorem or property at least suggests that the norms might have been slightly different than we first conjectured. For example, it could be that the norm is in fact that students are not expected to write or state the theorem or property that they used to set-up their equation(s). This alternative is supported by the fact that many of the participants' attention were drawn to the request to state the theorem of property, even in the CFCT scenarios.

In terms of the lack of recognition of the GCAF norm, although it could indicate that the norm does not exist, we argue that this is more likely a consequence of at least one of the following two issues with the scenarios. The first is that, in order to detect that the norm was breached, a participant would have likely had to work through the problem, which they might not ordinarily have to, if they assumed that the task was normative, as it had been put on the board by the teacher in the scenarios. Alternatively, there is also evidence in the open-response data that there were more distracting aspects of the scenarios than whether or not the norm was breached. In particular, many participants commented that the teacher took too long (3 frames) to write the problem on the board and that they should have instead used a document camera or have the student write the problem on the board, while the teacher circulated. We found the suggestion of having the student put the problem on the board to be especially helpful, as we conjecture that the teacher would also more likely analyze a problem if the student was the one putting it on the board, and are considering revising the items to integrate this change.

Last, as we are more likely to detect a relationship between the two norms if participants recognize the breaches of the first norm, we are considering adding a question, after they evaluate the first half of the scenario but before they evaluate the second half, that will ask participants to rate the appropriateness of the task in the scenario, expecting that this will also require them to analyze the GCA task (if they did not do so when it was put on the board). Similar to our other rating questions, their rating of the task and their explanation of that rating could also provide us with some evidence that teachers recognize the GCAF norm, even if breaches are not remarked in the first three open-responses.

INVESTIGATING SECONDARY MATHEMATICS TEACHERS' ATTITUDES TOWARD ALTERNATIVE COMMUNICATION PRACTICES WHILE DOING PROOFS IN GEOMETRY

Justin Dimmel

Pat Herbst
University of Michigan
pgherbst@umich.edu

We used multimedia surveys to investigate secondary mathematics teachers' reactions to storyboards that represented episodes of instruction. Participants were asked open-ended questions about the storyboards. We analyzed the responses to the open-ended questions for evidence of the attitudes *(Martin & White, 2005) that participants conveyed about the episodes. We found that, when presented with storyboards that depart from what is hypothesized to be routine instruction, participants' open responses included significantly more negative than positive linguistic markers of attitude. At the same time, when participants were shown storyboards that represented what routinely happens in classrooms, markers of positive and negative linguistic markers of attitude occurred with equal frequency.*

Keywords: Instructional Activities and Practices; Geometry

Introduction

For as long as mathematics has been taught in US public schools, there have been initiatives that have attempted to improve the quality of mathematics teaching in classrooms. A fundamental challenge for such initiatives is the paradox of *change without difference*: reform efforts that, in principle, could bring about fundamental shifts in classrooms emerge, in practice, as "shadows of their original intent" (Woodbury & Gess-Newsome, 2002, p. 763). One reason for this paradox is that the patterns of classroom interaction that practicing teachers have honed through years of experience are robust. Initiatives that aim to effect change in the way that mathematics is taught thus need to contend with the realities of the already established practice of mathematics teachers (Cobb, Zhao, & Dean, 2009). To understand how reform efforts might contend with such realities we need to raise a natural question: When teachers encounter reasonable departures from routine instruction, how do they relate to such actions?

To answer this question, we conducted a study that used multimedia surveys to investigate secondary mathematics teachers' reactions to storyboards that represented episodes of instruction. Participants were asked open-ended questions about the storyboards. We analyzed the responses to the open-ended questions for evidence of the *attitudes* (Martin & White, 2005) that participants conveyed about the episodes. We found that, when presented with storyboard representations of reasonable departures from what we hypothesized to be routine instruction, participants provided open responses that contained more negative than positive linguistic markers of attitude. At the same time, when participants were shown storyboards that represented what routinely happens in classrooms, positive and negative markers of attitude occurred with equal frequency.

The analysis reported below is part of a larger study whose objective was to investigate instructional routines that pertain to discipline-specific communication practices. The communication skills used by disciplinary experts have traditionally been thought to be gradually and tacitly developed by novices as the novices are apprenticed into a field (Lemke, 2013; Thurston, 1994). But recent work in analyzing mathematical communication suggests that discipline-specific ways of communicating are practices that can be described and taught (Fang, 2012; O'Halloran, 2011; Yore, Pimm & Tuan, 2007). *Doing proofs* is one classroom activity during which students could develop discipline-specific communication practices. As the geometry classroom has historically been the principal instructional setting in which students are introduced to mathematical proof (Knuth, 2002), the instructional situation of doing proofs in geometry (Herbst & Brach, 2006) was the focus of this study.

Theoretical Framework

Classroom activity can be modeled as a social system in which an agent playing the role of teacher and other agents playing the roles of students act in accordance with tacit but mutually held norms (Herbst & Chazan, 2012). Such norms help characterize instructional situations: stable segments of classroom activity in which students' work is exchanged for claims that they have acquired items of knowledge (Herbst, 2006; Herbst & Brach, 2006). Though the instructional activity of doing proofs in geometry has been criticized by mathematics educators for being a misrepresentation of the work of proving in mathematics (Schoenfeld, 1988; Martin & Harel, 1989; Lockhart, 2009), it endures as an instructional setting where students are introduced to the notion that there is such a thing as mathematical proof. The goal of this work was to describe norms of the instructional situation of doing proofs that pertain to how student proofs are presented and checked in geometry classrooms.

We use *norm* to refer to those aspects of social situations that not only regularly happen but also that participants (in social situations) *expect* to happen (Garfinkel, 1963). In social situations, when people confront departures from what they expect, they can react with anxiety, bewilderment, or anger (Mehan & Wood, 1975). Such negative reactions are ways in which people mark that a norm has been breached. The work reported here used the notion of a *breaching experiment* (Garfinkel, 1963) to investigate secondary teachers' reactions to episodes of instruction in which hypothesized norms[1] of instructional situations were breached.

Method

Our method of inquiry combined a planned-comparison study with a virtual breaching experiment (Herbst, Aaron, Dimmel, & Erickson, 2013) in an instrument that we call a *virtual breaching experiment with control* (Dimmel & Herbst, 2014). The instrument was a multimedia survey that used storyboards to represent episodes of geometry instruction that were inspired by video records of actual geometry classrooms. Our use of storyboards to probe for recognition of norms is analogous to how scripted classroom videos have been used to probe teacher professional knowledge (Kaiser, 2014) and is an application of the cyclical use of records of practice (Jacobs, Kawanaka, & Stigler, 1999). Each participant[2] in our study viewed two sets of parallel storyboards: one set of parallel storyboards represented departures from hypothesized norms (i.e., *breach* storyboards), and the other set of parallel storyboards represented instances of instruction that were hypothesized to be routine[3] (i.e., *control* storyboards). The storyboards that were designed to represent routine instruction (i.e., the control storyboards) were based on video records of actual geometry classrooms, hence our claim that these storyboards represent the instruction that might typically occur in geometry classrooms. The storyboards in a set were parallel in the sense that they targeted the same hypothesized norm.

After viewing each storyboard, participants were given four opportunities to provide open-response data. The first question that participants were asked is: "What did you see happening in this scenario?" The purpose of prompting participants with this broad, open-ended question was to capture participants' overall reactions to the instances of doing proofs (hereafter: situation instances) that were represented by the different storyboards. This general open response question has been used in previous virtual breaching experiments (Herbst, Aaron, Dimmel, & Erickson, 2013) as a means to capture participants' reactions to storyboards. Participants had three other opportunities to provide open responses, following their review of each storyboard. These open response fields followed episode—how appropriate was the teacher's review of the proof in this scenario?—and segment-specific—how appropriate were the teacher's actions in this segment of the storyboard?—appropriateness rating questions.[4] Following each rating question, participants were prompted to "Please explain your rating."

Responses to the four open response questions were coded using a scheme derived from the *attitude* system of the appraisal framework (Martin & White, 2005). Coding for attitude is a means to capture participants' ways of feeling (Martin & White, 2005) toward the situation instances represented by the storyboards. The attitude system differentiates statements of affect, judgment, and appreciation. Statements of *affect* convey personal feelings through linguistic markers of emotion, such as "sad", "happy" or "angry" (Read & Carroll, 2012). Statements of judgment convey evaluations of people and their deeds, such as "he is a good teacher." Statements of appreciation convey aesthetic evaluations of non-person things in the world (goods and services), such as "that is a clear proof" (Read & Carroll, 2012). The scheme we developed coded each response for all instances of attitude. Attitudes were classified by type—is it judgment, affect, or appreciation?—target—e.g., the teacher, the proof—and polarity—positive or negative.

An example of a response that conveys a positive judgment of the teacher is: "teacher is guiding students effectively." In this response, the teacher is the target of the attitude and "effectively" is a positive evaluation of the action—guiding—that the teacher is described as doing in the scenario. Since the response is about the quality of how a person (i.e., the teacher) performs an action, it is coded as a positive judgment. An example response that contains a negative judgment of the teacher is: "This teacher is being a bit ridiculous." These examples were coded as judgments because, in each case, the targets of the appraisals are people and their deeds. An example response that contains an appreciation is: "the math proof was not accurate." In this example, a mathematical proof is the target of the appraisal. It was coded as a negative appraisal because the response states that the proof is " not accurate."

Reliability of the Attitude Coding Scheme

The *attitude* scheme was tested for reliability by comparing coded responses of two independent coders[5]. The coders applied each scheme to 100 randomly selected texts in the corpus—25 of each of the 4 response types, roughly 10% of the total number of responses. Before each text was coded, it was blinded with respect to whether the response was provided for a storyboard in which the norm was breached or a storyboard in which the norm was not breached. The purpose of blinding the data was to minimize bias. The *kappa statistics* for the *attitude* coding for which there were sufficient instances of the codes to warrant the statistics are .79 for *negative judgments* of the teacher; .49 for *positive judgments* of the teacher; .77 for *negative mathematical* appreciations; .49 for *positive mathematical* appreciations. These *kappa* scores indicate moderate (.49), high (.76, .77, .79), and very high (.89) agreement between the coders.

Data

Data was gathered from 73 secondary mathematics teachers located within a 60-mile radius of Midwestern University. Participants completed the instrument during in-person and online data collection periods that occurred during the 2013-2014 academic year. The multimedia survey (described above) that contained the four storyboards was one of several instruments participants completed during a day-long data collection event.

Results

Each response in the corpus was coded for judgments, appreciations, or statements of affect, and each instance of an attitudinal appraisal was coded in each response. This means that it was possible for a response to contain multiple instances of the same kind of statement of attitude (e.g., there could have been several judgments of a teacher), as well as instances of different kinds of statements of attitude (e.g., a judgment of the students, an appreciation of the proof), and statements of attitude that had different polarities (e.g., a response could contain both positive and negative judgments of the teacher).

We hypothesized that, in the case of storyboards that represent a breach of a norm, participants would react negatively. These negative reactions would be evident by higher numbers of negative statements of attitude. By contrast, based on the premise that the control storyboards represent routine teaching, we hypothesized that open responses associated with control storyboards would contain roughly equal numbers of positive and negative statements of attitude. Such a distribution of positive and negative statements of attitude could be explained on the basis of individual differences (among participants) alone.

Table 1 shows the total number of positive and negative statements of attitude throughout the open responses in the corpus. The results are reported according to storyboard condition. The entire corpus contained 1168 open responses to the 4 different open response questions, with equal numbers of responses to the breach and control conditions (584 responses per condition). These were divided equally (146 per question) among the 4 open response questions that were described above. The results reported in Table 1 are for the entire corpus across all 4 question types. Furthermore, the results reported in Table 1 are simple counts of the number of statements of positive or negative attitude that were coded in the open responses to the storyboards in the breach and control conditions.

Table 1: Counts of statements of attitude, tallied by polarity and storyboard condition.

Storyboard Condition	Statements of Positive Attitude	Statements of Negative Attitude	Total
Breach Storyboards	211	473	684
Control Storyboards	309	310	619

The results reported in Table 1 are consistent with the hypotheses stated above. The open responses to the storyboards in which a hypothesized norm was breached had more statements of negative attitude than statements of positive attitude. In the case of the control storyboards, there were nearly equal numbers of positive and negative statements of appraisal. A chi-square test indicates that there is a significant association between storyboard condition and the number of positive or negative statements of attitude ($\chi^2 = 48.49$, $p < .001$).

The unit of analysis for the results reported in Table 1 is a statement of attitude. This means that each statement of attitude in a response was included in the totals. To further investigate the relationship between attitude polarity and storyboard condition, we recoded the data to eliminate multiples, by polarity, within each response. Thus, if a response contained 3 positive statements of attitude and 2 negative statements of attitude, it was recoded as (1) for *positive attitude* and (1) for *negative attitude*. Table 2 reports tallies of statements of attitude after applying this reduction. The unit of analysis for the results reported in Table 2 is an open response ($n = 584$ for each storyboard condition).

The results reported in Table 2 are consistent with those reported above. Across the corpus for the control storyboards, there were 248 responses that contained at least one statement of positive

Table 2: Counts of open responses that contain positive or negative statements of attitude, by storyboard condition.

Storyboard Condition	Statements of Positive Attitude	Statements of Negative Attitude	Total
Breach Storyboards	176	352	528
Control Storyboards	248	245	493

attitude and 245 responses that contained at least one statement of negative attitude. By contrast, across the corpus for the breach storyboards, there were 176 responses that contained at least one statement of positive attitude compared to 352 responses that contained at least one statement of negative attitude. A chi-square test of association indicates that there is a significant relationship between storyboard condition and attitude polarity ($\chi^2 = 29.54$, $p < .001$).

The results reported in Table 2 are a refinement of the results reported in Table 1 because multiples have been eliminated. The results reported in Table 3 (below) refine these results further by distinguishing 4 categories of response: those that contain only positive statements of attitude, those that contain only negative statements of attitude, those that contain both positive and negative statements of attitude, and those that contain no statements of attitude.

Table 3: Counts of open responses that contain only positive attitude, only negative attitude, both, or neither.

Storyboard Condition	Statements of Positive Attitude	Statements of Negative Attitude	Both Positive and Negative Attitude	None	Total
Breach Storyboards	78	254	98	154	584
Control Storyboards	166	163	82	173	584

The results reported in Table 3 are consistent with those reported in Table 1 and Table 2. The breach storyboards contained more responses that contained only negative statements of attitude than responses that contained only positive statements of attitude. By contrast, the control storyboards contained nearly equal numbers of responses that contained only positive statements of attitude and responses that contained only negative statements of attitude. A chi-square test of association indicates a significant relationship between storyboard condition and the categories of attitude in Table 3 ($\chi^2 = 54.12$, $p < .001$)

The results reported above provide evidence to support our hypotheses: Throughout the corpus, the responses to the breach versions of the storyboards yielded more negative statements of attitude than positive statements of attitude. That responses to the breach versions of the storyboards produced more negative statements of attitude is consistent with the results of the breaching experiments conducted by Garfinkel (1963) and the virtual breaching experiments conducted by others (Herbst, Aaron, Dimmel, & Erickson, 2013). In contrast with the breach storyboards, responses to the control storyboards contained roughly equal numbers of positive and negative statements of attitude. Because the breach and control storyboards were the same except during those frames where the teacher is shown breaching (or complying with) a hypothesized norm, it follows that the teacher's breach of the norm is what prompted participants to react negatively to the storyboard.

Conclusion

We began with the question: When teachers encounter reasonable departures from the routine, how do they react? The results reported above provide evidence that secondary mathematics teachers react more negatively to episodes of instruction that represent breaches of hypothesized classroom norms than to episodes of instruction that represent instruction that is hypothesized to be routine. We provide context for these findings here by describing the nature of the breaches.

The storyboards representing instances of *doing proofs* were scripted to investigate communication practices expected by secondary teachers when proofs are presented (by students) and checked in geometry classrooms. An example of a routine practice for presenting proofs is that of a student going to the board and creating a mark-for-mark reproduction of an already completed proof—an act we call *proof transcription*. Such transcriptions of proofs by students do not match the practices used by disciplinary experts, where a proof is described verbally (with accompanying gestures) as it is generated at a blackboard (Artemeva & Fox, 2011; Greiffenhagen, 2014; Núñez, 2009).

In our study, one set of breach storyboards depicted teachers interfering with student transcriptions of proofs, for example, by requiring students to provide labels on a diagram before using those labels in a proof. The teacher's interference could be defended as reasonable on the grounds that the teacher is steering the student presenter toward staging a discovery—as opposed to a reproduction—of the proof that shows how the student engaged with the material artifact of the proof (Livingston, 1999). Such a move on the part of the teacher could be seen as an effort to bring the student's proof presentation practices more in line with disciplinary practices for presenting proofs (Greiffenhagen, 2014). In fact, some participants in the study remarked on the positive instructional value of the teacher's interference in such storyboards. Yet on the whole, the attitudes that participants expressed toward the teachers that interfered with the student transcriptions tended to be negative. What are we to make of these findings?

One implication is that it is possible that teachers could recognize, in the abstract, the value of an instructional alternative yet prefer, in actuality, the routines they have developed. The tendency toward routine is not evidence of a deficiency in teachers but is rather a fact of social life (Garfinkel, 1963). We see teachers' preference for routines as a resource that could be used to design instructional alternatives that are likely to have greater uptake by practicing teachers. For the work of managing student presentations of proofs in geometry classrooms, the expectation that students create mark-for-mark reproductions of proofs could be the basis for alternatives that would help students develop discipline-specific communication practices. An example of such an alternative could involve asking students to present proofs in pairs, where one student is responsible for generating the transcription and the other student explains the proof as the transcription is being completed. Such an alternative practice would recognize the value in the existing routine—i.e., that the proof that is displayed on the board is an accurate record of the work the student completed—while at the same time provide a scaffold for students to develop the proof presentation skills that are used by mathematical experts.

Endnotes

[1]The target norms were: (1) hypotheses about the details students are expected to include in a proof, and (2) hypotheses about how students are expected to present proofs during class.

[2]Participants were randomly assigned to one of five different treatment groups.

[3]The design of the study was described in a prior report. See (Dimmel & Herbst, 2014) for details.

[4]Analysis of the closed-ended responses to the rating questions were reported in a prior study (Dimmel & Herbst, 2014).

[5]We acknowledge the support of Nicolas Boileau for assisting with the reliability study.

WHEN "HALF AN HOUR" IS NOT "THIRTY MINUTES": ELEMENTARY STUDENTS SOLVING ELAPSED TIME PROBLEMS

Darrell Earnest
University of Massachusetts, Amherst
dearnest@educ.umass.edu

This paper presents assessment study results addressing the question: Do students treat elapsed time problems differently if phrased as "half an hour" versus "thirty minutes"? A paper-and-pencil assessment was given to second (n=292) and fourth (n=205) grade students in six New England elementary schools. I compare responses on tasks presented in hour units and minute units. Results indicate that children respond differently to elapsed time questions as a function of the units provided in the question (half hour or thirty minutes) depending on the provided starting time (e.g., on the half hour versus on the second half of the clock).

Keywords: Measurement; Elementary School Education; Problem Solving

Objective

The teaching and learning of STEM topics has been identified as a key to our country's innovation as well as a gateway to individuals' job opportunities. Uniting the various STEM domains, time underlies many scientific explorations of *how things work*, from determinations of speed and impact in physical phenomena to the Earth's orbit and rotation to graphs of functions over time. At the same time, our understanding of how children interpret time in standard units is minimal. While a staple of early elementary mathematics instruction (National Governors Association Center for Best Practices [NGA Center] & Council of Chief State School Officers [CCSSO], 2010), time has been repeatedly referred to as one of the *least* studied mathematical symbol systems (Blume, Galindo, & Walcotte, 2007; Burny, Valcke & Desoete, 2009; Kamii & Russell, 2012), with little known about how children problem solve using conventional notation and units for time. This is of particular concern given the prevalent role of time underlying the mathematics of change in middle and high school (see Yerushalmy & Shternberg, 2000). Although our culture's pervasive use of digital clocks may imply a collective mastery of time, such tools mask the rich and complex mathematics that underlies the unitizing of time and in determining elapsed time.

Theoretical Framework

My theoretical framework coordinates two areas: time is an area of measurement situated within children's developing *theory of measure* (Lehrer, Jaslow, & Curtis, 2003); and cultural tools and representations mediate our thought and communication (Cole, 1996; Sfard, 2007, 2008).

First, children develop a theory of measure through everyday examinations of the attributes of objects or events. Ideally, instruction provides opportunities for children to coordinate sensorimotor actions and everyday experiences with principles of measure (such as unit iteration, the need for equal units, or tiling; see Lehrer, 2003). Such principles cohere across different measures, including length, weight, volume, and time. Like length measure, time is a measureable quantity for which humans have developed standard units. While developmentally we know how students develop an understanding of length measure and also when notions of sequencing and duration develop (Piaget, 1969), we have little understanding about how children draw upon notation for time as related to their theory of measure.

To support the development of children's theory of measure, research has emphasized the role of units (see Lehrer et al., 2003; Stephans & Clements, 2003). Unitizing is a core concept of measuring, with many measurement principles focusing on the role of unit or resulting entailments, such as the need for a zero-point. With standard units of time measure, a long social history has led to our current system of notation in which units of time are in groups of 12 or 24 (hours) and 60 (minutes). The groupings of these hierarchical units greatly contrast with base-10 system of numeration underlying much of the mathematics content in elementary school, suggesting that drawing upon the proportional relation between hour and minute units may pose challenges. However, little research exists that explores how children may apply and coordinate standard units for time in their problem solving. The present study seeks examines how children solve elapsed time problems in order to document whether such challenges involving unit exist and, if so, how to characterize them.

Second, I consider thinking and learning to be inextricably linked to culture (Cole, 1996; Earnest, 2015; Sfard, 2007), with tools (i.e., a digital or analog clock) and conventional notation serving mediating roles in thought and communication. This may include cultural and mathematical referents such as "half an hour" and "thirty minutes." Analog and digital clocks represent time and its properties in different ways, with the analog clock's intervals of time translating duration into spatial distance (Lakoff & Nuñez, 2000; Williams, 2012). Digital time provides a precise time to the minute without reflecting hour-to-minute relations. The digital time 5:10, for example, provides a quick and precise numeric realization of time. Contrasting with this, the analog clock indicates time through a length based representational context. If we consider the hour hand for 5:10, for example, one may interpret its position as not just showing the "5" as with digital notation, but its displacement from 5:00 to 5:10 as well as the length corresponding to the 50 minutes remaining in the hour from 5:10 to 6:00. Tapping into children's developing theory of measure, the analog clock is a cultural tool that builds on principles of measure reflected on a number line. A premise of this work is that, in children's problem solving involving time, prior experiences with notation and tools serve mediating roles, even when solving problems involving digital notation alone.

Mathematically, elapsed times are equivalent whether provided in hour-units (e.g., half an hour) or minute-units (e.g., 30 minutes). However, children may interpret such units in different ways, though prior research has not considered this. Various articles have provided important examples about how children may treat time notation in terms of base ten (e.g., Breyfogle & Williams, 2008; Kamii & Russell, 2012), such as adding 30 minutes to the time 4:40 to reach 4:70. An underlying complexity underlying standard time notation is that hierarchical units of hours and minutes are grouped by 12 (hours) and 60 (minutes and seconds), a stark contrast to the base-10 groupings underlying place value and standard algorithms in elementary mathematics. The present study seeks to contribute systematic research to support whether such issues are pervasive in children's problem solving.

Research Questions

The present study investigates the research questions: Do children perform differently on elapsed time tasks as a function of the units of elapsed time? Do such differences depend on the starting time provided in the task? Based on these questions, I investigate patterns of responses across the focal tasks.

Methods

Participants included 292 Grade 2 students and 205 Grade 4 students drawn from six elementary schools in urban, rural, and suburban contexts in New England. Grade 2 students were selected because standards indicate children in this grade have already mastered time to the hour and half hour and are currently working on time at the 5 minutes (NGA Center & CCSSO, 2010). Grade 4 students were selected because, according to standards, time concepts including elapsed time have been mastered in prior grades, and their performances therefore illuminate any persisting differences in performance on problems involving time.

The assessment featured 31 items, the design of which was informed by classroom observations and informal interviews with students in second and fourth grades over 1.5 years. This paper focuses on a subset of six assessment items: three items featured minute-units for elapsed time ("30 minutes") and three analogous items involving hour-units ("half an hour") (see Figure 1). For each problem type, one problem had a starting time at x:30, another corresponding to the first half of the clock (x:10), and the final to the second half of the clock (x:40).

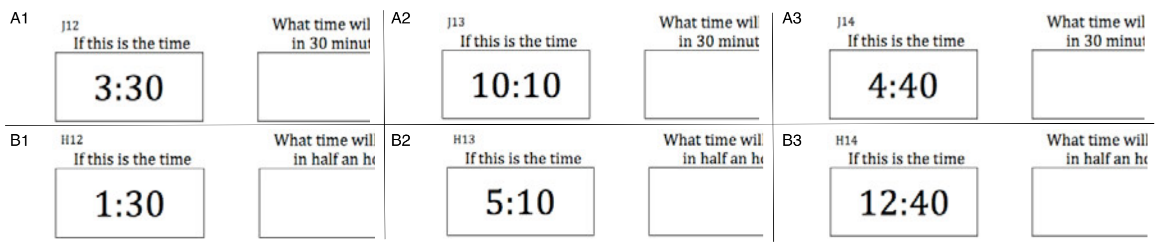

Figure 1: Assessment tasks by Problem Type (rows A and B) and Starting Time (columns 1, 2, or 3).

Teachers administered the assessments in December 2014 and January 2015 (dates were staggered due to weather-related school cancellations). Students had 25 minutes to complete the assessment; students that did not finish the assessment were not included in this analysis. The researcher was present to oversee each administration. All assessments were collected and scanned. Though not reported in the current paper, a subset of grade 2 (n = 72) and grade 4 (n = 72) students participated in problem solving interviews with analog or digital clocks.

Analysis and Results

The analysis is presented in two parts. I first present quantitative results that reveal students perform differently on "30 minutes" versus "half an hour" questions depending on the starting time. Following this, I present an analysis of responses on tasks in order to demonstrate that particular responses arise for one unit type but not for the other.

Performance by Problem Type and Starting Time

Six problems on the assessment addressed elapsed time in digital notation (see Figure 1). Each student was given one point for each correct response; incorrect responses were assigned 0 points. Means and standard deviations are represented in Figure 2. To determine whether there was a difference in performance, I conducted a Two (Problem Type) x Three (Starting Time) x Two (Grade) repeated measures analysis of variance (ANOVA) for performance.

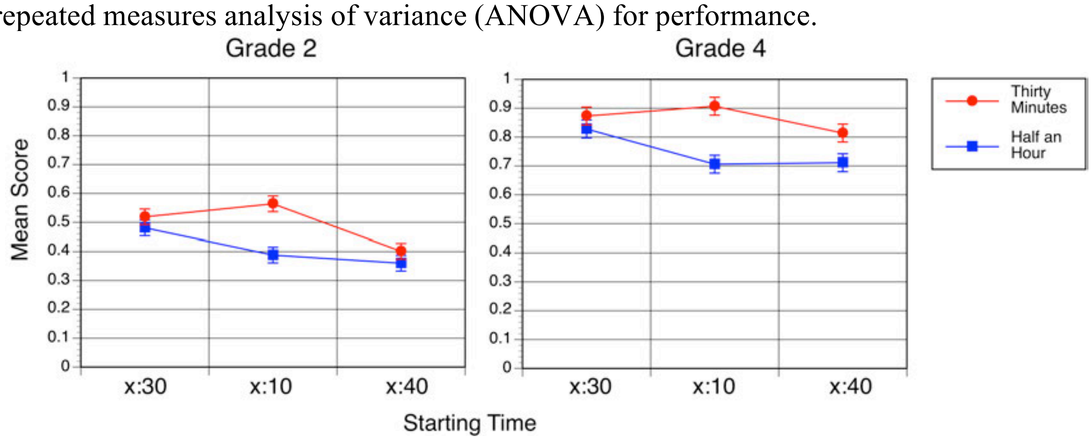

Figure 2: Mean scores with standard deviations on focal tasks.

I first report three-way and two-way interactions in the data. While there was not a statistically significant three-way interaction between Grade, Problem Type, and Starting Time, $p = .558$, there was a statistically significant two-way interaction between Problem Type and Starting Time, $F(2, 982) = 17.798$, $p < .0001$. There were no significant interactions between Problem Type and Grade ($p = .204$) or Starting Time and Grade ($p = .204$), suggesting a similar performance profile across problems independent of grade. Given the significant two-way interaction between Problem Type and Starting Time, I also compare performance for each Problem Type for each of the three starting times for the sample (corresponding to data points in the columns of Figure 1). There were statistically different performances on "half an hour" and "thirty minute" tasks for each of the three starting times: x:30 ($p = .020$), x:10 ($p < .0001$), and x:40 ($p < .0001$).

Results thus far confirm that students interpret questions phrased as "half an hour" versus "thirty minutes" differently, with students performing better on tasks phrased as "thirty minutes." These results lead to the following question: How do students' responses vary on tasks based on the units of elapsed time? In order to consider these questions, I turn to an analysis of students' provided responses for across the six tasks.

Examining Patterns in Student Responses

I now consider patterns in incorrect responses for the six tasks presented in Figure 1 identify incorrect responses according to how the final response reflects a particular displacement from the starting time. Five types of displacements emerged across problems (see Figure 3): (1) Displacement by an hour (e.g., 4:40 with 30 minutes elapsed is 5:40); (2) Displacement by 1.5 hours; (3) Displacement to a x:00 or x:30 point (e.g., 4:40 with 30 minutes elapsed is 5:30); (4) Displacement to a multiple of 5 between 5 and 55 minutes after the starting time (e.g., 4:40 with 30 minutes elapsed is 4:50); (5) Accurate displacement with inaccurate notation (e.g., 4:40 with 30 minutes elapsed is 4:70). In addition, Figure 3 reflects students that provided as a response: (6) the starting time or one minute after the starting time (e.g., 4:40 with 30 minutes elapsed is 4:40 or 4:41); (7) Idiosyncratic responses with frequencies of 1 or 2 in the sample; and (8) "I don't know" or no response. I draw attention to parts of the graphs in Figure 3 in which particular incorrect response codes were provided for one Problem Type and not the other. Note that since Figure 3 presents the proportion based only on incorrect responses, the *n*s for each problem do not include correct responses and, therefore vary across problems. When possible for each code, I reflect on how responses relate to children's theory of measure and/or the role of tools and notation.

1. Displacement by 1 hour. The first incorrect response code reflected displacement by one hour. Students provided this response across problems regardless whether phrased as "half an hour" or "thirty minutes." The proportion was greatest for the starting time of x:30; this may be related to children treating the "o'clock" time (e.g., 4:00) as a zero-point rather than the provided starting time. In this case, solving problem A1 (3:30 plus 30 minutes) may treat the next hour mark as the zero point, thereby adding 30 minutes to 4:00 to solve the problem. While this code was applied most for when the starting time was x:30 and when the problem was phrased as "half an hour," this does not well explain how this particular response occurs for starting times of x:10 or x:40, leading to further questions regarding children's problem solving.

2. Displacement by 1.5 hours. The second strategy code reflected a 1.5-hour displacement from the starting time. Students drew upon the use of mathematical words in "half an hour" to quantify both *half* and *hour*, adding them together for a total displacement of 1.5 hours. Across the sample, only once did this response occur when the problem was phrased as "thirty minutes." In this particular case, the two units—hours and minutes—differently mediate children's problem solving.

3. Displacement to x:00 or x:30. The third code reflected a translation of either "thirty minutes" or "half an hour" into a final time with notation ending with x:00 or x:30. This category arose for

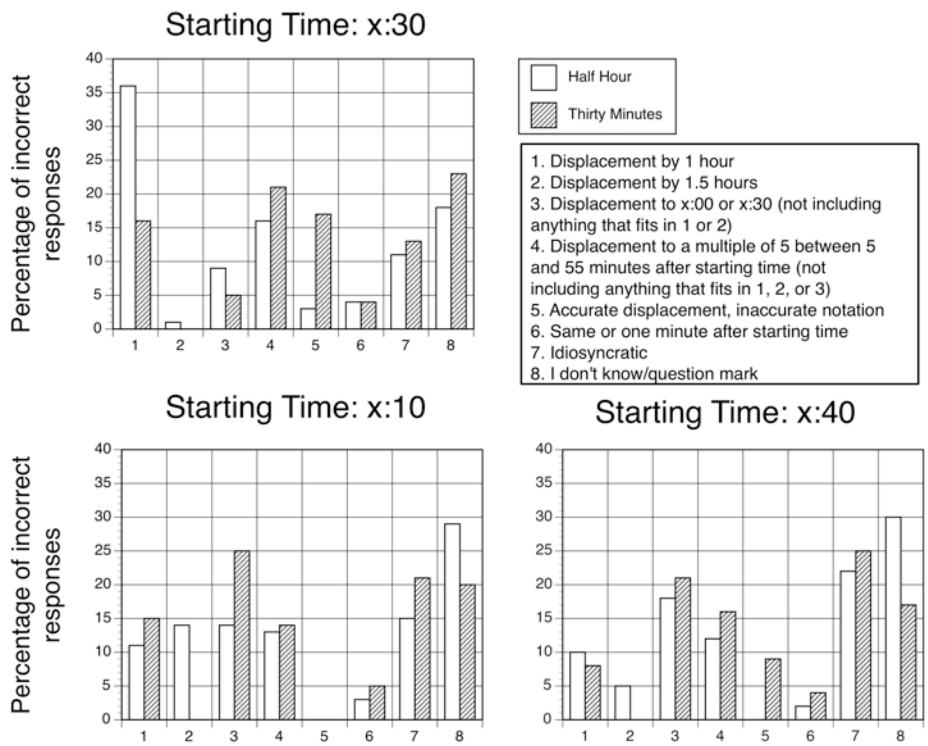

Figure 3: Proportions of incorrect response codes comparing tasks for "half an hour" or "thirty minutes" by starting time.

problem phrased both as "half an hour" and "thirty minutes." Students provided a variety of responses that resulted in this code. For example, for problem B3, students responding with "2:00" or "11:00" each received this code, though the different response choices do not reveal children's microgenetic constructions leading to these solutions. Assessment data alone do not well reveal the logic underlying the variety of responses receiving this code, though a conjecture underlying the frequency of x:00 or x:30 responses pertains both to the elapsed duration of 30 minutes/half an hour as well as the social relevance of times to the "o'clock" or "thirty."

4. Displacement to a multiple of 5. A common incorrect response for problems phrased both as "half an hour" and "thirty minutes" involved providing a new time at a multiple of 5. This particular category includes many different responses that do not fit into categories provided above. At the same time, the pattern of responses at multiples of 5 was striking. A conjecture is that the analog clock as a tool highlights time at five- minute intervals. Despite the fact that focal problems did not feature analog clocks, students' prior experiences with time, particularly the instructional and cultural emphases on identifying discrete positions in time to the five minutes (NGA Center & CCSSO, 2010), likely informed their problem solving leading to responses at five minute intervals.

5. Accurate displacement, inaccurate notation. The fifth strategy code reflected an accurate displacement with inaccurate notation, specifically adding minutes without regrouping such that the final minutes were greater than 60. This code was employed only for those tasks that reached or crossed the hour, and almost exclusively for those problems presented as "thirty minutes." This may be related to students' developing understanding of addition across elementary grades in which minutes to the right of the colon in digital notation are treated in terms of base-10 when asked to add thirty minutes. Conversely, "half an hour" tasks did not lead to this particular code. This may be because the unit "hour" cues for students spatial representations of time related to the analog clock, such that adding half an hour (as opposed to 30 minutes) to 12:40 involves does not cue the same base-10 reasoning. This suggests that issues with composition and decomposition in groups of 60 may result from problems phrased as “thirty minutes” in more prevalent ways than when phrased as “half an hour.”

Concluding Remarks

Results indicate that students treat problems phrased as “half an hour” and “thirty minutes” differently. While such displacements are mathematically equivalent, they pose differential challenges to children solving such problems. Based on assessment data, this paper makes the following claims and conjectures, though all must be further substantiated through interviews of children’s in-the-moment problem solving:

- Students treat “half an hour” and “thirty minute” displacements differently in their problem solving, despite the fact that such durations are equivalent;
- Students in each grade may translate an elapsed time of either “half an hour” or “30 minutes” into an hour of displacement;
- Students translate “half an hour” into 1.5 hours, but do not do this with “thirty minutes;”
- Students may translate displacements of “half an hour” and “thirty minutes” in coordination with treating the “o’clock” or “-thirty” time as a zero-point, leading to solutions ending in x:00 or x:30;
- Students draw upon the cultural emphasis of time to the five minutes when solving problems involving time;
- Accurate duration with inaccurate notation is observed when the resulting time either reaches or crosses the next hour, and when tasks are presented in minute- units.

While these findings provide information about children’s problem solving with time notation, the study leads to new questions that are yet unanswered in the current analysis. This paper reports on trends in data from an assessment given to elementary students, yet does not answer how or why students respond in such ways. For example, might students’ success on problems with a starting time of x:10 be related to whole number understandings, such that 30 is added to 10 without regard to time notation? Does “half an hour” cue for students part-whole relations and their understandings of fractions in a way that “30 minutes” does not?

Given the limited research in this area, the present paper begins to address questions about how elementary children respond to questions about elapsed time. Rather than answer such questions completely, results of this study lead to further questions. While clocks are certainly pervasive in culture, results of this study underscore that children’s conceptions of time in standard notation are quite varied. A concern of this project is in supporting all students in coordinating their developing notions of duration with standard time units, as such understandings are generative both in children’s developing theory of measure as well as engaging in any scientific investigation requires relying on time.

IDENTIFYING SIMILAR POLYGONS: COMPARING PROSPECTIVE TEACHERS' ROUTINES WITH A MATHEMATICIAN'S

Sasha Wang
Boise State University
sashawang@boisestate.edu

This paper reports two prospective teachers' and a mathematician's ways of identifying similar triangles and hexagons through the analysis of routines, a characteristic of geometric discourse. The findings show that visual recognition was a common approach for the mathematician as well as the two prospective teachers. However, when asked for justification, their routines of identifying similar polygons diverged. The paper also discusses the implication of classroom discourse practices to enhance prospective teachers' communication and reasoning skills while learning geometric concepts such as similarity.

Keywords: Geometry; Classroom Discourse; Teacher Knowledge

In geometry, similarity is an important concept connecting many other mathematical domains such as spatial reasoning, ratio, proportion, and transformation functions. *Similarity* is defined as a relation between figures. For example, similar figures in a plane can be seen as pre-images and images of dilations (similar transformation) that preserve their shape but not necessarily the size. Similarity is not only a cross-cutting concept in geometry for middle school students (CCSSM, 2014), but also a concept that has many applications in science and engineering (NGSS, 2011). Yet, for some teachers, similarity is still a difficult topic to teach because their prior geometry coursework made little mention of it. Therefore, it is important for prospective teachers (PSTs) to know with the topic and connect it with other concepts such as ratio and proportion. However, there is little known about PSTs' geometric thinking in the context of similarity in recent research. The purpose of the study is to address this gap.

Theoretical Framework

Sfard's (2008) framework is used to analyze participants' interviews. She has proposed that mathematical discourses differ one from another in at least four features: 1) *Word use* (mathematical vocabularies and their use), mathematical words that signify mathematical objects or process; 2) *Routines*, these are well-defined repetitive patterns characteristic of the given mathematical discourse; 3) *Visual mediator*s, these are symbolic artifacts related especially for particular communication; 4) *Endorsed narratives,* any text, spoken or written, which is framed as a description of objects, of relations between processes with or by objects, and which are subject to endorsement or rejection, that is, to be labeled as true or false. These features are interwoven with one another in a variety of ways. For example, endorsed narratives contain mathematical vocabularies and provide the context in which those words are used; mathematical routines are apparent in the use of visual mediators and produce narratives. Sfard's framework provides an analytical tool to investigate how thinking is communicated through interactions. To have a better understanding of PSTs and mathematician's geometric thinking and their ways of identifying similar polygons, this paper reports findings that address these two research questions: 1) what are PSTs' routines for identifying similar triangle and hexagons? 2) What are the mathematician's routines for identifying similar triangles and hexagons?

Method

Six PSTs who participated in the study were enrolled in a Midwestern university teacher education program in the US. The mathematician was a visiting professor at the university at the time of the study. The interviews were designed to investigate participants' geometric thinking in a 30-minute one-on-one interaction. In one task during the interviews, participants were asked to identify similar figures among fifty pre-selected geometric shapes. These shapes included triangles, quadrilaterals, hexagons, and circles; all mixed together on an 11" x 17" piece ofpaper (see Figure 1). As shown in Figure 1, all shapes on the paper are labeled with numbers from 1 to 50. Among them, some are similar figures, and some are congruent figures. All interview tasks are designed to elicit participants' thinking about similar polygons. For instance, in a task of identifying similar polygons, the interview questions such as "How do you know they are similar?" "What do you mean when you say 'they are the similar'?" were asked to capture participants' geometrical thinking in identifying similar figures. All participants were given the same tasks and were asked the same initial interview questions by the same researcher following the interview protocol. However, each interview was guided by individual participant's responses to the tasks and questions. All interviews were video recorded and transcribed. All transcripts document what participants said and did during the interviews.

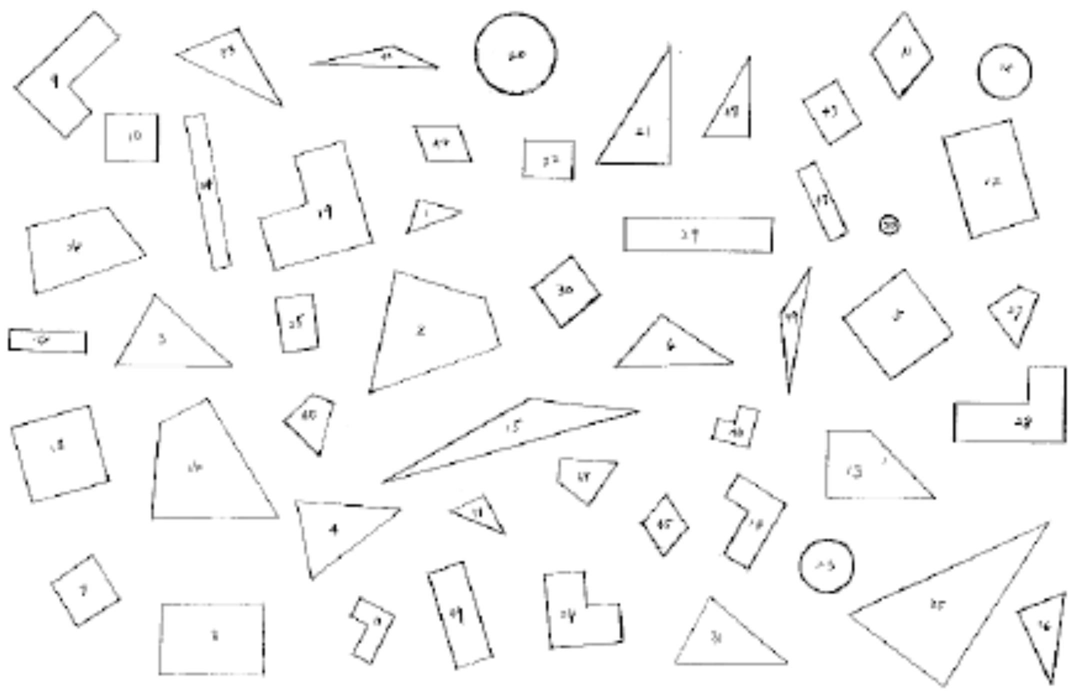

***Figure 1.* Identifying similar polygons**

Results

The results show the differences in PSTs' and mathematician's routines of identifying similar triangles and hexagons. In this paper, two PSTs' (PST1 and PST2) routines are used to illustrate these differences, and the three main differences are as follows:

- The mathematician was aware of the abstraction of similar figures at the abstract level whereas PSTs only focused on using measurements to verify similar figures at the object level.

- The mathematician looked for two possibilities of ratios "internal versus external," whereas the PSTs did not, but used one of them instead. That is, the mathematician explicitly explained the two possibilities of ratios, internal ratios and external rations and how they could fit together to determine similar figures.
- The mathematician considered different approaches when the first attempt did not work, whereas the PSTs refuted their conjectures and did not consider other possibilities that could show the polygons were similar.

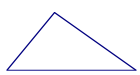
Matching Similar Triangles

For this task, the participants were asked to identify all figures that are similar to a right triangle (#21), from the fifty figures given on the grid paper. The mathematician identified a scalene triangle (#33) as a similar triangle to this right triangle by direct recognition. When prompted by the researcher, "how do you know they are similar not based on visual?" the mathematician measured the sides of the trianglesand attempted to check for the ratio between them. She then measured the included angles of the two triangles to check for congruency. The conversation between the mathematician (M) and the researcher (I) is as follows:

1 I: Which following figures are similar to this [#21]?

#21

2M: Just looking visually, this one maybe [marked a circle on a triangle].

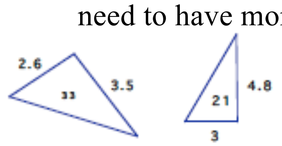


#33

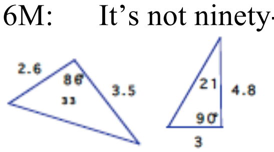
3I: If I would ask not just based on the visuals, what would you do?

4M: Can I do that [find measurements]? No, I can't necessarily; the best I can do is that to show it definitely is not similar.

5 M: 2.6 centimetres. Is that 3.5 centimetres [#33]? I would say 3 and 4.8 on this one [#21]. I need to have more information about the angle.



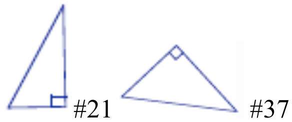
6M: It's not ninety-degrees, maybe eighty-six. That one is ninety degrees



7M: They definitely are not similar.

The mathematician identified a triangle (#33) as a candidate, which was similar to a given right triangle (#21). After measuring the sides and angles of the two triangles, she refuted her claim and concluded, "They definitely are not similar" based on different angle measures. The mathematician chose the two sides and their included angle to check if the triangles were similar. The mathematician did not calculate the ratio of the sides but checked measurement of the included angle first. When she found the angle measure did not match, she made her claim of "they definitely are not similar." In contrast to mathematician's responses to the task, PST1's routines procedures were different. She assumed the triangle (#21) was a right triangle by direct recognition. She identified another triangle (#37) that looked like a right triangle and concluded they were similar triangles:

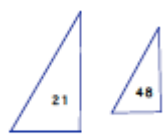
8I: Which following figures are similar to this figure [#21]?
9PST1: I am going to go with this triangle [#37] and marked right angle signs on both triangles.



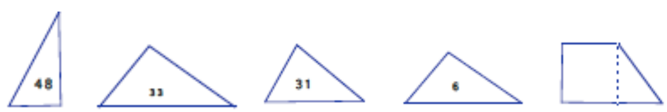
10I: How do you know this triangle[#37] is similar to this one [#21]?
11PST1: They both have a right angle.
12PST1: I am sure if you set up the proportions, they have the same angles.

PST1's routines procedures were direct recognition and it was self-evident. When prompted by the researcher, PST1 realized that two other corresponding angles of the two triangles were not congruent to each other and thenshe changed her claim about the two triangles were similar. Although PST1 did not say it explicitly, she used Angle-Angle-Angle (AAA) similarity criterion to check if the two triangles were similar. PST2's first reaction to same task was, "they should have same shape and same number of sides". That is she would consider all triangles were similar to each other:

13I: Which following figures are similar to this triangle [# 21]?
14 PST2: That is similar to it? It would be…number forty-eight.



15I: Why do you think they are similar?
16PST2: Because they have the same shape and same number of sides.
17I: Can you identify all the figures that are similar to this one [#21]?
18PST2: Circle them all?



#13

19PST2: Would that be considered a triangle if I divide a shape [#13]?
20I: Maybe not. We only focus on same number of sides like you said earlier.

PST2 identified triangle #48 as a similar triangle to #21, which was correct. However, her reasoning of why the two triangles are similar was incomplete. The following excerpt [18] showed that PST2 did not understand what similar figures meant mathematically. She focused on the visual appearance of the polygons (e.g., they have same shape) by counting the number of sides (e.g., all triangles are similar if they have same numbers of sides). To explore further, the interviewer prompted for a different verification:

21I: Why do you think these two triangles are similar to this triangle [#21]?

22PST2: By measuring their sides
23I: Show me
24PST2: 1-2-3-4-5.. I don't know.. I forgot how to write

25I: Are they similar to each other?

26PST2: They are not [similar]. They do have same number of sides, but their length measures are not the same. They are similar, but they are not the same. I am confused. It's Side-Side-Side (SSS).

Triangles #6 and #31 are not similar triangles. PST2 made a claim that the two triangles were similar because they had the same shape and the same number of sides. However, it appeared that she was confused about what "similar" meant because the two triangles had the same shape with same number of sides but different length measurements. PST2 remembered term "Side-Side-Side", but did not know how to use it in her reasoning. In addition to triangles, participants were asked to identify similar polygons to L-shaped hexagons.

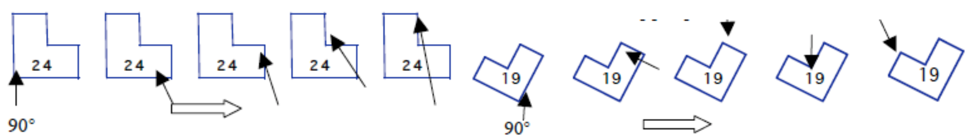
Matching Similar Hexagons

The mathematician identified an "L" shaped hexagon (#19) as a similar hexagon to the given hexagon (#24) by just looking visually again. When asked for substantiation, she measured all the angles in hexagon #24 and then in hexagon #19 accordingly, and checked if corresponding angles were congruent. After confirming the angles in the two hexagons were congruent, the mathematician proceeded to measure the sides in the hexagons, and to check the ratios between the two sides in each hexagon:

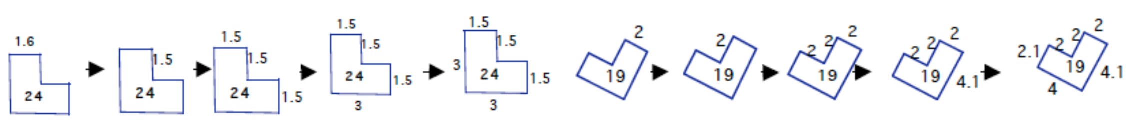
27 I: Which following is similar to this one [#24]?

28M: This one [a hexagon, #19] could be similar to [#24], just looking visually.

29M: [Used a protractor to measure the angles of the two figures].

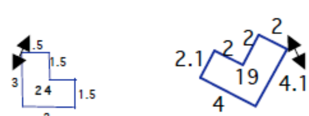


30M: Angle wise, they do seem to be all matched up. That would be not enough. I could do some measuring.



31M: [Used a ruler to measure the lengths of the two figures].

32M: This length is twice as much as that, and this is more than twice, so they can't be similar.

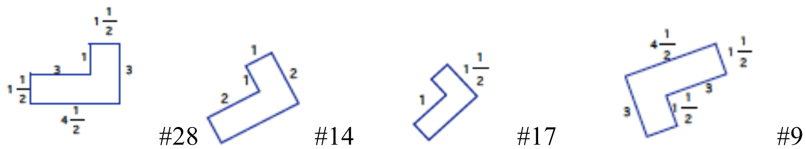


This excerpt highlights a set of actions describing how the mathematician substantiates the claim of "this one [#19] could be similar to [#24], just looking visually". She used direct recognition to identify a candidate that was similar to hexagon [#24]. After measuring the sides of the two hexagons, the mathematician found that the two hexagons did not share same ratios. She refuted her initial claim and concluded, "So they can't be similar." During the interview, the mathematician was concerned about the accuracy of the measurements. Her reaction to the use of measurements to determine similar figures was to "disconfirm" or to show "which is not."

In contrast, PST1 was asked to identify similar polygons to a hexagon [#28]. Her first reaction was to measure all the sides in hexagon #28, and then looked for L-shaped figures that had same shapes with hexagon #28:

33I: Which following figures are similar to this one [#28]?

34PST1: [Used a ruler to measure the sides of the given hexagon.

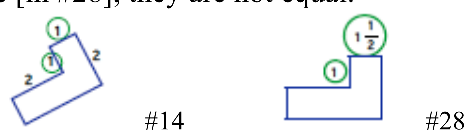


35PST1: This one [#9] is congruent to #28, so it is similar to #28 [a given hexagon].

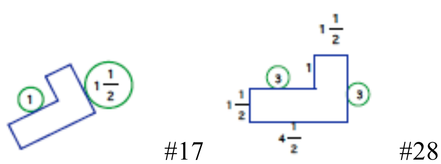
PST1 concluded that the two hexagons (#9 and #28) were similar because they were congruent. This is a correct response as congruent figures are special cases in similar figures because the ratios between all corresponding sides in congruent figures are 1:1. However, the task was not complete as the PST1 was expected to identify all similar figures. Therefore, the researcher prompted for more information:

36I: What about #14 (a hexagon) and #17 (a hexagon) are they similar to this one [#28]?

37PST1: I measured this side and this side [in #14], and they (ratios) are equal. When you compare it to this one [in #28], they are not equal.



38PST1: And this one [#17], I have these two sides, and they (ratios) are not equal to these two sides [in #28].



39:PST1: So they're not proportional to each other, and they are not similar to #28 [the given hexagon].

When verifying similar hexagons, PST1 focused on checking the ratios between the sides in one figure (#28) to the ratio of corresponding sides in other figures (17&14). She did not check any angle measures. PST2's response to the same question was different. PST2 first identified all L-shaped figures that would be similar to the hexagon (# 28) by direct recognition. When she was asked to verify, "How do you know this one (#24) is similar to this one (#28)?"(See Figure 2).

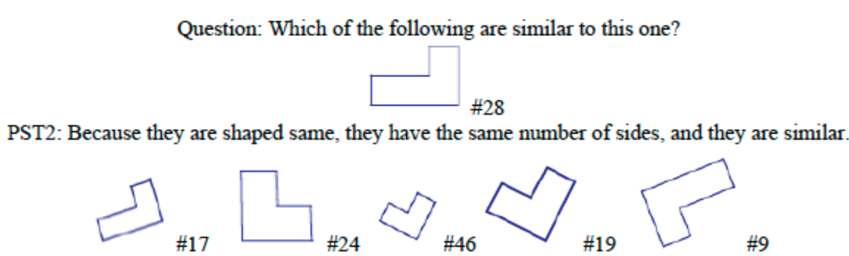


Figure 2.

PST2's responses of hexagons are similar to the given hexagon (#28). PST2 did not measure any sides and angles in the two figures, and replied by saying, "they're the same shape, but just different scale sizes," The researcher then asked, "Is this one [#9] also similar to this one [#28]?" PST2 replied, "It looks like it's the same size. Yes, I would have to say so. Yes." Figure 2 presents a collection of hexagons that PST2 considered similar to the given hexagon (#28). PST2's responses to this task showed a repeated pattern of focusing on the shape of the figures rather than checking the ratios of sides and measure of angles in the figures when identify similar hexagons.

Discussion

Findings suggest that when identifying similar figures, direct recognition is a common first approach to the PSTs and the mathematician based on the shapes of the figures and their orientations. This could be argued that geometry is one of the most intuitive areas of mathematics. However, procedures that are more rigorous are required to identify similar figures by checking the ratios of corresponding sides and the congruence of corresponding angles. Mathematically, congruence is a special case of similarity; however, findings show that one prospective teacher (PST2) did not think this is the case. When identifying similar triangles, the PSTs and the mathematician responded differently and their routines of identifying similar triangles showed the differences (see Figures 3, 4 & 5).

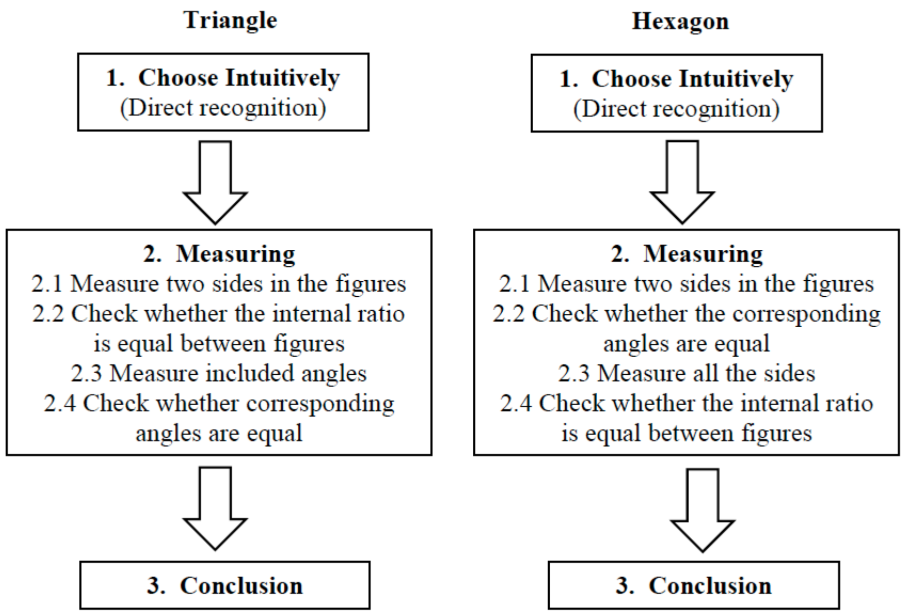

***Figure 3.* The mathematician's routines of identifying similar figures**

Between the two PSTs, PST1 demonstrated a better understanding in identifying similar triangles than she did in identifying similar hexagons, whereas PST2 showed difficulties and confusion in identifying similar triangles and hexagons. The findings also suggest the vague mathematical understanding the two PSTs had through their use of the words "similar" and "same shape." Note that both of them were aware of the informal definition of similarity, but there were confusions between the colloquial and mathematical meaning of the terms *same shape* and *similar* in the context of similarity. For example, PST2 did not understand what "same shape" meant when discussing similarity, and she interpreted the term as the figures shared the same number of sides, or that figures are shaped the same, which was not correct in the classification of similar figures. To the same word, similar, the two PSTs responded very differently: PST1 focused on the conditions of similarity (e.g., corresponding angles are equal, corresponding sides are proportional), which is more of the mathematical use of the term similar, whereas PST2 focused more on the "sameness" (e.g., same number of sides, shaped the same) between shapes than the mathematical reasoning (see Figures 4 & 5). The vague use of mathematical words such as *similar* and *same shape* provide information on how the concept of similarity was learned and understood by PSTs to make references to the wide range of relationships between shapes.

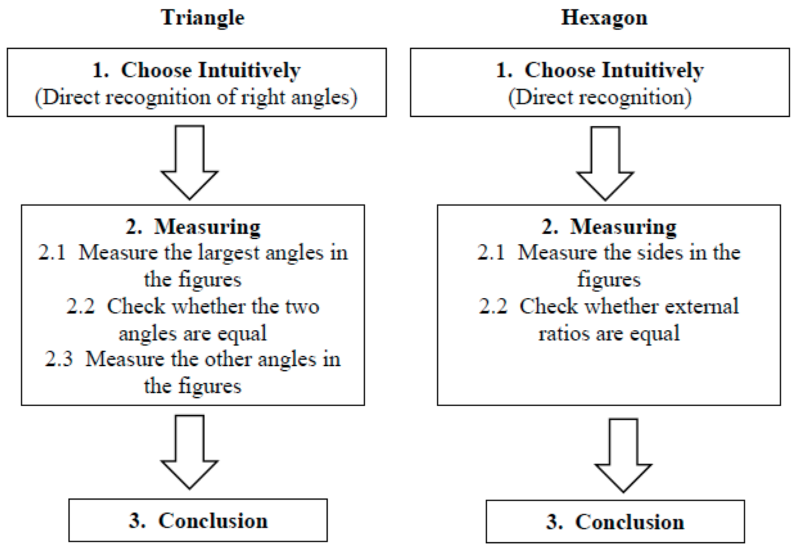

***Figure 4.* The PST1s' routines of identifying similar figures**

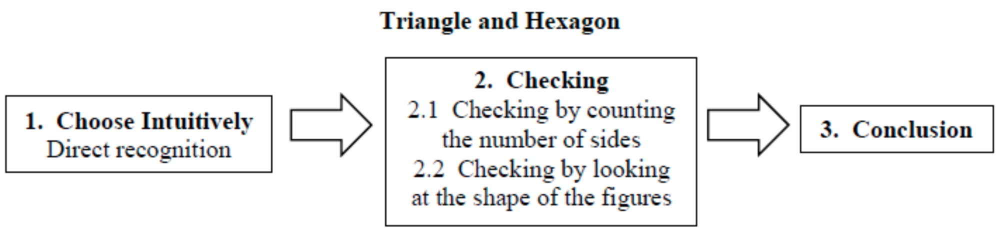

***Figure 5.* PST2's routines of identifying similar polygons**

Findings of the study suggest that many misunderstandings of a concept such as similarity will likely be missed if we only focus on the product or single answer of the task. When the PSTs' were asked to explain and to justify claims they made, and to clarify what they meant when mathematical terms (e.g., similar, same, proportion, etc.) were used, we started to see the vague understanding of similarity. It was through those interactions that the misunderstandings of the concept in similarity were detected by a series of questions that were designed to elicit their thinking. Therefore, one recommendation the study could make is to infuse discourse practices in our mathematics classrooms for PSTs to enhance their explaining, clarifying, and defining skills and to shed a light on their use of mathematical terms to ensure that the mathematical concepts are developed correctly. We need to ask more questions about "why" and "how" during the classroom discussions in order to help PSTs articulate their mathematical thinking and reasoning.

CONNECTIONS BETWEEN PROVING PRACTICES AND CONCEPTIONS OF FIGURES OF SECONDARY PRESERVICE TEACHERS

Mark Creager
Indiana University
macreage@indiana.edu

Reasoning and proof are an important part of the most recent curricular reform effort (NGA/CCSSO, 2010), but previous research has shown that many pre- and in-service teachers have insufficient conceptions of proof (Knuth, 1999; Martin & Harel, 1998). A limitation of studies of teachers knowledge of proof is that researchers have focused on whether or not the teachers work was or was not a proof without considering how those teachers understood the concepts with which they were being asked to prove. The intent of this study is to understand both the concepts that pre-service teachers (PST) have of triangles and quadrilaterals and how they applied those conceptions to proving conjectures about triangles and quadrilaterals. An interesting finding is that PSTs whose proofs displayed a restriction on the generality of their proof (Harel & Sowder, 1998) was a result of their conceptions of triangles or quadrilaterals.

Keywords: Mathematical Knowledge for Teaching; Reasoning and Proof

The Common Core State Standards for Mathematics place emphasis on reasoning and proof for instruction by including reasoning as one of their *Standards for Mathematical Practice* and putting proof in clusters in half of the domains of geometry (NGA/CCSSO, 2010). However research has shown that teacher's, whether pre- or in-service, elementary or secondary, have insufficient conceptions of proof (Knuth, 1999; Martin & Harel, 1998). Studies on teachers' knowledge of proof have focused on whether they consider an argument a proof or not or to what extent the arguments they create are proofs. Although it is relevant to understand how teachers reason about topics, what studies on teachers' conceptions of proof lack are an understanding of how their knowledge of the content affect their proving.

The purpose of this paper is to report findings from such a study. Specifically, this study found that pre-service secondary teachers (PSST) whose proof productions had a restriction on the generality of their argument was a result of how they thought about the figures on which they were proving. The organization of this paper includes a description of literature on conceptions of figures and proof, which is followed by a description of the study. Results from a PSST who was represented of others PSSTs will be presented along with supporting evidence from other PSSTs, but due to space restrictions a detailed summary of only one PSST will be given. Finally, implications for teacher education will be discussed.

Conceptions of Figures and Proof

There are two types of geometric definitions, partitional and hierarchical (de Villiers, 1994). Partitional definitions put figures into disjoint sets, for example a square is not a special case of rectangle. Hierarchical definitions classify figures so that more particular figures form subsets of more general figures. Hierarchical definitions are useful for proving (de Villiers, 1994) because if a conjecture is proved for a figure then all the figures in the subset inherit that conjecture.

A proof in this paper is meant to be an argument that convinces or persuades an individual or community (Harel & Sowder, 1998). Harel and Sowder (1998) created a taxonomy of proofs that they found individuals use. Two of their categories are relevant to this study so they will be the only categories described. The empirical proof scheme is marked by arguments that validate based on the conjecture being true for one or more examples. The transformational proof scheme contains three criteria (a) generality–understanding to justify for all cases, (b) operational thought–evidence of goals and sub-goals, and (c) logical inference. Individuals who reason in a transformational way can face restrictions on the generality of their proof. Meaning that proofs are proved in a specific case, like rectangle, but intended to prove for a more general case, like quadrilateral. The transformational proof scheme is considered the first deductive proof scheme.

Harel & Sowder (1998) suggest that it is necessary to have a dynamic conception of figure in order to prove, meaning that as one reasons about a quadrilateral, for example, it is important to understand the variety of images a quadrilateral can take on instead of focusing on one static or prototypical image. Prototypical image is meant to be a specialized case where even things like orientation are relevant. An example would be that a triangle has to have three congruent sides and a horizontal base. Having a diverse set of examples from which to reason on is considered an important skill for proving Sandefur, Mason, Stylianides, Watson (2013).

Method

Thirteen PSST agreed to participate in the study. All were enrolled in the second of two required methods courses and were in the last semester of their course work. One PSST was majoring in special education and getting an endorsement in mathematics, but all others were majoring in mathematics education. This population was targeted because they would be near the end of their mathematical course work and thus have finished their formal training in proof.

There were two phases of data collection. The goal of the first phase was to gain an initial understanding of the PSSTs' conceptions of triangles and quadrilaterals and what types of arguments they find convincing. The PSSTs were given a packet to take home and return in one week that contained thirty-four items. Items asked PSSTs whether definitions were valid or not, whether figures had or did not have certain properties, whether conjectures were valid or not, to interpret statements of inference, and whether certain arguments were or were not proofs. The items were in a multiple-choice format.

The second phase of data collection was an hour-long task-based interview. During the first ten to fifteen minutes of the interview, the PSSTs were asked to elaborate on some of their work from the take home packet. The rest of the time was spent asking the PSSTs to explore geometric conjectures that are typical of a high school geometry course. They were given a list of thirteen conjectures and told that some of them are true, some of them are false and all of them are based on Euclidean geometry. The majority of the conjectures (9) were false, but they were not entirely false meaning that they were often stated for the general case and were not valid for the general case but were true for a specific case. The purpose of this was to put the PSSTs in a position where they were first exploring whether the conjecture was or was not true in an effort to evoke transformational reasoning.

The PSSTs were asked to decide if the statement was or was not true. If they felt the statement was true, they were asked to provide a justification that they felt would prove the conjecture. If they felt the statement was false they were asked to give a counterexample and if possible amend the conjecture so that it would be true and prove that conjecture.

During the interview the PSSTs were given a ruler, straight edge, compass, protractor, a list of terms and their definitions taken from a high school geometry textbook, and geometer's sketchpad that had built in tools that would construct special cases of triangles and quadrilaterals. The PSSTs were told to choose the conjectures with which they felt most comfortable because there would not be enough time to finish all the conjectures.

The take home packets were scanned and marked for accuracy. Interesting patterns in the PSSTs answers were identified to be explored in the interview during the second phase. The interviews were video recorded and transcripts were made along with scans of written work. The PSSTs proofs were coded using Harel and Sowder's (1998) taxonomy of proof schemes. The constant comparison method of grounded theory (Corbin & Strauss, 2008) was used to analyze how the PSSTs conceptions of figures affected their proof productions. Initial passes created codes while continued passes through the data resulted in codes being removed, added, and refined until themes emerged. One particularly relevant theme that emerged is that the proof productions of the PSSTs that had a restriction on the generality of the proof were a result of the PSSTs holding a partitional, static conception of figures.

Results

During the first phase a PSST with the pseudonym Lara accepted all partitional definitions for rectangle and also accepted a definition that was not valid for rectangle. On another item Lara was asked if different classes of quadrilaterals had the property that the diagonals bisected each other. She drew prototypical images of the classes and based off of those images she accepted properties that were not true about quadrilaterals. This suggested that Lara did not have a strong concept of quadrilateral. Moreover, for Lara it seemed that any property of a figure was a defining property.

During the second phase, Lara worked on seven conjectures. She ran out of time on her last proof and we chose to stop before she finished. She proved one conjecture, had one purely empirical proof and had five proofs with a restriction on the generality of the argument. What was clear is that it was not Lara's inability to think deductively that lead to her struggles with proving the conjectures it was her limited conceptions of figures.

During the second phase, it became clear that Lara saw the general case, quadrilateral, as constituting only the special cases (e.g. rectangle, rhombus, parallelogram, and square). For example, she proved the conjecture "the diagonals of a quadrilateral cut the area in half" by proving that the triangles created by the diagonal of a quadrilateral would be congruent. When asked about her proof being for a rectangle she said, "A rectangle is a quadrilateral."

For that same conjecture, Ana was confused at first and said she would have to prove for each case. She then proved that the triangles created by a diagonal of a rhombus would be congruent using the Side-Side-Side Postulate (SSS). She stated that opposite sides being congruent was a property and that the third pair of congruent sides was the shared diagonal. She then drew a rectangle, parallelogram, and square and created the same proof that rested on SSS for all three cases. When asked if she needed each part for her proof to be formal she said "if you wanted to prove for all quadrilaterals you would need to show for each case." Another PSST did not think she could prove a conjecture for all quadrilaterals unless she proved each case. In total, five of the thirteen PSST reasoned as if quadrilateral only meant the special cases.

To compound this Lara's figures appeared to be static for her since she drew only one figure for each conjecture except one and on that conjecture her new drawing appeared congruent to her previous drawing she simply made her lines straighter. For example she proved the conjecture "isosceles triangles are congruent when their vertex angles are congruent" by creating two similar sized isosceles triangles and using SSS. She stated from the definition that two sides would be congruent and she falsely assumed that the two pairs must then be congruent to each other as well. She then reasoned that since the vertex angles are congruent the opposite sides would have to be the same length. After creating her argument she gave no indication of considering how her argument would stand up for other figures despite being prompted to do so. When asked if she felt there were other ways to draw her figure, she said "I don't think there's another way."

Two other PSSTs gave a similarly false deductive proof for the problem because they drew two isosceles triangles that appeared to be congruent. Two other PSSTs gave a proof that had a restriction on the generality of the argument. An example would be that one PSST took the measure of the vertex angle to be 40 degrees and then using that specific case showed that the other angle measures would have to be 70 degrees. Eventually she showed that all three pairs of sides and angles were congruent.

Finally, Lara's figures were in my opinion protypical. Her triangles were nearly perfect equilateral triangles. Her drawings for quadrilateral were either rectangles or squares. That is not to suggest that Lara would not have recognized a definition of triangle as a polygon with three sides. It is to note that because Lara often reasoned off of one figure and that figures often perceptually had properties that were not true for all figures in the class she often became confused as to whether or not the conjecture was true. For the previous proof she went back and forth three times before deciding it was true. Because she did not spend time exploring diverse examples of triangles she was likely convinced perceptually by her drawing.

Interestingly, Lara's only formal proof was for the conjecture "the diagonals of a rhombus are angle bisectors." She drew one diagonal and mentioned drawing either one would not matter. She then stated that because it was a rhombus the two triangles were isosceles since the sides were all equal. Because the triangles were isosceles she knew that the base angles were equal. She then proved the isosceles triangles congruent and showed that all four angles created by the diagonal were congruent. Lara, like the other PSSTs whose proofs had a restriction on the generality of the argument was able to create a formal proof, but the conjecture did not test her restriction as it was true for all rhombi.

Implications

It is often stressed that teachers need richer and/or more experiences with proof however, the struggle the PSSTs faced in this study was more a result of how they conceived of the figures. Therefore it may be critical to first improve teachers' conceptions of figures prior to improving their proving ability. Or PSSTs may improve both their understanding of figures and proving by exploring conjectures that are not necessarily true so that they need to be truly explored first.

We investigated elementary children's three-dimensional mental structuring to measure volume using a dynamic computer environment constrained by a fixed sequence of length, width, and height. The results of three case studies indicate that children's attention to multiplicative reasoning over additive reasoning, recognition of the importance of three-dimensions, and interpretation of two-dimensional representations as three-dimensional were important in their development of reasoning about volume. The constrained order of dimensions proved critical.

Keywords: Geometry; Learning Trajectories; Measurement

Measurement of three-dimensional space is an integral topic in children's mathematical and scientific development. However, children's development of volume concepts is a long and complicated journey. Two important conceptual advances in children's understanding of volume involve unitizing and spatial structuring. Young children begin to quantify volume by unitizing space and iterating that unit throughout space (Van Dine, et. al., in press). Development of exhaustive and efficient counting schemes for their units involves the grouping of units, and the further grouping of units of units (Battista & Clements, 1996). This spatial structuring is foundational for computing volume.

The purpose of this investigation was to further understand how students develop spatial structuring schemes by grouping units. We instituted a dynamic computer environment that we believed would help students establish and apply structuring schemes to three-dimensional tasks presented in a two-dimensional format to answer the following question: In what ways does a dynamic computer environment constrained by a fixed order of operating in each of three dimensions affect students' three-dimensional mental structuring? Based on the research of Clements (1999), we expected that a computer-based visual environment might function as a concrete manipulative for students in much the same way as physical objects. In addition, the environment provided a restricted structuring scheme that would profer the recognition and incorporation of groups of units rather than single units in a broad collection. The restrictive aspects of our microworld afforded us the opportunity to investigate children's change in their application of spatial structuring schemes to operate with groups of units, much as dragging in dynamic geometry software was analyzed by Arzarello, Olivero, Paola, and Robutti (2002) to infer types of thinking about geometric ideas.

Theoretical Framework

We used a learning trajectory (LT) about volume measurement (Van Dine et. al., in press) to analyze student progression because we were investigating children's development of spatial structuring schemes. This LT consists of a developmental progression that includes specific instructional goals and tasks that support students' growth. These goals and tasks derive from Hierarchic Interactionalism's stance that children progress through domain-specific, hierarchic levels that can be characterized by specific mental objects and actions.

The following volume LT levels specify reasoning children exhibit. At *Volume Quantifier* (VQ) children distinguish volume from other spatial dimensions. At *Volume Unit Relater and Repeater* (VURR) children relate size and number of units explicitly and understand that fewer larger than smaller units will be needed to fill or packspace. At *Initial Composite 3-D Structurer* (VICS) children understand cubes as filling a space andexplicitly relate size and number of units to volume. Children also use additive reasoning, such as skip-counting, converting units requiring ratios even more complex than 1:2. At *3-D Row and Column Structurer* (VRCS) children begin using multiplicative comparisons to carry out comparative analyses of volume among several shapes or objects.

Methodology

As part of a larger study, we used a case study approach to investigate the thinking of three students at a private school in the Midwest. Each student participated in two interviews with one or two researchers. During each interview we asked the student to find the volume of rectangular prisms, first without, and then with the support of a dynamic computer environment developed using GeoGebra (International GeoGebra Institute, 2015).

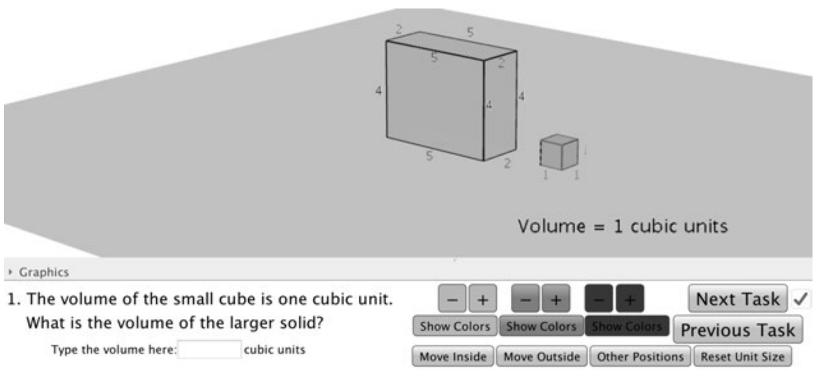

Figure 1: Dynamic Computer Environment

At the beginning of the first interview we introduced the student to the computer environment, (see Figure 1) asking him to push each color's '+' and '–' buttons and predict what would occur for each push. On each volume task, we first presented the student with a paper version identical to the task pictured in Figure 1. The interviewer said, "The volume of the small cube is one cubic unit. What is the volume of the larger solid?"

After the student solved the task on paper, the interviewer asked him to solve the same task using the computer environment. This allowed the computer environment to act as an intermediary between the two-dimensional representation and three-dimensional reality of the tasks. The computer environment allowed the student to move the unit cube inside a wire frame of the initial rectangular prism and add cubes to fill the wire frame controlled by the three sets of '+' and '–' buttons. Each set would add or subtract cubes in one of three directions.

We asked the student to use each set of buttons in succession, left to right, without returning to previous sets. When the student used the first set of buttons one cube at a time would be added or subtracted from the set of cubes, creating an n x 1 x 1 row of cubes. When the student used the second set of buttons new nx 1 x 1 rows would be added (or subtracted), one row at a time, resulting in an nx m x 1 layer. When the student used the third set of buttons new nx m x 1 layers would be added (or subtracted), one layer at a time. Any of the '+' and '–' buttons could be used at any given time, but we allowed few exceptions to the left to right succession. These restrictions created an environment conducive to students' spatial structuring development.

The interviewer asked questions of the student throughout the process of filling the wire frame on the computer. In a typical interview, just before using a set of '+' and '–' buttons, the student was asked to predict how many cubes there would be when he finished using that set of buttons. In some interviews, after filling the wire frame with cubes we asked the student to push one of the show colors buttons, which would alter the colors of the cubic units to show horizontal layers, vertical layers left to right, or vertical layers front to back in alternating colors.

Results, Discussion, and Conclusions

Peter, age 9, Tim, age 9, and Mike, age 10, were chosen as case studies because each demonstrated growth over the course of two interviews. Peter drew two-dimensional representations to solve three-dimensional problems and changed from a two-dimensional to three-dimensional counting scheme. Tim progressed from additive to multiplicative thinking and identified the importance of three dimensions in calculating volume. Mike changed his interpretation of the paper task and aligned his counting strategy with the computer.

Growth Along the Volume Learning Trajectory

At the beginning of the first interview Peter was using strategies typical of VQ when working on paper. For example, he was not accounting for hidden cubes, double counted cubes on the edge, and did not connect the displayed measures with the number of cubes that would fit along an edge. However, he also demonstrated strategies typical of VRCS when working with the physical 3-D objects and when using the computer environment. As Peter progressed through the two interviews he displayed fewer misconceptionstypical of VQ, such as double counting edge cubes, while working each task on paper. In their place, he began to use strategies typical of VRCS. This suggests that the analogous tasks in the dynamic computer environment helped Peter progress along the LT in his treatment of the paper tasks.

At the beginning of the first interview Tim demonstrated strategies and misconceptions ranging from VQ (failure to connect number with space) to VRCS (operating on a layer). Although Tim was able to calculate accurately on the final task, he did not demonstrate that he was operating at VRCS when solving the problem on paper. Using the computer environment Tim demonstrated, through consistent operation on composite units, that he was operating at VRCS. This suggests that the mediating power of the computer environment characteristic of Peter's experience might not have reached its full potential for Tim.

At the beginning of the first interview Mike was not operating at VRCS on the paper task, but was able to operate on a layer (typical of VRCS) using the computer environment. On the final task of the second interview Mike used VRCS strategies when solving the task on paper. This suggests that, in a manner similar to Peter, Mike progressed along the LT in his treatment of the paper tasks with the mediating influence of the computer environment.

Influence of the Dynamic Computer Environment

Students' three-dimensional spatial structuring schemes were influenced in several ways by the use of a dynamic computer environment that constrained students to a sequential use of length and width of base and then finally the height of a prism. First, the computer environment enhanced the opportunity for students to recognize the efficiency of multiplication for volume calculation. For example, Tim transitioned from additive to multiplicative strategies. Peter transitioned from a unit counting strategy to a combination of multiplication and addition.

Second, the computer environment highlighted the importance of three distinct measurements in the calculation of volume. Although all three students progressed from the use of many measurements to the use of only three, this was most apparent in the interviews with Tim. During the second interview Tim began writing the words tall, long, and wide with measurements ascribed to each.

Third, the computer environment acted as a mediator between two- and three-dimensional representations. Although it was difficult for all three students to interpret the two-dimensional representation of a volume task as a three-dimensional task, the computer environment facilitated a reinterpretation of the task that allowed the students to approach the task with a three-dimensional spatial structuring scheme.

Implications

We argue that there were three critical features of the study to support growth and we recommend that volume instruction include activities that incorporate these features. First, the computer environment implemented an implicit spatial structuring scheme by first adding single cubes to make a row, then adding additional rows to make a layer, and finally adding additional layers to create the full prism. This feature was important because it highlighted a reasonable spatial structuring scheme and the multiplicative nature of volume calculation.

Second, this iteration of rows and layers was accentuated by having students use each set of buttons in succession without repeated use of prior sets of buttons. This helped students visualize a beneficial structuring of space early in the process. It also accentuated the three-dimensional nature of volume and the use of those dimensions in sequence.

Third, the students were engaged in both paper and computer tasks. This was important because the computer provided a medium that allowed students to connect the two-dimensional paper representation with actual three-dimensional space. Although this took time, working the same task on paper and on the computer allowed the students to make connections between two-dimensional representations and three-dimensional space. Further research should investigate the efficacy of this intervention for instruction on volume measurement with elementary students.

Students' difficulties learning angle concepts constitute an enduring problem for the field of mathematics education that has been well documented at the elementary, middle, and undergraduate levels (Lehrer, Jenkins, & Osana, 1998; Mitchelmore & White, 2000; Moore, 2013). Recent research with undergraduate participants (Moore, 2013) has illustrated that instructional sequences with a focus on quantitative reasoning (Thompson, 2011) are productive for developing an understanding of angle measure as ratio. However, the outcomes of such an approach to teaching angle measure have not been documented in the existing literature with participants in other stages of education. While a ratio understanding of angle measure is productive for undergraduate students enrolled in a precalculus course, ratio may be a difficult starting point for some pre-college students learning about angle measure. Thus, research is needed to examine the effects of an instructional sequence with an emphasis on quantitative reasoning designed for students at other educational levels.

In this poster session, I present tasks, data, and findings from individual initial interviews conducted with two ninth-grade students who participated in an eight-month teaching experiment (Steffe & Thompson, 2005) focusing on angle and angle measure. The tasks in the initial interview protocol were organized around three themes that align with key principles of quantitative reasoning. First, prompts were developed to explore students' conceptions of angles as objects. Second, students were asked to describe the quality of an angle that is described by an angle's measure. Finally, students were provided with a series of tasks designed to explore how students order angles based on varying extents of this quality. This final theme was designed to engage students who have yet to develop an understanding of ratio. Findings regarding substantial differences in students' conceptualizations of angles will be presented. Additionally, three distinct strategies for making gross quantitative comparisons exhibited by one student will be presented. Implications for teaching about angle concepts will be considered.

Spatial-visualization using three-dimensional objects from different viewpoints is an important aspect of geometric reasoning and has been shown to be positively correlated to mathematics achievement (Cheng & Mix, 2014). Emergent work within a dynamic geometry spaces (i.e., Battista, 2007) calls for further investigations in these environments. We report on an exploratory study that aims to examine student spatial reasoning with tasks involving cube buildings in a popular computer game. Our study extends how students reason about spatial tasks when using the computer game Minecraft, an open-world building game, as a dynamic geometry environment.

We examined 16 4th and 5th grade students working collaboratively on spatial tasks in a Minecraft environment during an after-school mathematics enrichment camp. We gave participants a variety of spatial tasks to determine how the game Minecraft could be utilized as a dynamic geometry environment. The tasks were oriented around providing participants with three orthogonal views (front, top as seen from the front, and right side) of a cube building (Battista & Clements, 1998). The participants were asked to construct these buildings from the given orthogonal views, as well as create a written procedure to communicate their building strategy.

Our results indicate that the participants had trouble initially coordinating the multiple views and integrating them into one structure. Consistent with existing work (Battista & Clements, 1996), most students were eventually able to coordinate and integrate the views by exploring the placement of cubes. Our participants found the top view to be the most difficult to integrate, as they were initially not coordinating the other two viewpoints to account for depth. They interpreted the top view as the top layer of the structure. However, our participants used in-game features to create a labeling scheme by placing sign-posts to help in orienting their perspectives so that each participant could keep track of the same orthogonal view. By using the dynamic features of Minecraft to rotate around the cube building and observe a variety of viewpoints, the participants were able to explore the placement of the cubes, and thus coordinate and integrate the three viewpoints. Our poster will encapsulate our data, research and analytic processes, significant findings, as well as provide a guide for using Minecraft as a teaching and research tool.

INSTRUCTORS' PERCEPTION OF SPATIAL REASONING IN CALCULUS

V. Rani Satyam
Michigan State University
satyamvi@msu.edu

Keywords: Geometry; Post-Secondary Education; High School Education; Advanced Mathematical Thinking

Calculus may be regarded as a gatekeeper for students pursuing STEM careers, as a required course for many students in engineering and science. The calculus reform debates of the 1990s illustrated this ongoing struggle to improve the teaching and learning of calculus. There is a need for understanding what skills may be helpful for students to be successful in learning calculus.

One such skill is spatial reasoning, the ability to imagine manipulation of objects. Ferrini-Mundy (1987) investigated whether spatial reasoning training would improve students' achievement in calculus. She found that spatial reasoning relates to certain areas of calculus. Studying the relationship between spatial reasoning and calculus specifically has some grounding, because spatial reasoning is considered integral to studying engineering (Ferrini-Mundy, 1987). This study aims to answer the following research questions: What do calculus instructors perceive as topics from calculus that use spatial reasoning? What kinds of spatial reasoning are involved in learning calculus? The aim is to see (a) if and where spatial reasoning appears in calculus content and (b) identifying if there are certain types of spatial reasoning over others that are helpful to learning calculus.

Uttal et al. (2012) constructed a 2x2 framework for classifying types of spatial tasks. A task is (a) intrinsic or extrinsic and (b) dynamic or static. A spatial task is *intrinsic* if the focus of the task is about the object itself, whereas a task is *extrinsic* if the focus is on the relationship between an object and its environment. As a second dimension, a task is *dynamic* if the subject must mentally imagine movement, whereas a task is *static* if it does not involve movement.

Semi-structured interviews were conducted with four (N=4) calculus instructors at a large university. Participants discussed the role of spatial reasoning in single variable and/or multivariable undergraduate calculus. Then, they gave specific examples or topics they believed used spatial reasoning or where spatial reasoning would be helpful. These examples were analyzed using Uttal et al.'s (2012) framework to identify the types of spatial reasoning.

Some topics that the participants gave included the Fundamental Theorem of Calculus, epsilon-delta limits, integrals, level fields and planes, three dimensions in general, etc. This research is currently in the analysis phase, but preliminary results suggest that many of these calculus examples are dynamic and extrinsic in nature. This suggests that students who struggle with imagining movement, especially objects in an environment, may also struggle with understanding certain topics in calculus; this research hopes to illuminate how spatial reasoning is embedded in calculus.

HOW DO GEOMETRY TEACHERS CONSTRUCT MEANINGS IN RELATION TO STUDENTS' PRIOR KNOWLEDGE

Gabriela E. Vargas
University of Illinois at Urbana-Champaign
gvargas2@illinois.edu

Gloriana González
University of Illinois at Urbana-Champaign
ggonzlz@illinois.edu

Keywords: Geometry; Classroom Discourse; Teacher Knowledge

Researchers have stated the importance of broadening students' opportunities to establish connections with their funds of knowledge when doing mathematical work (Drake et al., 2015). By funds of knowledge we refer to the knowledge that students accumulate from their life experiences (González, Andrade, Civil, & Moll, 2001). We identify teachers' actions for activating students' prior knowledge in typical geometry lessons and provide a description of these actions. Drawing from a social semiotics approach to examine meaning making processes in mathematics classrooms (Morgan, 2006), we ask: *What meanings do teachers construct when establishing connections between students' prior knowledge and mathematical content?* We provide examples of actions that teachers perform with detailed descriptions about the relationships that teachers establish to support students' mathematical understanding.

We analyzed eight lessons from five different teachers in four different high-needs schools. We focused on how the teachers established connections with three sources of prior knowledge: mathematical content, the context of the problem, and out-of-school practices. We identified sixteen instances where teachers activated students' prior knowledge with 13 actions. Seven actions pertained to mathematical content, six actions pertained to out of school mathematics, and no actions were related to contextual problems. This finding may respond to the fact that none of the lessons were problem-based, so the teachers did not need have to discuss relevant contexts as in other investigations (e.g., Jackson et al., 2013). We then conducted a thematic analysis (Herbel-Eisenmann & Otten, 2011) to examine how teachers constructed mathematical meanings. For mathematical prior knowledge, teachers established relationships between students' knowledge of mathematical definitions, concepts, theorems, and algebraic operations. For out-of-school practices, teachers established relationships between spatial or environmental themes, cultural references, and embodying mathematics with properties of angle pairs. Actions connecting with out-of-school practices created multiple entry points to develop mathematical understandings. Our goal is to show how these actions promote students' understanding of geometric concepts in relation to their funds of knowledge. Furthermore, cataloging teaching actions have implications for teacher educators and researchers in documenting examples of activating students' prior knowledge in secondary mathematics.

STUDENTS' REASONING ABOUT CUBE-PACKAGE ENUMERATION PROBLEMS

Michael L. Winer
Ohio State University
winer.18@osu.edu

Michael T. Battista
Ohio State University
battista.23@osu.edu

Keywords: Cognition; Geometry; Elementary School Education

According to PSSM, "Spatial visualization—building and manipulating mental representations of two-and three-dimensional objects and perceiving an object from different perspectives—is an important aspect of geometric thinking" (NCTM, 2000, p. 41). In fact, almost all geometric reasoning and problem solving are intimately connected to spatial reasoning. More generally, the National Research Council claims that, "Underpinning success in mathematics and science is the capacity to think spatially" (NRC, 2006, p6), a statement backed by much research (Newcombe, 2010; Wai et al, 2009).

In this paper, we investigate the nexus of geometric and spatial reasoning by examining students' reasoning about 3D packing problems (Battista & Berle-Carman, 1996). For example: How many packages consisting of a line of 5 cubes fit into a 4-by-6-by-3 box? Such tasks add complexity to students' spatial structuring and enumeration because the packages may not completely fill the box, and students must properly visualize package orientations. Packing problems are not only important in mathematics, but provide an opportunity for students to deepen, clarify, and extend their reasoning about volume and geometric measurement.

In our analysis we use theoretical constructs from research on spatial visualization and research in mathematics education to investigate the reasoning, cognitive processes, and mental models students use to solve cube-package problems. We also analyze the cognitive obstacles students face. Our data sample consists of videotapes of four 5th grade boys who were working in pairs on cube-package problems in an inquiry-based classroom as part of a four-week unit on volume. In our data analysis, we discovered three cognitive processes above and beyond those used in standard cube-packing, volume problems—package-orienting, orthogonal projecting, and package-locating. We also found that students were using three types of mental models: layer composite-unit based, non-layer composite-unit based, and non-composite-unit based. Our research geometrically elaborates two general spatial reasoning strategies described in spatial visualization research—visualizing object transformations and decomposing objects into parts and reasoning about the parts (Hegarty, 2010).

A REFINEMENT OF MICHENER'S EXAMPLE CLASSIFICATION

Laurie O. Cavey
Boise State University
lauriecavey@boisestate.edu

Margaret T. Kinzel
Boise State University
mkinzel@boisestate.edu

In this paper we propose a refinement of Michener's (1978) well-known example classification based on data from university mathematicians. The refinement takes into account the mathematician's perspective on the role of examples in doing mathematics. More specifically, our work provides insight into the ways in which mathematicians talk about using examples in their scholarly work and their work with students. The proposed classification has the potential to inform our work as teachers as we strive to create opportunities to engage students in authentic mathematical work.

Keyword: Advanced Mathematical Thinking

Examples play a significant role in teaching and learning mathematics. Often it is with a carefully formulated example that subtleties in a definition or an algorithmic process can be detected. Examples make it possible to consider generalities, but can also limit one's mathematical perspective. Ideally, mathematical learning experiences provide opportunities to develop a rich array of examples that contribute to students' problem-solving skills and understanding.

Interestingly, what is known about the role of examples in doing mathematics is not adequately informed by the mathematician's perspective. Few studies on examples or related topics have mathematician participants (c.f. Lockwood, Ellis, & Knuth, 2013). On the other hand, there is evidence that mathematicians frequently generate examples in the process of validating a proof given by a peer (Weber, 2008) and that mathematicians use different types of examples in conjecture-related work (Lockwood, Ellis, & Knuth, 2013). In addition, given the number of proofs without words publications, it is reasonable to assume that mathematicians value opportunities to "see the general in the specific" (Mason & Pimm, 1984). That is, mathematicians sometimes use an example to make a proof. However, we have little evidence that speaks to the mathematicians' perspective on the use of examples in teaching or how examples support their own mathematical work.

Michener's seminal work (1978) presented an epistemology of mathematics from her perspective as a mathematician that classified example types for the development of mathematical thinking: start-up examples, reference examples, model examples, and counterexamples. Classifying an example is necessarily tied to the purpose the example serves in supporting mathematical learning. Studies on the use of examples with students continue to reference Michener's classification (e.g., Alcock & Inglis, 2008; Watson & Mason, 2002; Zaslavsky & Shir, 2005). Because of this, we wondered whether Michener's classification is useful when examining the ways mathematicians use examples in their work. In particular, we asked: do mathematicians' articulations of the uses of examples align with these classes? Do the classes capture the range of the mathematicians' articulations related to the uses of examples?

We describe our initial refinement of Michener's epistemology based on data from an earlier study where we examined how mathematicians make sense of definitions (Kinzel, Cavey, Walen, & Rohrig, 2011). We then use preliminary analysis of data from a current study focused on mathematicians' use of examples more generally to propose further refinements.

Background

Michener's (1978) epistemology of mathematical knowledge presents three interrelated categories of items: results (theorems), concepts (definitions, heuristics, advice), and examples (illustrative material). The interrelatedness of these categories is described in terms of a predecessor/successor relationship: Examples may lead to the construction of definitions and/or theorems or alternatively may serve to illustrate a definition or theorem. These relationships are connected through the notion of "dual relations" and the identification of "dual items." The dual items of a particular example are the ingredient concepts and results needed to construct the example and the results motivated by the example. Similar duals can be defined for results and concepts. Thus, examples are integrally entwined with the other categories of items.

Michener further states that because not all examples are "created equal," those more noteworthy deserve further attention and can be grouped into epistemological classes. These classes are not intended to be disjoint: A single example can play more than one role, perhaps even within a particular context or situation. It is these classes of examples in which we are interested. Michener's four classes of examples are paraphrased below (1978, pp. 366–368).

- *Start-up examples* are used to introduce a new subject by motivating basic concepts and useful intuitions, such as using a specific picture or visual representation to highlight key features of graphs of monotonically increasing sequences.
- *Reference examples* are widely applicable and provide a common point of contact, and so tend to be referred to repeatedly. This class can also include standard cases used to verify one's understanding of a particular concept or result as when a particular function is used to illustrate what it means for a graph to be concave down.
- *Model examples* suggest and summarize the expectations and default assumptions about results and concepts. The absolute value function could be a model example for the idea that a continuous function need not be differentiable on its domain.
- *Counterexamples* sharpen the distinctions between concepts and are used to show a statement is not true. The function $f(x) = x^3, x \in \Re$ is a counterexample to the statement that all cubic polynomial functions have two local extreme values.

Goldenberg and Mason (2008) elaborated on Michener's classes, pointing specifically to the role of "pertinent nonexamples" (p. 184) in clarifying the sorting of items into things *that are* versus things *that are not*. Nonexamples are not equivalent to counterexamples in that there may not be a statement whose truth is in question; however, the identification of nonexamples can also serve to sharpen distinctions or interpretations of results and concepts. Nonexamples may also be used to develop one's intuition (start-up example) or to verify one's established understanding of a concept (reference). The primary use of nonexamples is to highlight contrast, which can overlap with the purposes of other classes. In this paper, we include nonexamples as a fifth class in our framework, paying particular attention to instances when nonexamples can be classified otherwise. As we describe in the next section, data from our earlier research supported the inclusion of this fifth class.

Methodology

Interview data from our earlier research, which focused on how mathematicians make sense of definitions, revealed themes related to the role of examples within that work (Kinzel, Cavey, Walen, & Rohrig, 2011). Nine mathematicians participated in interviews in which they were asked to first describe how they make sense of a new definition for themselves and then how they support students in making sense of new definitions. Examples, and the purposes for using examples, were prominent in the mathematicians' descriptions. Making sense of definitions is a key component of mathematical work but does not capture the full range of that work. We used data from the earlier study to begin a refinement of Michener's framework, then returned to the same group of mathematicians to explore the role of examples beyond the context of definitions. In the follow-up study we asked the mathematicians to review the classes of examples presented in the framework and consider (1) how well the framework reflects the ways in which they use examples, (2) if there are uses of examples not represented in the framework, and (3) if the framework is a useful means for thinking about mathematical work, either for themselves or for students. As we are still collecting data from the follow-up study, what follows are the methods used to establish the initial refinement.

Interview data were transcribed and pseudonyms were assigned to the participants. Individual research team members reviewed transcripts to identify instances where the mathematicians made a reference to the use of an example (*example-instances*); coded transcripts were then shared and example-instances verified. To be identified as an example-instance, an articulation by the mathematician either explicitly included the word "example" or referred to illustrating a concept or result in some way; for instance, a description of how the mathematician uses examples to clarify which items fit a definition and which do not counts as an example-instance. The instances we identified did not always include the articulation of a specific concept or mathematical object. Where possible, the specific concept or result within the instance was identified (e.g., articulating the usefulness of providing visual examples to illustrate the concept of collinear points).

The second stage of analysis focused on coding the example-instances based on Michener's (1978) classes of examples. We focused the data analysis through two questions: (a) What types of examples did the mathematicians describe? and (b) How did they describe the purpose of each example? We began this part of the analysis with a discussion of Michener's classes and a group analysis of one transcript to clarify the shared understanding of the classes. This involved using transcript data to clarify distinctions between the classes. These distinctions often focused on the perspective of the learner as well as the intended use of the example by the mathematician. After these criteria were established, the remaining transcripts were analyzed by individual team members; two other team members then verified the coding. Within this analysis, we encountered several articulations related to the construction or analysis of *things that are not*; a function that would *not* meet the criteria of a particular definition, for instance. We introduced *nonexamples* as a fifth class in the framework to capture these articulations.

To illustrate the coding process, we present several example-instances and the resulting classification. Consider the articulation from Adam in response to what helps him to make sense of a new definition: "I start off with things that are familiar to me . . . I would start going through the list of standard examples that I have in my head for these." This instance was coded as *reference* because we inferred from this statement that Adam's "standard examples" were widely applicable. On the other hand, Sam responded to the same question as follows: "the simplest thing to try first is just to look at the specific concrete examples … you kind of get a feeling of how this specific definition is working." This instance was coded as a *start-up,* since we inferred from "get a feeling of how this specific definition is working" that Sam's purpose was to develop his intuition. About three-fourths of the way into the interview with Greg he began explaining the importance of using examples with students where the "main feature" of the concept is "worked out that we actually want to transport by those examples." By this, we inferred that he was articulating the importance of using an example that illustrates critical features, and thus coded it as *model*.

After we coded all the example-instances, we examined the instances within each class to identify themes in how mathematicians talked about using examples to support either their own or their students' learning. Broad epistemological themes emerged within each class of examples. Recall that mathematicians were asked to reflect on their own processes/experiences as well as on those they intend for students. Because of this, it was necessary to identify the intended learner within example-instances. Each instance could potentially refer to the mathematician, to their students, or to a hypothetical learner. When we refer to the intended use of an example, we always mean in reference to the learner, whether it be the mathematician or a potentially hypothetical student. However, the epistemological themes that emerged address both the instructor's and the learner's perspective. It was the identification of these themes that led to the refinement of Michener's classification of examples.

Initial Refinement of Michener's Example Classification

In this section we provide a description of our initial refinement of Michener's example classification. Data analysis led to clarification on the classes already noted in the literature (Michener, 1978; Watson & Mason, 2005). Informal conversations with mathematicians about our proposed refinement indicate that these categories are useful but may not be exhaustive, especially in relation to work with results or theorems. For this reason, we anticipated data from the follow-up study to lead to further expansion and clarification of our initial refinement.

See Table 1 for a list of the classes in our initial refinement and a summary of the purposes associated with each class.

Table 1: Initial Refinement Of Michener's Example Classification

Class	Purpose
Start-up	develop intuitive notions consider what is and what is not to isolate concept check initial understanding through generating examples
Reference	widely applicable or standard case isolate new subclasses of mathematical objects
Model	demonstrate salient features consider interplay between features of definition and example
Counterexample	refute the truth of a statement in question
Nonexample	demonstrate what *is not* show "control" of a definition consider particular features of a definition

Start-Up Examples

In presenting Michener's classification, Watson and Mason (2005) describe start-up examples as those from which "basic problems, definitions, and results can be conjectured at the beginning of learning some theory and can be 'lifted' to the general case" (p. 64). The articulations from the mathematicians provide further detail into particular ways in which this conjecturing might be supported. For example, analyzing a collection of examples can help to isolate essential features of a new concept. The activity of generating examples of a new idea contributes to clarifying one's emerging understanding of the idea. Creating variations of known examples can serve to further demonstrate or clarify one's understanding. From the learner's perspective, examples in this class should be familiar objects that also illustrate key features of the new concept.

Mathematicians described using examples to develop intuition about the features of the concept that distinguish it from other related ideas. Greg articulated that students may not know to what to pay attention at first: "And then I might try to work out with them a little bit, you know, what could be mathematically interesting there? What are the features there? . . . Then state a formal definition and then go and do plenty of examples to kind of work on that." Ned articulated this use of examples in his own work: "But if it was foreign or I read it and realized that I didn't truly understand it, then I probably would try to come up with an example. Which is a hard thing because you need your example easy enough to understand, yet hard enough so that it eliminates what needs to be eliminated." Wes gave a similar response: "And how is it new? And can I think of something that does this as well as something that doesn't do this?" Across these instances, the focus was on using examples of *things that are* as well as examples of *things that are not* to develop intuition for the essential features of a newly encountered definition.

Reference Examples

Reference examples are intended to be widely applicable and available for consideration as a standard case. A learner may return to one or more reference examples while in the process of developing understanding of a new idea or subclass of mathematical objects; perhaps using a familiar example of a group to explore a new property, for instance. A learner may have a known and familiar set of standard examples that are consciously used to verify or extend understanding. As with model examples, the level of awareness of the learner with respect to the essential features of these examples is critical in their appropriate use. Overuse of a specific case could lead to confusion between aspects of the particular with aspects of the more general concept.

Wes and Adam specifically discussed using familiar objects to *understand an unfamiliar subclass of objects*. Wes shared an experience of reading a student thesis in which a particular property was introduced. In considering whether he understood the property as it related to the thesis, he asked himself: "It says it does this, or these things do that, so why is this (stably free module) different from this thing that we have (free module)." To make sense of the notion, he noted that he began thinking of examples of free modules with which he was familiar and tried to identify which would have the new property and which would not. Adam expressed this same idea in his own work; a general practice for him when encountering a new idea is to check his "list of standard examples" to see which of those objects illustrate the new idea. Adam also explained how he uses this process with students. The instance he shared related to introducing the concept of algebraic groups; he drew students' attention to familiar sets with operations (such as integers under addition) and then engaged them in determining which of these familiar things met the criteria of a group. In this way, Adam seemed to intend that these familiar instances could become reference examples for the students for the concept of group.

Model Examples

Model examples are intended as paradigmatic and generic, and can be used to convey salient features of an idea. As noted by Sam, a model example may emerge from the analysis of a collection of examples; one exemplar from the collection may serve as an illustration of the desired concept. The presentation of a model example can serve to highlight the interplay between the use of the example and one's understanding of the idea; that is, the activity of determining *why* the presented exemplar qualifies as a model example potentially interacts with one's understanding. Poor choice of a model example can cloud one's understanding of an idea, in that this awareness of essential features may be (perhaps implicitly) compromised.

In choosing examples to present to students as potential model examples, Greg emphasized the need for the example to illustrate the key features, and that it be "not too trivial," yet also "not too complicated" as that could interfere with "seeing" the features of the concept. Marc also spoke of choosing pictures to convey relevant features to students. Ned stated that he uses the interplay between example and concept as a means for checking students' understanding. After presenting a (model) example, he makes small variations, such as changing a positive slope to negative. In his experience, students who were able to see the key features were less likely to be distracted by the variation. That is, we would argue that Ned was determining whether students saw the initial presentation as a model example for the presented idea; if so, students were more likely to be able to identify key components and perhaps not be distracted by variations that did not alter the underlying concept.

Nonexamples

Nonexamples clarify distinctions between *what is* and *what is not*, and thus are used to demonstrate the importance of key features of a concept. The purpose of a nonexample can overlap the purpose of start-up, model, or reference examples. A collection of examples can be used to draw attention to common features; contrasting such a collection with nonexamples serves to sharpen distinctions. The successful generation of relevant nonexamples can be taken as an indication of the "control" one has with regard to a concept or result. A learner's explicit attention to aspects of nonexamples is an indication of depth of understanding.

Mathematicians discussed using nonexamples to refine one's understanding of a definition or concept. In particular, the generation of nonexamples can focus attention on salient features and the purpose of those features. Often, this involved dropping or violating one or more criteria within the definition and asking, in Ned's words, "how does that change the outcome of what is permissible?" Sadie stated that nonexamples give a "different perspective" through analyzing what "it can't be." Sam acknowledged that "find[ing] an example in which this fails" can be challenging for students, but can be a critical step in developing understanding of the definition by forcing one to "look deeper at what things are."

Counterexamples

Counterexamples are used to refute a statement. Some become well-known and used often. While not an explicit focus of our analysis, we see some common aspects. In particular, the learner's awareness of why an instance qualifies as a counterexample for a given statement is key, and could serve as an indication of the learner's understanding of the underlying ideas.

Current Work

We are currently in the midst of a follow-up study focused on mathematicians' use of examples more broadly. We asked the mathematicians who participated in the definitions research study to read the results of that work, including our initial refinement of Michener's example classification prior to a face-to-face interview. We also asked each mathematician to respond to the following questions in writing prior to the interview:

- How well does the proposed example-use framework reflect the way you think about the purposes of different types of examples in your mathematical work? Please address this question as it relates to your scholarly work (writing, research, etc.) and teaching.
- Is there is a type of example that you use that is not articulated in the framework? Is there an example type that you rarely use? Please explain.
- Is the framework useful as a means of thinking about the different purposes of examples in doing mathematics? If so, in what ways?
- Is the framework useful as a means of thinking about teaching mathematics? If so, in what ways?

The mathematicians we have interviewed articulated benefits associated with thinking carefully about the purposes of different types of examples in their teaching but not in relation to their own mathematical work. They describe using examples for the purposes described in the initial refinement along with other purposes more closely related to their scholarly work. Thus far, it appears that there may be one or two other example classes that warrant defining. In particular, two mathematicians noted how examples can be preceded by definitions and results, providing the impetus for *existence examples*. The purpose of this class is to demonstrate the existence of a mathematical object and is thus distinct from the other classes. Greg noted, "You may actually indirectly prove that a thing exists without actually constructing it" while Evan noted odd perfect numbers as an instance where the definition has preceded examples. Another possible category is that of *boundary examples*—those that support understanding of "where the boundaries are" (Evan) with a concept or result. It not yet clear from the data whether this category stands on its own. The data suggest that there is overlap with the purposes of reference and nonexamples in that boundary examples can be used to identify subclasses of objects or to demonstrate control of a definition. Further analysis is needed to clarify these distinctions. Moreover, careful consideration of the epistemological value of potential new classes is needed. As noted by Michener (1978), the classes are not meant to be exhaustive but rather particularly informative in relation to thinking about how to fully support students in learning mathematics.

Discussion

Research indicates that students benefit from generating their own examples rather than passively accepting examples given by the teacher (Dahlberg & Housman, 1997; Watson & Mason, 2002; Sowder, 1980; Weber, Porter, & Housman, 2008). In our work, we observed mathematicians attending to perceived benefits of example generation both for themselves and for their students. Generating examples was seen to help build intuition about a new concept (start-up), to sharpen distinctions (non-example), and to reveal or verify understanding (start-up and/or model). In general, the ability to construct an appropriate example was taken as evidence of some level of understanding. Being able to then modify or create variations of the example could be further evidence of understanding. Constructing nonexamples was seen as more challenging, but was also seen as evidence of working knowledge of a concept.

Watson and Mason (2005) describe *example spaces* as a metaphor for the psychological structure of the ideas and examples associated with a particular concept. An interesting feature within the mathematicians' articulations was the interplay between examples and related ideas. For instance, Adam talked of drawing on his set of "standard cases" of objects to make sense of a new concept. He may think of standard examples of groups to make sense of a newly encountered type of group. Using Watson and Mason's metaphor, he pulls reference examples from one example space to be used as start-up examples in a related space. In discussing their work with students, the mathematicians talked of beginning with objects that should be familiar or known to students, using these as start-up examples for a new concept, or establishing them as reference examples for a concept. These descriptions align with Watson and Mason's characterization of mathematical activity as the reorganization of example spaces.

Our work aligns with work by Lockwood and colleagues (2012, 2013) in which they analyzed mathematicians' articulations of the role of examples within the context of exploring conjectures. We particularly agree with Lockwood, et al. (2012) as to the importance of "intentional example exploration" (p. 157). Our application of Michener's classification relies on identifying the intended role of the example; for instance, a model example is most powerful when the learner recognizes the features that exemplify the concept.

Implications

In general, refinement of the example classification provides the mathematics education community with a common language about the role of examples in teaching and learning mathematics. Having a common language is important for future advances in the area. Of course, this work also raises important questions regarding the role of exemplification in the teaching and learning of mathematics. In particular, how well does the classification capture the role of examples within a broader context of mathematical activity? How might the classification be used to guide instructional design? Could deliberate attention to the purposes support the selection of, presentation of, and plans for student engagement with examples?

A common language for example types can support more intentional selection of examples within instruction. From an instructional design perspective, one might attend to the intended purpose of an example to determine its place within the unit of study. Following Adam's suggestion, for example, a textbook author might include one or more start-up examples of a concept prior to introducing a definition. Likewise, reference and model examples may be better placed after a definition has been presented. Further, a classroom teacher might be more explicit about the role of examples, providing support to students' interpretations and use of examples.

STUDENTS' CONCEPTIONS OF DERIVATIVE GIVEN DIFFERENT REPRESENTATIONS

Michelle Cetner
North Carolina State University
mcetner@ncsu.edu

In Calculus, students are often both presented problems with and taught to use three interconnected types of representations: symbolic, graphic, and numeric. However, students often fail to notice the relationship between mathematical objects (and even the same object) that are presented using different types of representations. Using the APOS framework and student interviews, this study explores ways in which students conceive of tasks involving derivatives that are posed using the different representational types. Patterns are drawn among: problem conception and representation type; problem conception and task type; schema level and representation type; and schema level and problem conception. Though there were patterns between representation and student conception, stronger patterns emerged between task type and student conception.

Keywords: High School Education; Cognition

Introduction

In calculus, the concept of derivative is often taught using three interconnected types of representations: symbolic, graphic, and numeric (Schwarz & Hershkowitz, 2001). However, students often do not recognize and use the relationships between them well (Asiala et al., 1997; Aspinwall, Shaw, & Presmeg, 1997; Schwarz & Hershkowitz, 2001). This may be for a variety of reasons, such as that algebraic representations are typically used more on tests (Aspinwall et. al, 1997), that instruction focuses on specific translation skills instead of a discussion of relationships between representations (Schwarz & Hershkowitz, 2001), and that students are often asked to translate in one direction, but not in reverse (Asiala et al., 1997).

Anna Sfard (1991) discussed the interaction between visual (graphs and pictures) and analytic (equations and numbers) representations and grouped students' conceptions into two complementary categories: operational and structural. She claimed that analytic notation encourages an operational conception, for which the focus is the procedure, whereas visual notation encourages a structural conception of the mathematical entity as an object. Therefore, students might tend to think about derivative differently depending on the representation presented in a problem. For example, if a student is presented with a graph of a function, he may tend to use a structural conception, but if presented with an equation he may hold an operational conception. This does not give information about the student who is presented with a tabular representation, or that needs to translate between representations in order to solve a problem.

Similar to Sfard's operational and structural conceptions, Dubinsky posits the APOS theory, with which student understanding of a mathematical entity falls into one of four conceptions: action, process, object, and schema (e.g. Dubinsky & McDonald, 2001; Maharaj, 2013). The action and process conceptions align with Sfard's operational conception, while the APOS object conception aligns with Sfard's structural conception (Maharajh, Brajlall, & Govender, 2010; Tall, 2013). However, while a student may possess several different conceptions of a mathematical entity, the student may not access all of these equally in all situations (Baker, Cooley, & Trigueros, 2000), particularly when comparing visual and analytic representations, both during instruction and problem solving (Maharajh et. al, 2010).

Dubinsky & McDonald (2001) and Baker et. al (2000) also discuss the notion of the *triad*, a fixed order of three stages of schema development (intra, inter, and trans) in which students progressively

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

see more connections between events or objects. Students begin at the *intra* stage, where they see mathematical entities as disconnected objects, and as they develop connections between objects, they progressively advance through the *inter* stage to the *trans* stage, in which they possess a coherent schema with which they can reason about one or more related objects in a meaningful way. One might expect this triad to exhibit a correspondence of stages to the APOS conceptions of cognition, with the action conception corresponding to the intra stage, the process conception corresponding to the inter stage, and the object conception corresponding to the trans stage. This observation brings into focus the following research question: how are students' conceptions of derivative related to the ways in which they make connections within and among different representations? For example, is a student who is operating at the intra stage unable to utilize an object conception for a mathematical entity because that would require connections that are not yet made? Or, if a student displays an object conception of derivative when presented a graph, but an action conception when presented a table, would the student be able to draw the necessary connections between the information given by the graph and the table?

Framework

APOS theory has been used by a variety of researchers to analyze students' procedural and conceptual knowledge (e.g. Asiala et. al, 1997; Baker et. al, 2000; Hähkiöniemi, 2006; Maharaj, 2013). APOS stands for *action*, *process*, *object*, and *schema*, which are categories of conceptions that an individual might hold of a mathematical entity (Maharaj, 2013). Understanding APOS conceptions allows us to form a *genetic decomposition*, or model of the specific conceptions that a learner might make (Asiala et. al, 1997) to better describe students' understanding of mathematical concepts (Dubinsky & McDonald, 2001; Maharajh et. al, 2010).

An individual who has an action conception is able to carry out a step by step set of instructions or a written algorithm, but is able to do little more (Asiala et. al, 1997; Dubinsky & McDonald, 2001) or to control the action (Hähkiöniemi, 2006). While an action is always in response to a stimulus that is perceived as external, a process performs the same operation as an action, but may be contained completely in the mind of the individual (Maharaj, 2013). This internalization allows the individual to be able to reverse or compose operations (Dubinsky & McDonald, 2001). An object is formed as a complete entity in the individual's mind when a process can be transformed and acted on as a totality (Dubinsky & McDonald, 2001; Hähkiöniemi, 2006; Maharaj, 2013). A schema is a collection of actions, processes, and objects coordinated by the individual (Baker et. al, 2000; Dubinsky & McDonald, 2001).

Because an individual's schema is an evolving composition of actions, processes, and objects, it is more of a meta-cognitive development for problem solving than a conception in itself (Baker et. al, 2000; Dubinsky & McDonald, 2001). This means that at any given moment, when an individual uses either an action, process, or object conception to solve a particular problem, the individual is concurrently operating within their schema as well. For this reason, this study describes only the APOS conceptions of action, process, and object, and assumes that the individual is always operating within some personal schema.

Table 1 gives examples of what might be observed of a student using each conception if a problem involving derivative is given using each of the three main representations: table, equation, and graph. It is important to note that even though these conceptions seem to evolve from one to the next, the development of action, process, and object is not necessarily in that order (Dubinsky & McDonald, 2001). Though this study explores the student's conceptions as a snapshot, and not being developed over a substantial period of time, this is still a valuable reminder for the current study because, for example, it is possible for an individual to use an object conception without having ever thought through the action or process involved first.

It is a purpose of this study to determine if a student will tend to use different APOS conceptions given different problem representations. For example, if given a table, a student can perform steps to approximate a derivative at a point only when prompted for the steps, the student would be at the action conception. However, if the student is given the same question with a graphical representation and has no difficulty recalling that the derivative at a point being the slope of the line tangent to the graph, drawing the line, and approximating the slope, the student would be at categorized as having a process conception. This genetic decomposition is used in the analysis and discussion of students' responses to interview questions in this study.

Table 1: APOS Conceptions of Derivative Given Different Representations.

Conception	Table	Equation	Graph
Action	The student follows steps when prompted to find slope and write equation of tangent line.	The student can use steps to find equation for derivative and tangent line.	The student can use steps when prompted to find slope from graph and draw the tangent line.
Process	The student can easily apply procedures using tabular data, and can catch errors and explain reasoning.	The student can easily manipulate equations dealing with derivatives and provide some rationale.	The student can notice and use parts of the graph to answer questions about tangent line and derivative.
Object	The student uses the table to reason about derivative and solve problems.	The student uses the equation to reason about derivative and solve problems.	The student uses the graph to reason about derivative and solve problems.

APOS theory has been further refined through the introduction of the *triad* to recognize the evolving nature of schemas (Baker et. al, 2000). The triad consists of three stages, *intra*, *inter*, and *trans*, which occur in that order (Baker, Cooley, & Trigueros, 2000). As is suggested by their names, at the intra stage, the individual is concerned with and isolates the single action, process, or object of focus, while at the inter stage, relationships are formed between cognitive entities (Dubinsky & McDonald, 2001). For example, a student given a graph at the intra stage may be able to draw a tangent line but not look for numerical information to find its slope. The student at the inter stage would use the graph to find numerical values or an equation that could then be used to solve the problem, but these connections would still be isolated and superficial and while the student may reason about why a particular representation is chosen, the student does not reason about more than one representation at a time. An individual operating at the trans stage exhibits a schema with the most coherence, for example, recognizing all situations requiring the computation of a derivative at a point as interconnected (Baker et. al, 2000). Table 2 describes what might be observed of a student at each stage given different representations.

Methods

Four students were interviewed using a series of calculus questions to determine their understanding of derivatives. The researcher recruited volunteers from an AP Calculus class at a mid-sized, southern high school. The volunteers from this class are considered to be typical students who take AP Calculus at this school. They have all taken two courses in algebra, a course in geometry, and a preparatory class for calculus (Pre-calculus). Two are female and two are male, with one of the females in twelfth grade and the other three students in eleventh grade. All four of the students interviewed perform well in their class, with an average grade of either an A or high B. At

Table 2: Triad Stages for Derivative Given Different Representations.

Triad stage	Table	Equation	Graph
Intra	The student makes decisions using only a tabular representation.	The student makes decisions using only equations.	The student makes decisions using only a graphic representation.
Inter	The student uses the values in the table to construct a graph or equation.	The student uses the equation to find numerical values or construct a graph.	The student uses the graph to find numerical values or an equation.
Trans	The student reasons about connections between the table and an equation and/or graph to solve the problem.	The student reasons about connections between the equation and table and/or graph to solve the problem.	The student reasons about connections between the graph and the equation and/or numerical values to solve the problem.

the time of the interviews, students had been in the calculus class for about eight months, and were studying integrals. They began their study of derivatives several months before the interviews took place, completed a unit focused on derivatives, and have continually used and applied them to other calculus problems since.

Each interview was conducted outside of school hours at a local public library, and lasted between 30 and 45 minutes. Interviews were recorded using a Livescribe pen and paper, which records the interview and connects the audio recording to the written work.

Each of the three interview questions presented the student with information about a problem using a different representation (table, equation, or graph). Question 1 (tabular representation) is shown in Figure 1 as a representative of each of the questions asked. Though the representation is different across the three questions, the tasks in each part are the same across questions. The reason for the repetition of the four tasks across interview questions is to determine if students tend to use a particular conception over another for a task when given different representations. In addition, these tasks were designed to assess the student's ability to translate between representations, thus assessing the triad stage that the student uses.

#1: The following table gives values of a differentiable function f(x) for different values of x:

X	-1	0	1	2	3	4	5	6
f(x)	-2	2	5	8	12	8	4	7

a. Approximate f'(1).

b. Approximate $\lim_{h \to 0}\left(\frac{f(4+h)-8}{h}\right)$

c. If f'(-1) = 5, write the equation of the line tangent to f(x) at x = -1.

d. Is f'(x) probably increasing or decreasing at x = 3?

Figure 1: Interview Question #1

The data from each interview was then analyzed to determine each student's APOS conception and triad stage for each interview question. The results were then reviewed to determine if there is a correlation between the representation given to the student, the APOS conception that the student used, and the triad stage at which the student operated.

Results

While there was at least one instance for each APOS conception given each representation, some strong patterns emerged. Table 3 compares the given representation to the APOS conception that the student used. Since each problem contained four tasks, and each was asked to four students, the total for each row is sixteen. The *no determination* column was added because there were some problem parts where the student either said that they did not know how to do it or else created an incorrect "rule" with no justification.

Table 3: Students APOS Conceptions Across Given Representations.

Representation	No determination	Action	Process	Object
1. Table (numeric)	7	2	3	4
2. Equation (analytic)	1	3	9	3
3. Graph (visual)	5	1	5	5

Students felt the most confident when given the equation, with which they almost all immediately started writing out answers, compared to where they generally stopped to think about a course of action given the other representations. They exhibited a strong process conception in that there was a routine and they were following it, but they also knew why they followed each step and could give appropriate justifications for each part of their answers.

A stronger pattern that emerged was that between the type of information asked for in each task and the students' APOS conception used in approaching the task. Table 4 compares the task type to the APOS conception used.

Table 4: Students APOS Conceptions Across Task Type.

Task Type	No determination	Action	Process	Object
a. Find derivative (at a point)	3	1	5	3
b. Find derivative by limit.	9	3	-	-
c. Write equation of tangent line.	-	1	10	1
d. Is the derivative increasing or decreasing?	2	-	2	8

Students had the most difficult time with the limit part of each question. All four students verbally said that they had forgotten how to find limits, but this again was dependent on the given representation. In the questions that give the table and graph, students could describe what a limit is, but when actually approaching the problem, mostly said that they do not "remember how to do it." Given the equation representation, three students of the four made much more of an attempt to try different algebraic rules until they came to an answer for the limit. The student in the following excerpt demonstrates an action conception in trying to find the limit of a difference quotient given an equation (A denotes the student, R the researcher):

A: [draws graph] I feel like this is not the way to do it, but if you plug in -1… you get 33, and at 1… it's 51. [sighs] I know there is another way to do this, it's been so long.

[The student skipped to parts c and d and then came back to b.]

R: So when you were doing limits, did you just plug numbers in, or did you cancel first and then plug numbers in? Did you do anything with simplifying?

A: Oh, wait, wait, ok. Ok, um, you factor, not factor, but, um… 3 times 2, 6, plug 3 times h equals 3h [continues to simplify part b at the right of Figure 1]… Yes! Ok, sorry, yeah, so then you factor h out, you have 9h plus 42 over h, those cancel, and nine times 0 plus 42, so the limit at that point is 42!

In contrast, the students held a process conception in ten of the twelve instances of writing the equation of a tangent line, and did this part of each question with the least effort, regardless of representation, and also regardless of whether they could find the derivative. The student who struggled with the limit went through the solution to using the equation of the function to find the equation of the tangent line at x = 0 almost without pause:

A: Ok, so all you gotta do is plug in 0 to the derivative so that's 6, so that's the slope of your tangent line. And to find y, you plug it into your original equation, that's 1, so I need slope-intercept form, b = 1, the equation of the tangent line is 6x + 1 at x = 0.

The students used an object conception in eight of the twelve instances when thinking about how the derivative changes, regardless of given representation. In this excerpt, the student is reasoning about if the derivative is increasing or decreasing given the graph of the function:

B: All right, k' is the rate of change of the graph itself, and it's decreasing the entire time.
R: What's decreasing?
B: Well, the original function is decreasing all throughout this set, but it's getting less and less steep of a decrease, which means that the, uh, the derivative or k' is increasing on this period because it is uh, it's sort of like, it's approaching 0 which it does, it hits at 0 or somewhere near there it looks like, and it's negative before that because it's going downwards, and it's positive afterwards because it's going up afterwards. So in between here it's negative, or increasing, because it's approaching zero from a negative number.

However, the way that students thought about finding the derivative to begin with depended more on the representation. All of the students used the chain rule quickly and easily and could give appropriate justifications when given the equation. In contrast, there is only one instance of a student that was given a graph or table who held a process conception of finding a derivative. For these representations, the students were much more likely to reason about the function as an object, or to decide that they did not know how to get the answer. Students also looked at the graph and table in much the same way. One student actually remarked when they got to #3 (the tasks using the graphical representations) that they looked a lot like #1 (the tasks using the tabular representation), even though the questions were identical for all three representations:

C: Ok, so this is pretty similar to the first one.
R: Ok, in what way?
C: Well, I mean it gives you data, except it's in a graph, not a table. And it uh, in general it's pretty much the same thing. When it says approximate k'…

The given representation did not seem to make much of a difference in the schema level that the students employed (see Table 5). The intra schema, for which students stay within the given representation, seems to be more common with equations; however, that is affected by the students being willing to try the limit question when given the equation, effectively moving three scores from

Table 5: Schema Stage Across Representation

	No determination	Intra	Inter	Trans
1. Table (numeric)	4	6	3	3
2. Equation (analytic)	1	8	4	3
3. Graph (visual)	4	4	6	2

no schema to intra. The inter and trans schemas show similar amounts of instances across representations.

There was a very strong relationship between APOS conception and the schema employed. Table 6 shows the amount of instances of reasoning within each conception at each schema level.

Table 6: Comparison of APOS Conception and Triad Stage

	No determination	Intra	Inter	Trans
No determination	9	3	1	-
Action conception	-	3	3	-
Process conception	-	10	7	-
Object conception	-	2	3	7

Not surprisingly, most instances in which the conception is not determined also had no determined schema with which to deal with the problem. This occurred most often with the limit task, but also in two instances of finding the derivative at a point and in determining whether the derivative was increasing or decreasing. At the intra and inter level, students with undetermined conception substituted in numbers or came up with some false "rule," which they applied to the problem.

All of the students interviewed revealed an action or process conception at least part of the time, and in all instances that the action or process conception was held, the student operated at the intra or inter schema level. This means that the student either stayed entirely within the given representation, or that they translated part of the information given to a different representation without reasoning about the relationship between representations. For example, when asked to find a derivative given an equation, all four students operated under a process conception and simply applied the chain rule. They stayed within the given representation, and when prompted, they explained how the chain rule works, but did not include other representations in their description. When asked to find the equation of the tangent line at a point given an equation, all four again used a process conception, and one student stayed in the intra schema level, but the other three moved into an inter level, translating between representations to either complete the task or describe it, but not reasoning about the connections between representations.

Finally, students who used an object conception did use all three schema levels, but tended to be at the trans level more often, reasoning about connections between representations in order to complete the task. For example, in reasoning about whether the derivative is increasing or decreasing a student set the derivative equal to zero and solved. She then explained that this would help her find whether there is a local maximum or minimum. She sketched graphs of a minimum and maximum and gestured the slope along each graph to reason about which derivative would be increasing or decreasing. The student then went on to sketch a number line and populate the number line with the solution she found by setting the derivative to zero. She related the number line to her graphs by cross-comparing the points she had made before determining that the derivative is going from negative to positive so it is increasing. Though it seems like she answered the question several times in different ways, in her mind she only answered it once because her answer consisted of connecting all of the pieces of her schema in forming her object conception of the derivative to complete the task.

Discussion

This study uses APOS theory to guide the theoretical framework for analyzing students' conceptions of derivatives in calculus. Four students participated in task-based interviews in which tasks were presented using three different representations. While findings agree with the existing literature that students tend to use a process conception more when given an equation and less when given a graph, there is also evidence to suggest that a relationship may exist between task type and student conception. In particular, students tended to use an action or process conception when determining the derivative of a function or the equation of the tangent line, and an object conception when reasoning about the change in derivative. The students in this study also used an intra or inter schema in conjunction with their action or process conception, and only operated on the trans schema level when using an object conception. However, even with the object conception, the trans schema level was only employed in seven out of 12 instances.

This study contributes to our understanding of students' conceptions of derivative, which can be useful for instructors in planning course instruction and assessment. For example, teachers may find it helpful to be cognizant of the conceptions that students tend to have when given different tasks such as writing the equation of a tangent line or reasoning about the change in derivative for a function. It may also be useful to consider students' schematic levels for thinking of derivative when considering problems to pose that may lead to action, process, or object conceptions by students.

Students complete many other tasks in calculus that were not analyzed in this study, and further research is needed to determine if the relationship between task type and APOS conception relies on cognitive demand, type of representation, class routine, or other contributing factors. Further research is also needed to determine the strength of the relationships between representation and conception, between task type and conception, and between conception and schema level for students in a variety of calculus classes.

A MATHEMATICAL MODELING LENS ON A CONVENTIONAL WORD PROBLEM

Jennifer A. Czocher

czocher.1@txstate.edu

Luz Maldonado
Texas State University
lm65@txstate.edu

Given the Common Core's dual emphases on mathematical modeling, there is a need to understand modeling as a practice and content standard to develop students' mathematical modeling skills. This study of 12 students from differing levels of mathematics instruction and English Language proficiency includes analysis of their modeling with mathematics and a focus on their transitions through a mathematical modeling cycle. Findings suggest that students were engaging in critical processes that support mathematical modeling. We posit that conventional word problems can augment the benefits of using mathematical modeling tasks and can help educators explore a process-oriented approach to mathematical modeling.

Keywords: Modeling; Standards; Cognition

Globally, research in the teaching and learning of mathematical modeling spans the past 40 years. In the US, the models and modeling perspective (Lesh & Doerr, 2003) has given rise to model-eliciting activities (MEAs) (Lesh, Hoover, Hole, Kelly, & Post, 2000), model-development sequences (Lesh, Cramer, Doerr, Post, & Zawojewski, 2003), and a design approach to developing these sequences. These research programs have focused on developing novel classroom instructional tools in order to teach significant mathematical concepts and on providing transformative teacher professional development.

Elsewhere, other mathematical modeling research theorizes the modeling *process* carried out by the modeler. The modeling process transforms a real world problem into a well-posed mathematical problem that can be analyzed mathematically. The results are then interpreted in terms of real world constraints and the model is validated. The mathematical model, or its representation in conventional mathematical terms (e.g., equations, graphs, etc.) is then iteratively refined. One such widely adopted mathematical modeling cycle (MMC) was posed by Blum & Leiß (2007) and has been used as a framework for examining and developing students' modeling skills It also serves as the basis of the CCSSM's description of mathematical modeling (CCSSM, 2010). Two complementary perspectives on mathematical models in the secondary curriculum are offered in the Common Core: one with the Standard of Mathematical Practice #4, Modeling with Mathematics and one with mathematical modeling as a Standard for Mathematical Content. Missing in the current literature is research on how to link the research findings (models of students' mathematical modeling) to the daily practice of solving conventional word problems in the secondary classroom.

The goal of this paper is to offer insights on students' mathematical thinking generated from a *process*-oriented view of their work on mathematical modeling tasks. It is a timely contribution as the mathematics education research community embarks on emphasizing mathematical modeling in the K – 12 U. S. classrooms. We choose to begin from the stance that the status of the task and the modeler's work is determined by the research lens rather than intrinsic properties of the task and we pose the question: What does a mathematical modeling perspective on a conventional word problem afford us?

Mathematical Modeling Cycle

The MMC is a description of the modeling process in terms of stages of model construction and modeling activities that are transitions between the stages. (See Figure 1.) The MMC was adopted as a research framework and focus was on the observable mathematical activities underlying each of the transitions in order to understand what a process view reveals about students' mathematical modeling. The MMC was operationalized via an observational rubric which conceptualizes each of the six transitions as a suite of mathematical activities (Czocher, 2013). The rubric was developed, refined, and validated via the method of constant comparison. Table 1 summarizes the transitions, the process they capture, and a sample indicator from the rubric. We offer an analysis of student work in the results section below. It is important to note that students may not exhibit all stages and transitions in order, or at all. Focusing on the transitions is intended to draw attention to mathematical thinking and activities being carried out, not to serve as a checklist of requirements.

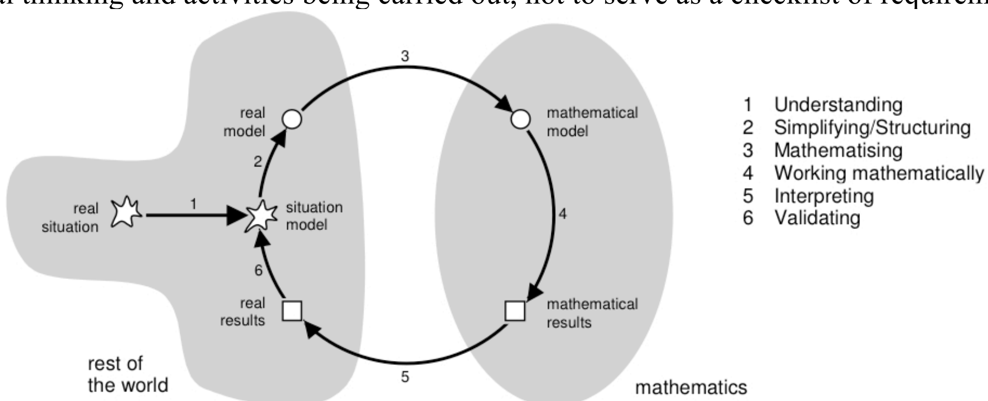

Figure 1 Schematic for a mathematical modeling cycle (Blum & Leiß, 2007)

Table 1 Modeling cycle transitions and sample indicators from the observational rubric

Activity	Trying to Capture	Sample Indicator
Understanding	Forming an initial idea about what the problem is asking for	Reading the task
Simplifying/structuring	Identify critical components of the mathematical model; i.e., create an idealized view of the problem	Listing assumptions or specifying conditions
Mathematizing	Represent the idealized model mathematically	Writing mathematical representations of ideas (e.g., symbols, equations, graphs, tables, etc.)
Working mathematically	Mathematical analysis	Explicit algebraic or arithmetic manipulations
Interpreting	Recontextualizing the mathematical result	Speaking about the result in context of the problem or referring to units
Validating	Verifying results against constraints	Implicit or explicit statements about the reasonableness of the answer/representation

Methodology

This study draws on a larger qualitative research design project aimed at understanding students' mathematical modeling processes. Participants were 12 middle and high school students who were selected so that four each were pre-algebra (6th grade), algebra (9th grade), and post-algebra (two in 10th grade; two in 12th). From each mathematical level, two had at some point in the U.S. schooling been identified as an English Learner (EL). All performed at the satisfactory or advanced level on the Texas mathematics standardized exam (STAAR) in the most recent year taken. 81% of the students at the middle school and 27% of the students at the high school that participated in this study are eligible to participate in the free or reduced price lunch program. The sampling plan was developed to be inclusive of mathematical approaches and representative of the diverse student population in

Texas. Tasks were provided in Spanish for EL students if they preferred. All of the EL students elected to conduct their interviews in English and explained their thinking in English. Due to the research design, this study reports qualities of students' modeling processes rather than an exploration of student characteristics.

The students participated in a series of three semi-structured, task-based interviews. For this study we consider their work on a conventional word problem, attempted by all 12 students, and similar to problems that appear in the algebra curriculum and on standardized tests. The students were asked to solve the following Turkeys & Goats problem (T&G): *A nearby farm raises turkeys and goats. In the morning, the farmer counts 48 heads and 134 legs among the animals on the farm. How many goats and how many turkeys does he have?* The task has value as a cornerstone of the institution of classroom algebra, but we do not claim that T&G is itself a modeling task. It is best classified as a concept-then-word problem (English, 2010) because it is designed and assigned to encourage students to practice already-learned procedures. T&G has the potential to reveal student thinking about making and justifying assumptions (e.g., one-to-one correspondence between heads and animals), working with real-world-imposed constraints (e.g., only whole-number animals should be considered), creating representations (e.g., equations or algorithms), and validating the resulting mathematical model. The ubiquity of similar tasks in mathematics classrooms suggests that analysis of student work via a mathematical modeling lens may be valuable in helping educators identify mathematical modeling processes carried out by students and therefore using such tasks to help students develop modeling skills.

The objective of each interview was to elicit the students' mathematical thinking and reasoning about the task, not to teach mathematics nor to teach mathematical modeling. The students were reassured that we were interested in their responses and explanations and not in whether the obtained the correct answer. Interviewer interjections were kept to a minimum. The interview sessions used design research principles of *cross-fertilization* and *thought experiments* (Brown, 1992). Cross-fertilization is when information and experiences from one interview session inform interviewer sensitivity and follow-up questions in another session. The interviewer posed clarifying and follow up questions ("Can you help me understand what you did here?") or asking the student to think aloud ("What are you thinking about?") or to provide additional reasoning ("Can you say more?"). Another set of interventions could be classified as scaffolding questions. For example, the interviewer adjusted the numbers in the problem if they proved too large for the student to reason about or calculate with. Thought experiments pose *what-if* questions that tweak the task as follow-ups to student explanations. For example, the interviewer could change the kinds of animals present on the farm so that the number of legs could not be realistically distributed among the animals.

Interviews were audio and video recorded and transcribed. The transcripts were summarized holistically according to the following dimensions: what approach did the student use, how it was executed, and what result was obtained. We used the observational rubric calibrated to the transitions in the MMC to look for evidence that the students were engaging in mathematical thinking that supported mathematical modeling (which is described below). When a mathematical activity was observed in the transcript or in the student's writing, it was tagged with a descriptive indicator and then coded with the associated transition from the modeling process. For example, if the student was observed to be carrying out a mathematical activity that could be described as an *explicit algebraic or arithmetic manipulation* that segment of transcript was coded *working mathematically*. In this way, the transcripts and students' written work were microanalyzed according to the MMC. Coding was carried out individually and then in pairs. All discrepancies were resolved. We then conducted a cross-case analysis looking for patterns in the students' modeling and to generate a list of questions and insights that arose from the two-layer analysis. This list guides our discussion of the implications of using a mathematical modeling lens on tasks currently used in mathematics K-12 classrooms.

Results

A solution to the Turkeys & Goats problem satisfies two conditions simultaneously (a fixed number of heads and a fixed number of legs). An algebraic solution strategy was defined as an attempt to write symbolic, algebraic expressions describing the relationships among the total number of heads and the total number of legs. A partitioning strategy was defined as some intention to separate the total number of heads into goat heads and turkey heads (or separate the total number of legs into those belonging to goats and those belonging to turkeys) and work out how many legs (heads) must belong to each group. The 6 students who attempted a partitioning strategy began with a halving strategy that there were 24 goat heads and 24 turkey heads. Based on typical student explanations, this is because there were two kinds of animal and $48/2 = 24$.

The partitioning strategy led to a guess-and-check approach where the number of heads (legs) was adjusted based on the outcome from the previous assumption. This approach handles the two conditions sequentially and iteratively. The strength of the algebraic approach is that it generalizes the guess-and-check strategy by simultaneously evaluating the cases that arise and so it is more mathematically efficient. However, using an analytic, algebraic approach requires that both conditions are made explicit via the implicit assumption that each animal has one head and the constraints that goats have one head and four legs and turkeys have one head and two legs. The modeling lens recognizes that this transformation is nontrivial and it allows us to decompose students' difficulties in formulating mathematical constraints. Regardless of student level, the task has the potential to afford insights into their mathematical thinking. Table 2 summarizes the students' work on the task according to mathematical level and EL status.

Table 2 Summary of student strategies and answers

Level	EL	Algebraic Strategy	Partitioning Strategy	Both Constraints	Any Answer	Correct Answer
Pre	EL	0	2	1	2	0
	Non EL	0	1	1	2	1
Algebra	EL	0	1	1	1	0
	Non EL	2	0	1	2	1
Post	EL	1	1	1	1	1
	Non EL	1*	1*	1	2	1

* The same student used a partitioning strategy and then transitioned to an algebraic strategy.

At each level there was at least one student who executed neither solution strategy. Of the 9 students who attempted either strategy, only 6 recognized the need to satisfy both constraints at once. This discrepancy may point to a reason why the other 3 students were unable to use a solution strategy and they may have been unable to see a way to handle both constraints simultaneously. Ten of the 12 students obtained an answer but only 4 obtained a correct answer. For the pre-algebraic students, this may not be surprising since solving the task without algebraic techniques is cognitively demanding and computationally inefficient. However, of the 8 students who were in algebra or post-algebra classes, this is quite surprising given that such systems-of-equations tasks are a focus of instruction and high stakes tests.

Due to space constraints, we present a synopsis of one student's work on the Turkeys & Goats problem. Bree was a pre-algebra, non-EL student. Her work was selected because she developed a non-algebraic of the situation and because she focuses autonomously on satisfying both constraints. Thus her work illustrates what the students, regardless of mathematics level, are capable of doing. Transitions from the MMC are marked in the first part of the synopsis to demonstrate how the MMC is present in the student's work. Though we highlight one student's work, all students exhibited transitions from the MMC, demonstrating that they were engaging in mathematical modeling when working on the task even if no answer or conclusion was ultimately reached.

Bree began by reading the problem aloud (*understanding*) and then questioned the number of legs on a turkey (*simplifying/structuring*). She initially tried 48×4 (*mathematizing, working mathematically*) to obtain the total number of legs (*interpreting*) because "it'd be easy." She abandoned this approach because "some of them have two legs" (*validating*). She continued, "since there's turkeys I have to figure that out. So it's either that most of them could be like, I'm going to try half" (*simplifying/structuring*) and decided to find the number of legs among 24 turkeys and 24 goats by combining 24×2 with 24×4 (*mathematizing*) and using the standard algorithm (*working mathematically*) to get 144 legs (*interpreting*). Bree noted that she needed 134 legs. She wondered what to do about the "10 extra" legs. The interviewer asked her what she was thinking. She responded "What I was thinking first is if I, maybe if I div…cut the 48 in half, 24 turkeys and 40, 24 goats, then I figure I would, so 48 legs for the turkeys and 96 legs for like goats…I got 144. But I think we needed 134 legs, so I'm trying to figure out right now how I could put that down." Bree switched her focus from the heads constraint to the legs constraint. As a follow up, the interviewer asked how she would reduce the number of legs. She concluded that there would have to be more goats. Next, Bree tried 22 turkeys and 26 goats and realized that she added legs. She reversed her guess and tried 22 goats and 26 turkeys to obtain 140 legs. She shook her head because she recalled that "We're trying to find 134."

Bree changed her approach yet again: "So I guess I could try to find how many times 4 goes into 134 or how many times 2 goes into 134." She proceeded to carry out long division via the standard algorithm for $134/4$ and $134/2$. She obtains 32 goats and 6 turkeys, but did not realize that she was missing 13 heads. She became confused on how to figure out the number of legs for a given number of heads and backpedals to her computation $134/2$. She states that this would yield 67 turkeys and no goats which is impossible because there were only 48 animals. At this point, Bree announced "There has to be an answer" and began working quietly doing various multiplicative computations.

The interviewer asked, "Could you summarize for me what you know about what the possible combinations [of turkeys and goats] might be?" This prompts Bree to organize her work into a list of goat/turkey combinations she had tried and begin systematically adjusting those values. She stated her strategy, "I've tried 22 goats and 26 turkeys and I got 50, 52, and 88 goats, but that equaled 140. So that one didn't work. And 9, 8, I guess I could try other ones just like that. I just have to keep on going down 'til I got to 134." She used her algorithm developed from trying 24 goats with 24 turkeys and 22 goats with 26 turkeys to "keep on going down" until she found the combination 19 goats with 29 turkeys yielded 134 legs. When asked to explain how she knew to increase the number of turkeys and decrease the number of goats, she responded that "4 doesn't go into many numbers as much as 2 does 'cause it's bigger," indicating that she had some sense of needing the net number of legs to decrease.

Implications and Conclusions

The Turkeys & Goats problem is a conventional word problem similar to those found in algebra textbooks and on standardized tests. We presented two layers of analysis on students' work: one focused on solution obtained by the student and how the student carried it out and one that examined students' mathematical activity in support of mathematical modeling processes. The first is a product-oriented perspective that focuses on representation of the solution and its correctness. According to this perspective, many of our students were unable to solve a conventional word problem. However, this kind of surface level analysis is limited in that it does not reveal the deeper complexities of student's mathematical thinking and understanding which are useful for informing classroom instruction. A closer examination of students' mathematical thinking showed that students took an algebraic approach or used a partitioning strategy. Analysis of student strategies reveals how they were thinking about the task.

The process-oriented perspective focused on mathematical modeling as a process. Operationalizing the MMC in terms of mathematical activity and then applying the rubric to students' work showed that all students were engaging in mathematical modeling processes. Analysis revealed how students progressed through the task even if they did not ultimately obtain a right (or any) answer. Bree's work demonstrated that students are capable of modeling with mathematics, a Standard of Mathematical Practice (CCSSM, 2010) without necessarily using an explicitly algebraic approach. She carried out a guess-and-check strategy, but her guesses were not haphazard. She developed an algorithm based on constraints implied by the problem statement in order to relate the number of heads of each kind of animal to the total number of legs among the animals. To do so, she introduced two parameters: the number of turkey heads and the number of goat heads. After each trial, she adjusted her estimates in ways that anticipated their effects on the outcome (number of legs). That she was capable of organizing her work into a systematic algorithm after some prompting and encouragement suggests that she was at a participatory stage of forming a concept about satisfying multiple constraints simultaneously but that she had developed an activity-effect relationship between adjusting the head parameters and verifying the number of legs (Tzur & Simon, 2004). In essence, she was able to apply her mathematical model as an algorithm dependent on input parameters.

Thus a product-oriented perspective on a conventional word problem can impede educators from fully understanding students' mathematical activity because it emphasizes what students could accomplish. Therefore, it reveals student struggles in achieving objectives in mathematics instruction. In contrast, a process-oriented perspective on mathematical modeling offers more information that educators can base decisions on because it shifts attention to the students' mathematical activity and allows for articulation of what students are capable of doing. The shift has implications for helping classroom mathematics teachers identify and harness student success in mathematical modeling in a way that is grounded in students' current mathematical activity rather than solely on obtaining a correct answer.

Our analysis suggests that independent of where the student is in their formal mathematical instruction, they are capable of and spontaneously do exhibit the kinds of thinking that support mathematical modeling. These results parallel the findings of Cognitively Guided Instruction (CGI) research: children do not need explicit direct instruction in modeling (Carpenter, Fennema, Franke, Levi & Empson, 2015). Children come to school with ways of thinking about mathematics that do not need to be formally taught. Instead, the goal is to understand their thinking and original strategies and guide them toward more efficient and proficient ways of solving problems. Likewise, the goal in teaching modeling should be providing opportunities for the students to develop their judgment to become comfortable making assumptions that will satisfy a complicated situation. As demonstrated by Bree, the students may already have a sense of needing to validate their models and revise their assumptions. Reinforcement of the idea that assumptions and representations may require revision could be provided by working on techniques for validation.

Thus, classroom mathematics teachers may not need to consider the modeling standard and practice articulated by the CCSSM as something "new" to add to the curriculum. Our analysis shows that even on conventional word problems, students are already thinking in ways that support mathematical modeling. The challenge becomes helping teachers identify what the modeling process looks like so that they can recognize when a student is developing a model (not just that the strategy is inefficient) and ask specific questions of students at specific times. A comparison between process- and product-oriented views of students' mathematical activity can help educators focus on mathematical structure instead of just correcting mistakes in carrying out procedures. Such emphasis may also push students toward process-oriented views of their own mathematical activity instead of focusing on obtaining the correct answer. .

Using the MMC to see beyond solution strategies on a seemingly straightforward task led to conversations about the role of the interviewer (and by extension, the role of the teacher in a classroom setting). Though all students were capable of making progress in the modeling process, the realization that the models needed revision and some encouragement as to how to do so was influenced by interviewer questions. In Bree's case, to fully develop her algorithm she was prompted to summarize what she had done so far. Perhaps realizing that their models may need revision later contributed to some students' unwillingness to commit to a solution strategy. Future research must critically examine the role of interviewer prompts in scaffolding mathematical modeling. Such analysis would have implications for when and how teachers may most productively intervene in students' modeling processes while respecting the students' ideas and model development. In addition, due to the ELs opting to conduct their interviews in English, we can continue to question and think about the implications of past schooling on their mathematical modeling. One of the challenges in implementing the CCSSM has been that teachers may not share the same vision of how to operationalize the standards in the classroom as the standards writers intended. There is a need for research-based understandings of what teachers may be currently doing in classrooms which may need to be reconsidered or adjusted in order to fully realize a mathematical modeling perspective. We suggest that mathematical modeling need not be a wholly new undertaking. The participants in this study demonstrate that K-12 students are engaging in mathematical modeling processes whether it is taught explicitly or not. The challenge becomes helping teachers identify it – it's not foreign -- and how their students are doing it.

STUDENTS' STRATEGIES FOR ASSESSING MATHEMATICAL DISJUNCTIONS

Paul Christian Dawkins
Northern Illinois University
dawkins@math.niu.edu

This paper presents results from three teaching experiments intended to guide students to reinvent truth-functional interpretations for mathematical disjunctions. The initial teaching experiments revealed that students' emergent strategies for assessing disjunctions did not entail or facilitate the development of a relevant partitioning of example space (comparable to Venn diagrams). Students were unable to form generalizable strategies for finding relevant exemplars to evaluate quantified disjunctions. The latter teaching experiment, in contrast, successfully prompted students' to attend to reference and partitioning of the referent space through an alternative instructional sequence. I set forth the methodology and findings of this study to demonstrate how conventions of mathematical logic can emerge within students' mathematical activity toward the end of their apprenticeship into proof-oriented mathematics.

Keywords: Cognition; Advanced Mathematical Thinking; Post-Secondary Education

In proof-oriented mathematics, mathematicians embed mathematical meaning in mathematical language (definitions, theorems, proofs, etc.). This requires a high level of clarity and precision in mathematical language, which is why mathematicians were the first to invent formal languages (Azzouni, 2009). Formalizing language requires attending to the relationship between linguistic form and meaning. For mathematicians, this involved 1) creating equivalences – *but* and *and* are mathematically equivalent connectives, 2) disambiguation – distinguishing *or* and *either…or* as capturing the inclusive and exclusive everyday meanings of *or*, and 3) creating truth-functions relating truth-values of component and compound predicates. These aspects of formal language and its acquisition stand in contrast to natural language, which is learned through many more implicit or preconscious processes and which entails looser relations between form and meaning (see Stenning, 2002).

How then can mathematics students in proof-oriented mathematics courses learn formal, mathematical language, specifically as it pertains to the relation between form and meaning? Using the guided reinvention heuristic of Realistic Mathematics Education (Gravemeijer, 1994), I sought to engage students in conscious and effortful systematization of their use of mathematical language. I guided students to reinvent truth-functional definitions for mathematical disjunctions and conditionals in a series of short teaching experiments (Steffe & Thompson, 2000). In this paper I report on the major patterns of student interpretation of mathematical disjunctions, how failure to partition example spaces inhibited their ability to reinvent normative interpretations of quantified disjunctions, and an alternative instructional sequence that supported the emergence of normative interpretations of quantification.

Studies of students' interpretations of linguistic form

Because there is ample evidence that students' untrained interpretations of mathematical language differ significantly from that of mathematicians (e.g. Durand-Guerrier, 2003; Epp, 2003), many Introduction to Proof courses include a unit on logic. However, my method departs from many of the common approaches to teaching these topics in mathematical logic because 1) I want students to impose logical form on meaningful mathematical statements rather than abstract or nonsensical ones and 2) I problematize students' *reasoning toward an interpretation* (Stenning, 2002; Stenning & van Lambalgen, 2004) of language. The majority of psychological and mathematics education studies of student's interpretations of linguistic form tend to elicit students' preconscious interpretive processes (Evans, 2005; Inglis & Simpson, 2008), but assess those interpretations against a single, formalized linguistic meaning. This assumes some logical structure is embedded in language or semantic content and that people are irrational for reasoning alternatively (e.g., Stanovich, 1999). As Stenning (2002) eloquently argues, everyday linguistic interpretation is far too complex and varied for this approach. One may distinguish three views of *logic*'s relation to language use that clarify my stance. Logic can be thought of as a description of language use (common in later 20th century logic, Stenning, 2002), a prescription for proper language use (as many psychologists deem it), or the constructed product of a learning process of systematizing language (my proposal). I call this third view students *reasoning about logic* to denote its conscious and reflective nature. I adopt this lens because many studies suggest formal logic is a poor model of most students' reasoning, but proof-oriented mathematics requires that students conform their reasoning to mathematical norms. Stenning's (ibid.) findings support this study's use of meaningful mathematical statements, as he states, "formal teaching can be effective as long as it concentrates on the *relation* between formalisms and what it formalizes" (p. 187) and "logic teaching has to be aimed at teaching how to find form in content" (p. 190). So, I operationalize logic not in terms of students learning formalisms (e.g. truth-tables, Venn diagrams), but as their progressive systematization of their interpretations of mathematical statements till they impose a consistent, generalizable, and normative form.

Methods

I recruited three pairs of Calculus 3 students from a medium-sized Midwestern university to take part in short teaching experiments. I chose this course to find students who were mathematically proficient, could benefit from learning formal mathematical language, and who had not taken proof-oriented mathematics courses. I identified their background in learning logic via an online survey. Students met in pairs with the author for six one-hour sessions, and were compensated monetarily for their participation. The first three sessions focused on mathematical disjunctions and the latter three sessions on mathematical conditionals.

The guided reinvention approach helped to identify the interpretations students imposed upon the statements, how those interpretations shifted upon reflection, and which tasks elicited reasoning that approximated normative interpretations. I asked students to determine whether provided mathematical statements were true or false, then to systematize and describe their method, before asking them to negate the statements. It was initially anticipated that disjunctions would be easier for students to formalize and provide a foundation for interpreting conditionals (known to be a problematic linguistic form, Evans, 2005). Instead, disjunctions were quite challenging for mathematically important reasons. Thus, I only report on data from the first three days of each teaching experiment. The first two pairs met simultaneously and employed the same instructional activities. The third met several months later using modified activities. As such, data is presented as two experiments distinguished by their anticipated learning trajectories and instructional tasks. Table 1 presents a selection of the statements used in the study, with "D1:3" denoting the third statement on Day 1. An apostrophe denotes an item from Experiment 2.

Consistent with the teaching experiment methodology (Steffe & Thompson, 2000), during Experiment 1 the author served as teacher/researcher and another researcher served as outside observer. The observer kept field notes during each session and the researchers debriefed after each teaching session. Video recordings were also reviewed each day to form and test hypotheses about student learning to inform the teaching activities for the following session. Full retrospective analysis commenced after the experiment ended. The author coded data in the open and axial method of grounded theory (Strauss & Corbin, 1998). Codes related to 1) truth-value assessment strategies (e.g., one condition false makes the disjunction false), 2) paraphrases of provided statements (e.g., introducing "either…or" language), 3) modes of reasoning about logic (e.g., attending to the meaning of the *or* connective), 4) clarification of semantic information (e.g., identifying relevant warrants such as “all squares are rectangles”), and 5) negating actions (e.g. negating [A or B] with [not A or not B]). I report on common trends in students’ interpretive behavior and emergent links among their strategies, interpretations, and particular disjunctions.

Table 1: Sample disjunctions provided to study participants

D1:1 “Given an integer number x, x is even or x is odd” D1:2:“The integer 15 is even or 15 is odd. D1:7 “The real number 0 has a reciprocal $\frac{1}{0}$ such that $0 \cdot \frac{1}{0}$ 1 or 0=0.” D1:9 “Given any even number z, z is divisible by 2 or z is divisible by 3” D2:6 “Given any triangle, it is equilateral or it is not acute.” D2:7 “Given any triangle, it is acute, or it is not equilateral.”	D3:3 “10 is an even number or 20 is an even number” D3:4 “13 is an even number or 6 is an even number.” D2’:6 “For which integer numbers *z* is it true that ‘*z* is divisible by 4 or *z* is divisible by 3’” D2’:10 “For which real numbers y is it true that “y<3 or y>5” D2’:12 “For which triangles is it true that ‘it is equilateral or it is not acute.’”

Experiment 1

Of the four participants in this experiment, one pair had no training in logic and the other pair had completed a philosophy course in logic. Their patterns of reasoning were nearly identical. When initially assessing the truth-values of non-quantified disjunctions, both groups declared a disjunction with a false component false (e.g. D1:2 and D1:7). Only on D1:9 did either group begin explicitly attending to the connective *or* and its role in the statements’ meaning. Both groups at this point also began distinguishing the truth-values of the two components from that of the disjunction. For instance, Ron said, “This just got interesting cause when you say “or” only one of ‘em has to work, not both of ‘em.” When asked to revisit their initial decisions, both groups reinterpreted D1:2 as true because of the *or* connective. Students were more reluctant to affirm D1:7 as it seemed more mathematically absurd, but later decided that the 0=0 condition also made it true. By the end of the first session, both groups were consistently interpreting non-quantified disjunctions in a manner consistent with the normative truth-functional definition. As Ovid said, “Cause “or” for me means either it could be one or the other or both.”

Students generally had more trouble with quantified disjunctions where the truth-function was not sufficient to assess the truth-value of the statement. Some statements afforded semantic affirmation without testing particular cases as with D1:1 where the categories are exhaustive. In other cases, though, students used a *sentential testing strategy* in which they picked examples and reread the statement to evaluate whether it “covered” the given case (often reading left to right). This strategy reduced quantified disjunctions to a sequence of non-quantified disjunctions, but it also necessitated a strategy for picking cases and organizing the example space.

Partitioning the example space

Experiment 1 participants did not spontaneously develop an intentional way to partition the spaces of examples because each space was pre-organized according to familiar mathematical categories (e.g. even, acute, rectangle). The normative logical partitioning of examples (as portrayed in Venn diagrams) distinguishes cases that satisfy each component condition of the disjunction such that the examples fall into four categories (TT, TF, FT, and FF). Because students’ reasoning stayed focused on the statements themselves, they failed to attend to how the statement provided a novel partitioning of example spaces. This was not problematic for cases that could be easily and exhaustively seriated such as the integers or even integers. Students tested cases sequentially (2, 4, 6, 8…), usually assigning a truth-value after 3-5 examples. However, both pairs of students struggled to assess geometric statements such as D2:6 and D2:7. This is because they reasoned about triangles in terms of familiar semantic categories – equilateral, acute, right, obtuse – rather than treating right and obtuse as equivalent relative to the given statements – non-equilateral, non-acute. Without a simple way of exhausting the example space, they were never sure if a statement was true of all triangles.

Students developed some other normative and non-normative strategies that helped them resolve quantification issues. First, recognizing that all equilateral triangles are acute, some students incorrectly concluded that not equilateral meant not acute, implying that statements like D2:6 were true. Students struggled in other ways with how to interpret negative predicates, often substituting a positive predicate that was non-complementary, such as replacing "<" with ">" or "not acute" with "is obtuse." In general, students did not seem aware that a negative predicate ("not acute") could be thought of as denoting the complement of the set of cases satisfying the positive predicate ("is acute"). As a result, students were disinclined to reason about negative predicates without paraphrasing ("can't be acute") or substituting positive conditions.

However, students' sentential testing strategy led to some other strategies that more closely approximated normative interpretations and led students to make appropriate determinations of truth-values. Two participants began anticipating that anything satisfying the first condition made the statement true. So, they began ignoring such cases, as when Ron interpreted D2:6 as, "if it's not equilateral, it must be obtuse." I call this strategy an *"if not…then" paraphrase*. While not identical to the Venn diagram partitioning of examples, this strategy allowed students to reduce the set of cases they had to attend to by excluding cases satisfying the first predicate. Their reasoning also implicitly approximated the negation of the disjunction – negating both predicates – because it led students to question whether anything failing the first condition must necessarily satisfy the second. For instance, Ron rejected that any non-equilateral triangle must be obtuse, which led him to find the non-equilateral, acute counterexample[1]. Though they used it repeatedly, students in Experiment 1 did not consciously identify or abstract their "if not…then…" strategy. Furthermore, without specific guidance students did not reinvent the Venn diagram partitioning of examples and consistently used sentential testing of a few cases.

Negating disjunctions

One of the challenges in reinventing logic is to find experientially real activities (Gravemeijer, 1994) that foster language systematization as entailed in *reasoning about logic*. Assessing truth-values successfully prompted students' reinvention of truth functions. Negating statements appeared a natural next activity, but it was unclear how to describe logical negation to participants unfamiliar with the notion. In Experiment 1, I asked students to find a systematic way to produce an opposite statement that always had the opposite truth-value. This description of the negation of a statement proved to be underspecified for reinvention.

Experiment 1 participants commonly engaged in syntactic manipulations of the statements to produce a negation such as 1) negating both conditions with the same connective ($\neg(A \vee B) \leftrightarrow \neg A \vee \neg B$) or 2) negating with a non-complementary property ($\neg(x < y) \leftrightarrow x > y$). Even when provided with various statements intended to dissuade such strategies, students were unperturbed to negate different statements in different ways. Ron and Drew negated "10 is even" with "10 is odd," but more appropriately negated "π is even" with "π is not even." Anticipating that the *and* connective in the negation would not be obvious, I asked participants to negate D3:3 and D3:4. Students in both pairs negated D3:3 as "10 is an odd number or 20 is an odd number," which yielded the opposite truth-value as desired. They then recognized a problem when the same transformation of D3:4 yielded another true statement. Drew responded by negating D3:4 with "13 is an even number or 6 is an odd number." This statement is false, as required, but Drew did not show evidence of anticipating whether this method would work for any other statements. Ron and Drew proposed and tested various transformations of the statement before introducing an *and* connective, seemingly by trial and error. Upon testing, they recognized that this method properly negated the given statements, but could not semantically justify why. Contrary to the researcher's intentions, study participants did not perceive any connection between why a counterexample falsified a disjunction (it satisfied neither condition) and a systematic method of negating a disjunction (not A and not B). There was also no evidence that they understood why the negation of a universally quantified disjunction should be an existentially quantified conjunction, though the counterexample heuristic might suggest it. It appears from these two teaching experiments that the negation criterion of merely having the opposite truth-value was too underspecified to foster students' recognition of a generalizable method. They relied on trial and error syntactic transformations of the statement in lieu of any intentional, semantic strategy.

An alternative criterion for mathematical negation

One episode from the third interview with Ovid (his partner Eric was absent) suggested an alternative approach to reinventing negation. Ovid was already comfortable with abstracting from each non-quantified disjunction the two component truth-values and applying their truth function. Ovid recognized that negating a disjunction with a disjunction would not work because each of the two components would reverse truth-values. He said, "If this is false-true, then the opposite would be a true-false statement." Like Drew, Ovid initially wanted to change the way he negated the components rather than changing the connective. I invited him to explore all such component patterns and the desired outcomes for the negation, which produced the table in Figure 1. Analyzing this representation, Ovid said, "So we would have to do, probably would be an *and* statement. Because then it would have to fit both criteria rather than either, or, or both." He went on to check that "13 is not an even number and 6 is not an even number" properly negated D3:4 (i.e. produced the opposite truth-value as desired).

Parts	St	Parts	Neg
TT	T	FF	F
FT	T	TF	F
TF	T	FT	F
FF	F	TT	T

Figure 1: Reproduction of Ovid's truth table for negating disjunctions.

Ovid's discovery that the negation of a disjunction must be a conjunction was significant for two reasons. First, this was one of the clearest cases where the formalization and abstraction of the truth-value structure of the mathematical statements led a student to reinvent a normative logical theorem. As Stenning (2002) discussed, Ovid learned from the relation between the formalization and what it formalized. Ovid translated the semantic statements into a logical representation system (a truth table), deduced the appropriate pattern from that representation, and then translated it back to the semantic system of mathematical statements.

The second reason I highlight Ovid's discovery is that it suggested an alternative way of characterizing negations. Each of the statements Ovid reasoned about in this episode could be viewed as a case of the condition "x is even or y is even." As in Ovid's truth table, the negation of the condition must yield the opposite truth-value for each pair of numbers. Thus the negation of a quantified disjunction must be a case-wise negation (yielding opposite truth values for each example) in addition to a global negation (having the opposite truth-value overall). This insight, combined with the need to guide students to attend to partitioning the example space suggested the revised teaching activities employed in Experiment 2.

Experiment 2

The teaching activities on the first day of this teaching experiment were nearly identical to those in the former, except that some uninformative items were removed and the geometry items from the second day were added. The participants in Experiment 2, Cid and Macy, attended to the *or* connective much earlier (on D1:2), but still rejected D1:7 as false due to its apparent absurdity. Unlike the participants in Experiment 1, Macy had been taught logic in a mathematical context. Despite this, she consistently imposed a non-normative "exclusive or" interpretation, though it took her some time to recognize when it applied to quantified disjunctions. Like the first group, Macy and Cid distinguished and coordinated the three truth-values in a non-quantified disjunction according to truth-functions, though they disagreed about the output when both predicates were true. Like the previous pairs, neither Cid nor Macy developed a generalizable strategy for finding example cases, especially for the geometric items. Cid himself explained that he was merely "stabbing at examples in [his] head." He implicitly used a *sentential testing strategy* and *"if not…then"* paraphrases, but did not recognize or abstract these approaches. Macy attempted semantic substitution, inappropriately paraphrasing D2:6 as "is acute or is not acute" because "equilateral triangles are acute."

Alternative activities intended to emphasize quantification of predicates

On day 2, many of the same conditions were presented to the students, but the activity was reframed from assigning truth-values to quantified disjunctions to finding the set of cases that satisfied a disjunctive predicate (see the D2' items in Table 1). This sequence of tasks was intended to guide students to associate classes of examples with each condition rather than single examples, leading to the normative interpretation that mathematical predicates entail sets (rather than simply describing cases). The close association between "divisibility by 2" and $\{x \in \mathbb{Z} : 2|x\}$ (the set of even integers) is commonplace in proof-oriented mathematics, but analysis of Experiment 1 suggested that it was not a natural association for study participants.

I anticipated that visually representing some of the sets described by these disjunctive predicates might lead students to an interpretation approximating the Venn diagram for *or*, the principle of which is that a disjunctive predicate entails the union of the sets of cases entailed by the two component predicates. For this reason, I included items such as D2':10 that would easily lend themselves to visual representation.

The third reason to shift from declaring quantified disjunctions true or false to identifying the set of cases that satisfied a disjunctive predicate was to provide a natural segue to case-wise negation. Rather than negating statements by other statements that have opposite truth-values, the negation of a disjunctive predicate "X or Y" is the predicate that entails the complement of the cases. Thus I anticipated modifying the task to, "For which integers is the condition false?"

Results of the alternative instructional activities

Cid and Macy approached the second day's activities initially using verbal strategies as they had done the day before. In some cases, they could describe the set easily as "all real numbers" or "all even integers." They ran into difficulty when they tried to use "and" to denote the union of two sets, which confused the intended meaning of the connectives. Beginning with the geometric items, they began instead describing the cases that do not satisfy the condition. Regarding the correlate task to D2:6, Cid said, "An acute triangle doesn't satisfy it. I think." Macy clarified, "An acute triangle that's not equilateral." The interviewer invited them to extend this strategy and specify the set of cases making each condition false. By the next item, Macy generalized the strategy, saying "I am trying to think if there's any counterexamples where you can make both of those statements false. Cause then you can exclude some of the triangles." In this way, Macy recognized that the statement was false for cases that failed both component predicates. Both Cid and Macy later noted that it was much easier to describe the set of counterexamples to disjunctive conditions than describing the cases that satisfied them. They could not articulate why this was easier, though. In addition, they implicitly recognized the complement relation between the satisfying and falsifying cases.

I intended for a visual representation to suggest the relationship that the cases satisfying a disjunctive condition consist of the union of the cases satisfying each condition (as the Venn diagram suggests). Cid and Macy drew number lines for D2':10, but they described the resulting set in spatial terms ("It's false when y is between 3 and 5.") rather than in inequality language. This dissociated the set from the negations of the two component predicates and led to no generalizable strategy. The interviewer then revisited D2':6 and invited the students to create two number lines that demonstrated which numbers satisfied and falsified the given condition. The students did so (Figure 2) including the truth-values of the two components for each number. This led them to rediscover Ovid's observation that the component truth pattern of the negation will invert that of the original and that the connective *and* will ensure the proper pattern of truth-values for the disjunction and negations overall. While this alternative visual representation did not emphasize the union property, it clearly fostered truth functional analysis leading Cid and Macy to reinvent the case-wise negation of a disjunction.

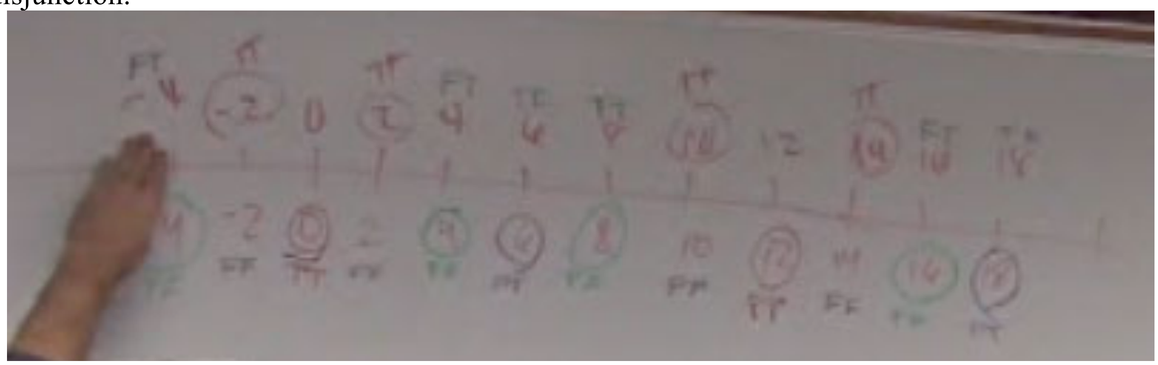

Figure 2: Representing the sets entailed by a disjunctive predicate and its negation.

Summary and discussion

From the diversity of strategies employed, and the frequency with which study participants paraphrased the given statements in various ways, it was clear that study participants had not systematized the meaning of *or* in mathematical sentences prior to the teaching experiments. Rather, students *reasoned toward an interpretation* (Stenning & van Lambalgen, 2004) of each sentence trying to find some way to have the language or content suggest a means of assessing each statement. Several key strategies emerged repeatedly and independently such as sentential testing and "if not…then," but students did not apply such strategies consistently. Due to the methodological choice to work in meaningful mathematical contexts, participants had to impose logical form in their mathematical interpretations. Participants only slowly developed meta-language for describing and abstracting patterns and strategies across various contexts.

In each study, students reinvented the standard truth-function for inclusive or exclusive *or* in one session. The activity of assessing truth-values did not lead study participants to develop strategies for quantified disjunctions that approximated the normative Venn diagram partition of examples. Students selected examples according to the semantic structure of the content of each sentence (numbers, triangles, etc.) rather than according to the predicates in the disjunction. This suggests that instruction in proof-oriented classes must help students begin associating any property or predicate with the set of examples satisfying that predicate and its complement. Properties describe single cases, but they also organize or partition sets of examples. None of the study participants approached the given tasks in this quantified way without being guided to do so. Motivated by the need to attend to quantification of predicates and to develop a case-wise meaning of negation, I developed the instructional sequence used in Experiment 2. This approach successfully led Cid and Macy to formulate the normative negation of a disjunctive condition and to identify that a condition and its negation entailed complementary sets.

A theoretical goal of this project is to recast mathematical logic within students' activity. These results provide several instances of students *reasoning about logic* such as problematizing linguistic interpretation, reinventing the standard definition of *or*, comparing interpretations across statements, developing meta-language to abstract patterns, and truth-table analysis leading to new discoveries. These data support the hypothesis that students can reinvent the structures of logic when engaged in the activity of logic: systematizing language. However, further studies are needed to better understand reinventing logic's instructional affordances and implications.

Endnote

[1]While Ron's paraphrase also falsely suggests right triangles are counterexamples, his line of reasoning led him to the correct counterexample.

LINGUISTIC NORMS OF UNDERGRADUATE MATHEMATICS PROOF WRITING AS DISCUSSED BY MATHEMATICIANS AND UNDERSTOOD BY STUDENTS

Kristen Lew
Rutgers University
kristen.lew@gse.rutgers.edu

Juan Pablo Mejía-Ramos
Rutgers University
pablo.mejia@gse.rutgers.edu

We studied the linguistic norms of mathematical proof writing at the undergraduate level by asking two mathematicians and five mathematics undergraduate students to read seven partial proofs based on student-generated work and to identify and discuss uses of mathematical language that were out of the ordinary with respect to standard mathematical proof writing. By asking participants to discuss the seriousness of each breach, we not only identify and discuss some of these linguistic norms, but also describe important differences between the ways in which mathematicians and students understand them.

Keywords: Reasoning and Proof; Advanced Mathematical Thinking

In professional mathematical practice, proofs are an essential type of communication. In an influential paper on the role of proof in mathematics, Rav (1999) wrote that proofs "are the heart of mathematics" and that they play an "intricate role […] in generating mathematical knowledge and understanding" (p.6). As a result, fostering undergraduate mathematics students' abilities to understand and construct valid proofs is one of the primary goals of mathematics instruction at the advanced undergraduate level. However, evidence of undergraduate students' difficulties when reading and constructing proofs is pervasive in the mathematics education literature (Weber, 2003). One potential difficulty students have when constructing proofs concerns students' inability to understand and use mathematical language and notation (Moore, 1994).

Mathematical language has been studied and interpreted in a variety of different ways: as a foreign language composed almost entirely of technical symbolic representations (Ervynck, 1992), as a combination of natural language and a system of mathematical symbols (Kane, 1968), and as a set of meaning that is created and expanded with the creation of terminology and the designation of technical definitions to natural English words (Pimm, 1987). In particular, researchers have focused on the differences between mathematical language and neutral or common language. For example, Veel (1999) discussed the precision necessary when implementing certain verb phrases in mathematics and Halliday (1978) noted the nominalization of mathematical language, in which a mathematical action or phenomenon becomes an object (e.g., differentiation). As these aspects of precision and rigor in mathematical writing may cause difficulties for students, a number of mathematics educators have suggested ways to improve students' use of mathematical language (e.g. Veel, 1999; Moschkovich, 1999; Lemke, 2003). However, these suggestions have focused on school level mathematics. Research on how mathematicians and undergraduate students understand the language of mathematics is lacking: to our knowledge, there are only two studies (Konior, 1993; Burton & Morgan, 2000) to date that have explicitly and empirically investigated the language of mathematical proof writing, and neither study investigates how undergraduate students understand such language.

Objectives of the Study

This qualitative study is a first attempt to address this gap in the literature by examining how mathematicians and undergraduate students understand the linguistic norms of mathematical proof writing. By interviewing both mathematicians and undergraduate students, this study not only identified various linguistic norms of undergraduate mathematics proof writing, but also illustrated how students understand these norms. In particular, this study addressed the following research questions:

1. How do mathematicians view and describe the linguistic norms of mathematical proof writing at the undergraduate level?
2. How do undergraduate mathematics students taking an introduction to proof course understand these norms?

Theoretical Framework

This study is informed by Herbst and Chazan's (2003) body of work on practical rationality. In particular, Herbst (2010) described norms as statements that articulate practice, as made by an observer of the practice. Since participants may not be fully aware of the norms they follow, Herbst and Chazan (2003) adapted the ethnomethodological concept of breaching experiments (Mehan & Wood, 1975) to study these norms. Herbst and Chazan hypothesized that when a participant of a practice is engaged in a situation where a norm has been breached, the participant will attempt to repair the breached norm highlighting not only what the norm is, but also expounding on the role that the norm has in the practice (Herbst, 2010). Adapting this methodology, this study used the concept of breached norms to investigate the linguistic norms of mathematical proof writing at the undergraduate level.

This study also employed the use of Scarcella's (2003) conceptual framework for academic English. Scarcella defined academic English as a "register of English used in professional books and characterized by the specific linguistic features associated with academic disciplines" (Scarcella, 2003, p. 9). This framework has previously been applied to mathematics education with regards to English learners studying mathematics (e.g. Silva et al., 2008; Heller, in press). However, we propose to apply the framework as a tool to begin to investigate important aspects of the mathematics sub-register of academic English. The framework of academic English specifies that there are three dimensions of language; the linguistic dimension, the cognitive dimension, and the sociocultural-psychological dimension. For the sake of brevity, we focus on the linguistic dimension and its components.

The linguistic dimension of academic English involves phonological, lexical, grammatical, sociolinguistic, and discourse components. The phonological component "includ[es] stress, intonation, and sound patterns" (p. 11) and "knowledge of graphemes (symbols) and arbitrary sound-symbol correspondences" (p.13).

The lexical component requires knowledge of the words used in a field. In particular, Scarcella (2003) distinguished between general words used in everyday language, academic words used across academic fields, and technical words that are field-dependent. She also included knowledge of fixed expressions, which are "expressions that tend to stick together and cannot be changed in any way" (p. 14), as part of the lexical component.

The grammatical component of academic English entails knowledge of "the grammatical co-occurrence relations that govern the use of nouns" (Scarcella, 2003, p.15). For instance, Scarcella (2003) noted students need to learn the associated grammatical features for these technical words, that "certain nouns […] are generally followed by prepositional phrases" and that some "verb + preposition combinations […] cannot be changed" (p. 16).

The sociolinguistic component involves developing competence in a variety of functions of language, including an understanding of the appropriateness of a given sentence in a particular context. Scarcella (2003) noted that "signaling cause and effect, hypothesizing, generalizing, comparing, contrasting, explaining, describing, defining, justifying, giving examples, sequencing, and evaluating" (p. 18) are examples of different academic language functions.

The discursive component entails understanding and using linguistic forms necessary to communicate successfully and coherently. For instance, in every day language, greetings and parting phrases indicate to speakers the beginning and end of conversations. Scarcella (2003) noted academic English "includes specific introductory features and other organizational signals" and that "writers' presentation of ideas must be orderly and convey a sense of direction" (p. 19).

This conceptual framework of academic English highlights important aspects of learning an academic language, and the components of the linguistic dimension provide a lens for analyzing mathematicians' and undergraduate mathematics students' understandings of the linguistic norms of proof writing in undergraduate mathematics.

Methods

Based on the methodology used by Herbst (2010) and Herbst and Chazan (2003), this study investigates the linguistic norms of undergraduate mathematics proof writing by showing participants student-generated proofs and asking them to identify and describe uses of mathematical language that are out of the ordinary with respect to standard mathematical proof writing at the undergraduate level. By identifying these non-standard uses of mathematical language, mathematicians and undergraduate students discuss their understanding of the linguistic norms of proof writing at this level.

Two mathematicians and five undergraduate students were interviewed for this study. Both mathematicians had experience teaching an introduction to proof course at the large research university in the United States. The undergraduate students were all enrolled in an introduction to proof course at the same university at the time of the study. Interviews with individual participants were conducted by the first author, videotaped, and lasted one to two hours.

Materials

The materials for this study include seven partial proofs that are based on student-generated work and truncated to help participants focus on the use of mathematical language and not the attempted proof's logical validity. One example of a partial proof used in the study is presented in Figure 1.

Let R and S be relations on a set A. Prove: $(S \circ R)^{-1} = R^{-1} \circ S^{-1}$.

Suppose $(S\circ R)^{-1}$ such that $(x,z) \in (S\circ R)^{-1}$, $x,z \in \mathbb{Z}$.

Since $(x,z) \in (S\circ R)^{-1}$, then $(z,x) \in S\circ R$.

Since $(z,x) \in S\circ R$, then $(y,x) \in S$ and $(z,y) \in R$.

Figure 1: Example of the partial proofs presented to participants

These partial proofs were chosen from student exams given in an introduction to proof course at the same university of the study. For each one of these proofs we created a copy with markings of what we considered to be breaches of linguistic norms of mathematical proof writing at the undergraduate level. An eighth partial proof was constructed to illustrate the interview procedure prior to the beginning of the interview.

Procedures

Mathematicians were presented with the student-constructed partial proofs one at a time and were asked to mark the partial proofs for anything that was out of the ordinary with respect to the use of mathematical language in the writing of mathematicians.

The interviews made two passes through the materials. In the first pass, mathematicians were

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

asked to explain why they made each mark indicating an unconventional use of mathematical language. For each of those unconventional uses, the mathematician was asked if the issue at hand was a logical issue, if it would affect the validity of the proof, if it was an issue of mathematical writing, if it was definitely unconventional or a matter of personal preference, if it significantly lowered the quality of the proof, and if the mathematician would have deducted points based on this issue when grading the student generated proof in an introductory proof course. These prompts were designed to elicit the mathematician's views on mathematical language with respect to proof writing. In particular, the prompts addressed the severity of each breach and enabled a differentiation between issues of logic and issues of mathematical writing in the analysis of the data.

In the second pass through the data, mathematicians were presented with marked copies of partial proofs presented in the first pass. That is, they were presented with a copy of a partial proof marked with one instance of an unconventional use of mathematical language as identified by the authors. These marked partial proofs were presented for each of the predicted instances of unconventional use of mathematical language that had not been previously identified by the participant in the first pass of the data. In particular, mathematicians were asked whether or not they would agree with a colleague of theirs who had suggested that these were indeed unconventional uses of mathematical language. If the participant agreed, the interviewer would then prompt the mathematician to discuss the breach as in the first pass of the data.

The structure of the interviews with the undergraduate students mirrored the structure of the interviews with mathematicians. However, the instructions and prompts used in the student interviews specified that the participants were to indicate and describe what they believed a mathematician would find out of the ordinary with respect to the use of mathematical language in the writing of mathematicians in formal settings. The only two other differences with the previously described protocol was that in the first pass students were not asked to make an assessment regarding the deduction of points in the grading of the partial proofs, and that in the second pass they were asked whether or not they would agree with a *classmate* of theirs who had suggested each unconventional use of mathematical language not identified in pass 1.

Analysis

Interview videos were transcribed and materials generated in the interviews were scanned for analysis. Data was analyzed using memoing and grounded theory in the style of Strauss and Corbin (1990). Memos were used to conceptualize the breached linguistic norms and to categorize the broken norms.

Results

The analysis of the mathematicians' interviews identified ten breaches of linguistic norms in the partial proofs presented to them. The number of mathematicians and the number of students who identified each one of these breached norms in the first part of the interview (pass 1) are listed in Table 1. Analysis of the interviews provided us with participants' descriptions of each breached norm, their perceived seriousness of each breach (whether they considered the breach to be definitely unconventional, or a matter of personal interest or context), and in the case of mathematicians, whether or not they would deduct points when grading a proof containing such a breach. A summary of some of this information is included in Table 1. However, for the sake of brevity, we only describe how four of these ten norms emerged from the data and how the student participants understood these four norms.

Include Necessary Antecedents

In the interviews, both mathematicians identified an unclear referent in a partial proof. Specifically, the proof included the word ‘it’ referring to a function that had not been explicitly defined in the partial proof. One of the mathematicians said:

Table 1: Identification of Norms and Their Severity by Mathematicians and Students in the First Pass

Linguistic Norms of Mathematical Proof Writing	Mathematicians*	Students**
Specify each variable	2 – 2 – 2	2 – 1
Include necessary antecedents	2 – 2 – 2	0 – 0
Use proper imperative sentence structure	2 – 2 – 2	4 – 3
Use standard mathematical vernacular	2 – 2 – 2	3 – 2
Write in full sentences	2 – 2 – 2	0 – 0
Make relations between statements clear	2 – 2 – 1	3 – 3
Do not use abbreviations in formal settings	2 – 2 – 0	4 – 1
Do not use formal propositional logic	1 – 0 – 0	0 – 0
Explicitly indicate the structure of a proof	1 – 1 – 1	1 – 1
Use notation appropriately in texts	1 – 1 – 0	3 – 1

*Number of mathematicians (out of 2) who identified the norm breach in the first pass (1st number), deemed the breach definitely unconventional (2nd number), and would deduct points for this type of breach (3rd number).
**Number of students (out of 5) who identified the breach of the norm in the first pass (1st number) and deemed the breach definitely unconventional (2nd number).

> Yes, I mean it’s always, in writing in general, you need to have… the pronouns have to have an antecedent. And so, not just mathematical writing, but in particular you have to be careful about mathematical writing.

In this quote the mathematician indicated the necessity of including antecedents to avoid unclear referents and suggested that it is not only the case that the rules of English grammar apply to mathematical language, but also that the adherence to this rule in mathematics is particularly important. Using Scarcella’s (2003) framework, we identify the inclusion of necessary antecedents as a linguistic norm regarding the grammatical component of the language of mathematical proof writing. Both mathematicians judged the use of pronouns lacking clear referents as definitely unconventional in mathematical proof writing and indicated that they would deduct points from an exam in an introductory proof course based on that breach.

However, none of the students identified the unclear referent in the first pass through the data. After presented with the marked partial proof indicating the unconventional use of mathematical language, four students agreed that the word ‘it’ introduced ambiguity. But these students did not see this issue as severely as the mathematicians. In particular, the students indicated that they believed a mathematician would view this issue as a matter of personal preference. Failing to view the grammatical necessity of including antecedents could be interpreted as evidence that these students are not proficient in this aspect of the grammatical component of mathematical proof writing.

Use Proper Imperative Sentence Structure

The interviewed mathematicians indicated that the following phrases from the partial proofs were ungrammatical and meaningless: 1) “Suppose $(R \circ S)^{-1}$ s.t. $(x, z) \in (R \circ S)^{-1}$” and 2) “Let $\forall n \in \mathbb{Z}$”. These are both imperative phrases beginning with transitive verbs. As such, English grammar dictates that the phrases need both a direct object and an object complement to be a complete sentence. That is to say, that the sentence must suppose the direct object in relation to another object or a property about the direct object.

Both mathematicians judged these two statements to be definitely unconventional and worthy of deducting points on an exam in an introduction to proof course. In particular, one mathematician said that the former "just doesn't make any sense at all, I don't know what they were… what they mean to be saying." He continued to say "Suppose what about $(R \circ S)^{-1}$? Following it with the 'such that' is not a statement about $(R \circ S)^{-1}$, so you can't say suppose", indicating that the sentence is incomplete. Concerning the phrase "Let $\forall n \in \mathbb{Z}$", the second mathematician said:

> It's not a statement. I mean, let something implies that the something is a statement that's being assumed and this is not a statement. […] Linguists probably have a word for this; it's just not a sentence. […] It's not a correctly constructed meaningful thing.

Here the mathematician attempted to describe that using the word 'let' needs to be followed by a meaningful statement. While the mathematicians had difficulty explaining the breached linguistic norm exactly, it is evident that both believed the phrases included unconventional use of mathematical language.

Four of the student participants agreed in the first pass that these sentences are unconventional uses of mathematical language. Moreover, one of the students indicated that the statements were incomplete sentences and were grammatically incorrect. However, they did not agree with the mathematicians' severe opinions of this type of breach. While three students indicated that this was indeed an unconventional use of mathematical language (and not simply a matter of writing style), each of students also believed such a use of language was harmless to the quality of the proof.

Make Relations Between Statements Clear

Both mathematicians discussed the importance of using verbal connectives to show the relations between different statements within the partial proofs. Moreover, they both agreed that lacking these verbal connectives was definitely unconventional and would merit point deductions on an exam in an introductory proof course. In particular, one mathematician said:

> No, it's not harmless. […] I mean if I'm worried about a student actually getting broken of a habit of making these kinds of, here's a statement, here's a statement, here's a statement, without drawing the connectives in between. Then that's not a logical issue, but it's a serious presentation issue.

In this quote, the mathematician indicated that he did not want students to write proofs as a series of unrelated statements, and deemed this breach as a serious presentation issue. Such relations between statements show the flow of the argument to readers, which is an aspect of the discursive component of mathematical language.

However, there was less agreement among the students. The three students who indicated in the first pass that one must make relations between statements clear each agreed that this use of mathematical language was definitely unconventional. One student said:

> I don't know if he's just stating it or if he means it to be part of that [assumption], but I think if you're writing it out formally, you should be more clear about it, like put an assume.

This student indicated that lacking verbal connectives could lead to ambiguity, which puts unnecessary stress on the reader to decipher the flow of the argument. On the contrary, two of the five students indicated in the second pass that there was no need for verbal connectives and a proof lacking words was conventional. One of these students said, "in some homework assignments, I have done this before and it's not wrong. You could write it in words or you could write it like this." This student did not seem to believe in the necessity of connecting the various statements in a proof.

Use Notation Appropriately within Text

One partial proof included the sentence "So there are 19 possible differences in $\mathbb{N}\times\mathbb{N}$ that are ≥ -9 and ≤ 9". One of the mathematicians indicated in the first pass that this sentence used the mathematical symbols $\geq$ and $\leq$ inappropriately. In particular, the mathematician said:

I would say that those should have been said in words rather than using the symbols. Or complete expression – that is, there are 19 possible differences, *d*, such that $d \geq -9$ and $d \leq 9$. [...] Do it in a symbolic phrase or do it in words, but don't kind of mix it in.

In this quote, the mathematician indicated that the binary operators $\geq$ and $\leq$ require notation on both the left and right sides of the symbols. Relating the to lexical component of academic English, this quote suggests that using the binary operator without notation on both sides of the operator is an unconventional use of mathematical language. This mathematician indicated that inappropriately mixing the symbolic notation with text would significantly lower the quality of the presentation and that he would deduct points from an exam based on this use of language. While the other mathematician agreed in the second pass that such a use would be unconventional, he believed that mixing the symbolic notation with text is a personal preference and would not deduct points off of an exam. This mathematician however discussed that one should not technically use this type of "short hand" in formal settings, but that it is commonly used despite it being unconventional. This indicates the sociological component of mathematical proof writing includes understanding the appropriateness mixing mathematical notation and prose.

Three of the five students' responses in the first pass also indicated that mixing the notation and text in this way was an unconventional use of mathematical language. For example, one student said:

> I think it's just more the notation. It looks odd to just have the greater than sign without having something like directly in front of it. So I think it should be written out in words.

In this quote, the student described that the binary operators $\geq$ and $\leq$ require notation on both the left and right sides of the symbols, suggesting that the students agreed with the first mathematician on what was the appropriate way to use symbols in prose. On the other hand, many of the students also believed that this mix of notation and prose was harmless. In particular, one student said that "it's faster than writing greater than or equal to or less than or equal to [… and] I've seen lots of teachers use that when like they do lectures." So this student emphasizes that since teachers mixed the notation and prose when writing on the board, there is no reason why he should not do so as well.

Discussion

As this qualitative study considers only a small sample of mathematicians and undergraduate students, the findings are simply suggestive of how mathematicians and undergraduates view the language of undergraduate mathematics proof writing. In particular, based on mathematicians' interviews we have identified ten linguistic norms of mathematical proof writing. Our analysis suggests that while interviewed students showed some competence in certain aspects of the lexical and grammatical components of mathematical proof writing, there were significant differences between these students' understandings of some aspects of the sociological and discursive components of mathematical proof writing and the corresponding understandings of the mathematicians interviewed in this study.

While the nature of this study precludes any claim of sample-to-population generalization of these findings, we believe the linguistic norms of mathematical proof writing identified in this study, as well as the method suggested for studying such norms, opens interesting avenues for future research in an area that is both under-researched in mathematics education and important in our attempt to understand students' difficulties reading and writing mathematics. In particular, these findings suggest the following research questions: To what extent does the larger community of undergraduate mathematics professors agree on the linguistic norms of undergraduate mathematics proof writing identified in this study? To what extent do students in transition to proof courses (and beyond) agree on the described views of these norms, and to what extent do students' perceived views of these norms align with those of the professional mathematical community? How do students' understandings of these norms develop and change throughout a semester of an introduction to proof course? We are currently designing studies that address some of these questions.

Action-Process-Object-Schema (APOS) Theory is applied to study student understanding of directional derivatives of functions of two variables. A conjecture of the main mental constructions that students may do in order to come to understand directional derivatives is proposed and is tested by conducting semi-structured interviews with 26 students who had just taken multivariable calculus. The interviews explored the specific constructions of the genetic decomposition that student are able to do and also the ones they have difficulty doing. The conjecture, called a genetic decomposition, is largely based on the elementary notion of slope and on a development of the concept of tangent plane. The results of the empirical study suggest the importance of constructing coordinations of plane, tangent plane, and vertical change processes in order for students to conceptually understand directional derivatives.

Keywords: Advanced Mathematical Thinking

Introduction and purpose of the study

The calculus of functions of several variables is of fundamental importance in the study of mathematics, science, and engineering. Some work has been published regarding functions of two variables (see for example, Trigueros and Martínez-Planell, 2010; Martínez-Planell and Trigueros, 2012). However, there are very few publications on the differential calculus of such functions. The only publication we'll refer to, Weber (2012), includes a discussion of the rate of change of functions of two variables focusing on the use of covariational thinking to help students build a notion of rate of change in space which centers on students' development of a symbolic representation of the directional derivative. In this paper we focus on students' geometrical understanding of directional derivatives and its relationship to other important ideas in the schema of the differential calculus of functions of two variables. Our research questions are: What are students' conceptions of directional derivatives after taking a Multivariate Calculus course? What are the main mental constructions involved in learning this concept?

Theoretical framework

APOS Theory is used as a theoretical framework to study the cognitive development of students who completed a course using a traditional lecture/recitation model, as discussed in Arnon et al. (2013, p. 106). As APOS is a well-known theory it is briefly discussed (see Figure 1). In APOS, an Action is a transformation of a mathematical object that is perceived by the individual as external. It could be the step by step implementation of an algorithm according to explicit instructions or the application of a fact or result that has only been memorized. Activities that lead students to repeat and reflect on an action can help them to interiorize the Action into a Process. A Process is characterized by the individual's ability to imagine doing the main Actions and to anticipate their result without having to explicitly perform them; In a Process the Actions are perceived as internal. A Process may be coordinated with other Processes, and may also be reversed. As an individual needs to apply Actions on a Process, he/she may become aware of the process as a totality. In this case, when the individual applies or can imagine applying Actions to the Process, then it is said that the Process has been encapsulated into an Object. Actions, Processes, and Objects may be organized into Schemas. A Schema for a given mathematical notion is a coherent collection of Actions, Processes, Objects, and other Schemas that are related in the individual's mind to the notion that is being considered. Actions on a Schema may result in its being thematized into an Object. Schemas develop as relations between new and previous Actions, Processes, Objects and other Schemas are constructed and reconstructed. Their development may be described by the Intra-, Inter-, Trans- "triad": At the Intra- stage relations among the Schema components are being constructed but they remain for the most part isolated from one another. At the Inter-stage, transformations between some of the Schema components are recognized. The Trans- stage is defined in terms of the construction of a synthesis between them, so that the Schema is coherent and the individual can decide when its use in problem solving is needed.

Also, although it might be thought that in APOS theory there is a linear progression from Action to Process to Object and then to having different Actions, Processes, and Objects organized in Schemas, this often appears more like a dialectical progression where there can be partial developments, passages and returns from one conception to another. What the theory states is that a student's tendency to deal with problem situations in diverse mathematical tasks involving a particular mathematical concept is different depending on whether the student understands the concept as an Action, a Process, or an Object or has constructed a coherent Schema.

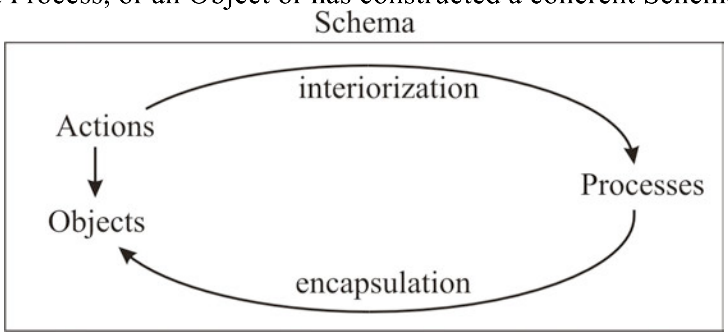

Figure 1: Mental structures and mechanisms

The application of APOS theory to describe particular constructions by students requires that researchers develop a genetic decomposition - a model that describes the specific mental constructions a student may make in understanding mathematical concepts and their relationships. As a model, a genetic decomposition predicts the constructions needed to learn the concepts of interest. It is proposed by researchers and needs to be tested experimentally. The genetic decomposition that follows was developed from reflection on the mathematics itself, considering what it takes to make the idea of a directional derivative understandable to students, and the classroom experience of the researchers implementing initial versions of the idea for several consecutive academic years.

Our genetic decomposition of the directional derivative is essentially based on the notions of directed slope in R^3 and vertical change on a plane. Moreover, the genetic decomposition of vertical change on a plane can be used as a starting point to describe the mental construction of several important concepts of the differential calculus of functions of two variables including tangent plane, differentials, and directional derivatives. Hence, while based on the elementary idea of slope, it can potentially provide a unifying framework for the description of the main ideas of the differential calculus of two-variable functions, thus contributing to help students construct, at least, an Inter-Schema stage of development for the differential calculus of functions of two variables.

The genetic decomposition is as follows: Given a non-vertical plane, the Processes of slope of a line and fundamental plane (planes of the form $x = c$, $y = c$, $z = c$) are coordinated into new processes of vertical change in the x and y directions, where it is recognized that vertical change in the x direction can be described as a function of the horizontal change in the x direction ($\Delta z_x = m_x \Delta x$), and similarly for vertical change in the y direction ($\Delta z_y = m_y \Delta y$). These processes are coordinated into a Process of total vertical change on a plane, so that total vertical change in any plane is given in terms of the sum of vertical changes in the directions of the coordinate axes: $\Delta z = \Delta z_x + \Delta z_y = m_x \Delta x + m_y \Delta y$ (see Figure 2). Actions and Processes which are treatments and conversions in and between representations (Duval, 2006) are performed on the Process of total vertical change to encapsulate it into the Object conception of plane in three dimensions. In particular, the point-slopes formula for a plane, $z - z_0 = m_x\left(x - x_0\right) + m_y\left(y - y_0\right)$ may be seen as the vertical change from an initial point $\left(x_0, y_0, z_0\right)$ to a final generic point $\left(x, y, z\right)$ on the plane.

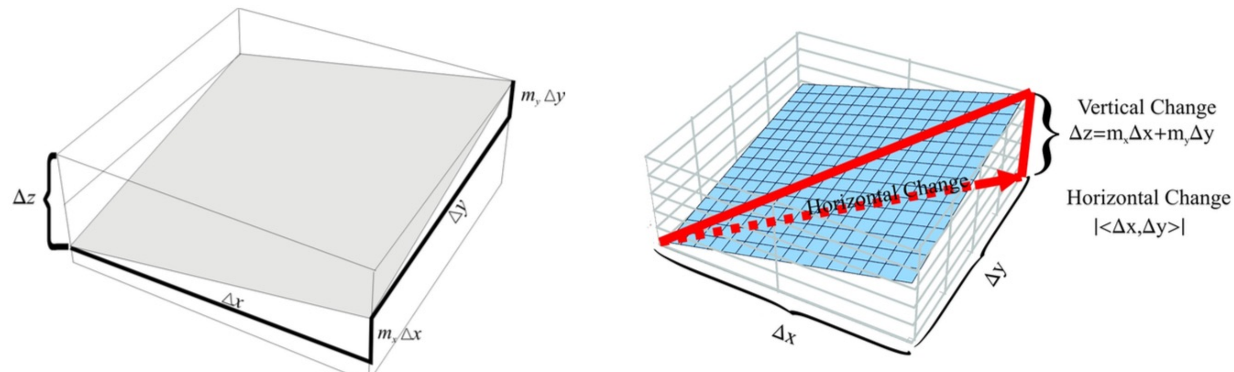

Figure 2: Vertical change on a plane and directional derivative

The Process of partial derivative is coordinated with that of plane in three-dimensional space into a new Process where tangent planes to any surface at different points can be considered and calculated. When there is a need to consider particular tangent planes and perform actions on them to describe the surface in terms of the behavior of partial derivatives, this Process is interiorized into an Object conception of tangent plane.

To do the mental construction of $D_{\vec{v}} f(a,b)$, the directional derivative of f in the direction $\vec{v} = \langle \Delta x, \Delta y \rangle$ (not necessarily unitary) at the point (a,b), the student may coordinate the Process of three-dimensional space with the Process of function of two variables in order to locate and represent in space or imagine the point $\left(a,b,f\left(a,b\right)\right)$. Further coordination with the Process of vectors allows use of the point $\left(a,b,0\right)$, or more generally any point of the form $\left(a,b,z\right)$ as a starting point from which to represent the direction vector $\vec{v} = \langle \Delta x, \Delta y \rangle$ in space as $\langle \Delta x, \Delta y, 0 \rangle$. Then, the Processes of vector, slope, and derivative of function of one variable are coordinated to represent physically or geometrically, and recognize, the directional derivative as the slope of the line tangent to the graph of the function at the point $\left(a,b,f\left(a,b\right)\right)$ in the given vector direction (a directed slope). To obtain the value of $D_{\vec{v}} f(a,b)$ (see Figure 2), the student would then coordinate the Process of slope of a line with the Process of tangent plane to obtain the vertical change as $f_x(a,b)\Delta x + f_y(a,b)\Delta y$, and with a Process of vector magnitude to obtain the horizontal change as the magnitude of the direction vector $|\vec{v}| = \left|\langle \Delta x, \Delta y \rangle\right| = \sqrt{\left(\Delta x\right)^2 + \left(\Delta y\right)^2}$, and thus obtain $D_{\vec{v}} f(a,b)$, as $\dfrac{f_x(a,b)\Delta x + f_y(a,b)\Delta y}{\left|\langle \Delta x, \Delta y \rangle\right|}$. These

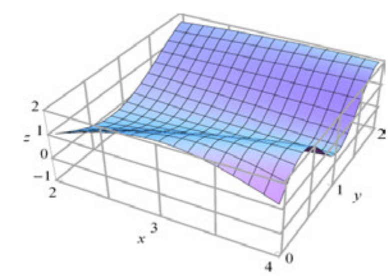
Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

Processes and coordinations must be constructed in different representations. The computation of $D_{\vec{v}} f(a,b)$ at a fixed point (a,b) for different direction vectors $\vec{v}$ and at different points (a,b) for a fixed direction vector $\vec{v}$ allows the encapsulation of the directional derivative Process as a function that depends on the direction vector $\vec{v}$ while also recognizing the functional dependence of the directional derivative on the starting point (a,b).

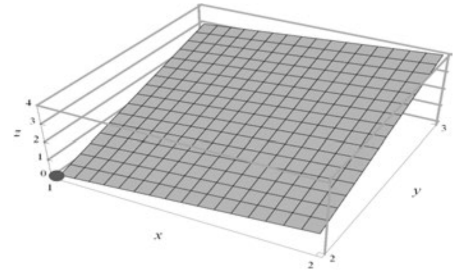
Method

An instrument consisting in 6 multi-task questions was designed to conduct semi-structured interviews with 26 students to test their understanding of the different components of the proposed genetic decomposition. Of these 6 questions we will only report on the 2 which directly considered directional derivatives. All participants were students of science and engineering that had just finished a course on multivariable calculus. Nine (9) of them came from a group where a traditional teaching approach was followed, and the other 17 students came from two groups where activities designed in terms of the genetic decomposition were used. All students used the same textbook (Stewart, 2006) and covered the same material in the course. The three instructors of the groups were asked to choose 9 students from each of them, considered as above average, average, or below average based on their performance in the class, providing as balanced a distribution as possible, to participate in the interviews. One of the students did not show up to the interview and hence we were left with a total of 26 students. All participating professors were experienced (with at least 20 years of experience and having repeatedly taught the course during those years), popular with students (judging on how fast their sections fill up and on student evaluations), and had, throughout the years, shown concern about student's learning. Each interview lasted on the average from 40 minutes to 1 hour. The interviews were recorded and transcribed. Data was independently analyzed by the researchers and conclusions were negotiated among them. We now discuss the questions that dealt directly with the directional derivative and that were analyzed in terms of the structures described in the genetic decomposition:

1. Suppose the graph of $z = f(x,y)$ is as follows. State the sign (positive, negative, zero) of $D_{<-2,1>} f(4,0)$.
   (This is the second part of a question in the original interview instrument. In the first part, students used the same graph to determine the sign of $f_y(4,0.7)$.)



2. The following plane is tangent to the graph of $z = f(x,y)$ at the point (1,2,0). Use the given figure to find $D_{\langle 1,1\rangle} f(1,2)$.



It is important to note that in the first question, the function initially is increasing in the given direction and thus the directional derivative is positive, $D_{<-2,1>} f(4,0) > 0$, while in the second one, thinking of the directional derivative as a slope, the vertical change may be obtained looking at the given figure as $\Delta z = 4 - 0$, and the horizontal change as $|\langle 1,1\rangle| = \sqrt{2}$. Hence the value of the directional derivative is $4/\sqrt{2}$. Using the Process of vertical change on a plane this may also be obtained as $D_{\langle 1,1\rangle} f(1,2) = \dfrac{m_x \Delta x + m_y \Delta y}{|\langle 1,1\rangle|} = \dfrac{1(1)+3(1)}{\sqrt{2}} = \dfrac{4}{\sqrt{2}}$.

Results

It seems to be commonly assumed in instruction that students can readily represent the vector direction in a directional derivative. However, we found that frequently this is not the case. Tania, one of the best performing students, could quickly and without hesitation identify the sign of $f_y(4,0.7)$ in problem 1, but seemed unable to represent the vector direction and thus was not able to give the sign of $D_{\langle -2,1\rangle} f(4,0)$.

Interviewer: Will that directional derivative be the slope of a tangent line or not?
Tania: Yes, it is the slope of a tangent line.
Interviewer: Of what line?
Tania: That's the tricky part. That's the line I'm looking for.

In the case of David it was observed that in problem 1, he made the necessary coordinations to identify the base point and correctly represented the direction vector. However, he did not coordinate the vector and derivative of a function of one variable Processes. Furthermore, he remembered a formula that would give him a correct answer but did not seem to have constructed a Process of vertical change on a plane that would enable him to give geometric meaning to it:

David: The directional derivative at the point $(4,0)$ … x is -2, y is 1, it goes this way…

[Correctly representing the vector direction with a dashed line starting at the base point; see Figure 3.] Then the directional derivative at this point will be equal to … $\dfrac{f_x(4,0)(-2)+f_y(4,0)(1)}{\sqrt{5}}$ … [He went on to interpret this as the slope of the secant line he drew in Figure 3.]

After a while, the interviewer suggested to David that he think of a tangent line. He then managed to correctly draw a tangent line (see Figure 3), however, the slope he came up with was not the **directed** slope:

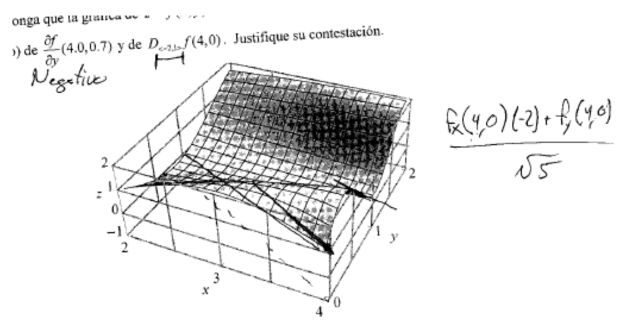


Figure 3: David's drawing on problem 1

Interviewer: And if I were to tell you that the directional derivative is the slope of a tangent line, could you draw the tangent line to that graph at that point in that direction?
David: At this point in that direction? [He draws a tangent line that seems to be correct.]
Interviewer: Will that slope be positive or negative?
David: it will be a negative slope… it is negative because… while the value of z decreases, the value of x increases, so it would, it would be negative, it would be coming down.

Even though David manages, without hesitation, to obtain the correct answer to problem 2, he gives no evidence of having coordinated the Processes of vertical change and plane or of tangent plane to give geometric meaning to his conception of directional derivative:

David: Use the given figure to find … it would be the partial with respect to x at the point (1,2) times 1, the partial with respect to y at the point (1,2) times 1, over the square root of 2… 4 over the square root of 2 (see Figure 4).

Overall we can only say that David seems to show a conception of directional derivative that is in transition from Action to Process because, even though he showed some evidence of having constructed a Process conception of directional derivative, as evidenced by his ability to locate base points, represent vectors' directions, and do some computations, he was still mostly dependent on a memorized formula.

$$\frac{\overbrace{f_x(1,2)}^{1}(1)+\overbrace{f_y(1,2)}^{3}(1)}{\sqrt{2}}$$

$$\frac{4}{\sqrt{2}}=\frac{4\sqrt{2}}{2} \qquad 2\sqrt{2}$$

Figure 4: David's written answer to problem 2

Some students like Luis, were able to do these coordinations to explain correctly the expected answer. His behavior on problem 1 is consistent with a Process conception of directional derivative. Of course, his behavior on just one problem is not sufficient to guarantee he has constructed this type of conception of directional derivative, since a student's conception can only be ascertained by considering the student's **tendency** to deal with different problem situations involving directional derivatives.

Luis: [On problem 1] The directional derivative, I'm given (4, 0). Here I have located the point. I have to look for the direction $\langle -2,1\rangle$ which would be 2 units to the left on the graph, that vector, and 1 unit to the right in y. It should be positive there since the slope of z [he probably means the value of z] in that direction is increasing.

Continuing with the genetic decomposition, after the student was able to locate the base point and the vector direction, and after coordinating the Processes of vector and that of derivative of function of one variable to think of the problem in terms of tangent lines and directed slopes (in problem 1), the student was expected (in problem 2) to coordinate the Process of slope with the Process of tangent plane in order to compute the vertical change along the plane and to coordinate this last Process with that of vectors in order to compute the horizontal change as the magnitude of the direction vector. However, in problem 2, Luis was not able to coordinate the Processes of vertical change, horizontal change, and slope of a line to deal with the directional derivative, but rather seemed to be depending on a memorized and unconnected formula (used in the class textbook; Stewart, 2006) which is valid only for unit direction vectors. After writing:

$$D_{\langle 1,1\rangle} f(1,2) = m_y\Delta y + m_x\Delta x = 3(1) + 1(1) = 4$$

Luis: The directional derivative should have the value of 4. I'm not completely sure, but I am quite sure this should be the value of the directional derivative.

Interviewer: Does the fact that the vector is not unitary play any role?

Luis: … Well, in this case, since it is a plane… I believe that in this case since it is a plane it won't make much of a difference… the directional derivative will have the same value as long as it is in the direction $\langle 1,1\rangle$… maybe if it were a more complex graph… in this case it shouldn't be. Maybe there's a problem but I'm not sure.

Although Luis showed that he was certainly on his way to constructing a Process understanding of directional derivative, he did not show he was able to coordinate the Process of vertical change on a plane needed to interpret $D_{\langle \Delta x,\Delta y\rangle} f(a,b)$ as a slope with vertical change given by $f_x(a,b)\Delta x + f_y(a,b)\Delta y$. The reason for this is, probably, that in his classroom and in the textbook, $D_{\vec{u}} f(a,b)$ was defined only for a unit direction vector $\vec{u}$ and the geometric interpretation of the directional derivative as a slope remained hidden both in a graph and in the formal development of the mathematics (see Stewart, 2006).

Daylin was able to compute the directional derivative in problem 2 while justifying geometrically her computations. Hence she seems to have constructed the conjectured coordinations needed to be able to think of the directional derivative as a slope and obtain the necessary vertical change and horizontal change (see Figure 5). Further, since she also gave evidence of doing the conjectured mental constructions required to solve and explain problem 1, one may reasonably state that she seems to have constructed a Process conception of directional derivative.

Daylin: Then the height at the new point will be 4, if I put this triangle [see Figure 5] my height here is 4… this is the direction $\langle 1,1\rangle$ and I want the slope… here z is zero, I have the rise, I need the run, the run will be … the square root… so the slope will be 4 over $\sqrt{2}$.

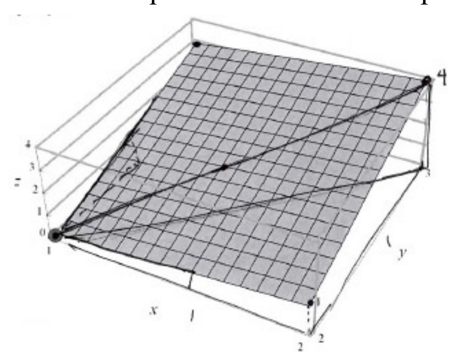

Figure 5: Daylin's drawing on problem 2

Summary and Discussion

Only 4 of 26 students gave evidence of having made all or most of the mental constructions required in the genetic decomposition. This tells us that the idea of a directional derivative is difficult for most students and they need more help understanding even the most elementary notions associated with this idea. It also suggests that much work still remains to be done designing and improving activities to help students do the conjectured constructions.

We just saw that although teachers probably frequently assume that students will be able to imagine the base point and the role of the vector direction to understand directional derivatives, this seems not to be the case for many students, and that explicit attention to the necessary coordinations can help students make the desired mental constructions. Also, many students did not show a Process conception of derivative of function of one variable to be used in the proposed mental constructions of directional derivative. This suggests that rather than assume they have constructed this Process, instruction can start by, once again, explicitly considering ways to help them construct it, but now in the context of functions of two variables. The construction of a Process of vertical change on a plane

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

was shown in this study to be important to facilitate the mental construction of the processes of tangent plane and directional derivative that help students give geometrical meaning to directional derivative, and that students may not be able to construct it without explicit attention in their classroom instruction.

Overall, results show that most of the students who had successfully finished a course on multivariable calculus did not have a deep understanding of the concept of directional derivative. Many students relied on memorized facts and formulas and thus showed difficulties when responding to questions that needed a deeper conceptual understanding. Most students lacked geometrical understanding of the basic components involved in the definition of a directional derivative. The lack of understanding of those concepts impaired them from realizing that the symbol $D_{\vec{v}} f(a,b)$ denotes a special type of derivative and that, as such, it can be represented as a slope of a tangent line in the given direction, as well as understanding that, in three-dimensional space, the notion of slope would be ambiguous unless it is a directed slope, and recognizing that for a vector direction $\langle \Delta x, \Delta y \rangle$, which is not necessarily unitary, the directional derivative represents the directed slope of a line on the tangent plane with vertical change given by $f_x(a,b)\Delta x + f_y(a,b)\Delta y$ and horizontal change given by the magnitude of the direction vector $\langle \Delta x, \Delta y \rangle$. This is necessary to make sense of the formula traditionally used in textbooks, where the direction vector $\langle u_1, u_2 \rangle$ is unitary.

The assumption that students will, look at textbook figures and on their own, come to understand the geometric ideas involved in directional derivatives, apparently held by many teachers who just present students with the formula $D_{\langle u_1,u_2 \rangle} f(a,b) = f_x(a,b)u_1 + f_y(a,b)u_2$, seems not to be valid since the simple geometrical explanation of the notion of directional derivative as a slope remains hidden. Of course, any instructional approach will need to eventually consider only unitary direction vectors since this formula can be expressed as the dot product of the gradient vector and the unitary direction vector, an observation which is crucial in exploring the properties of the gradient vector. Results obtained suggest that instruction might start by exploring the basic property of slope where the vertical change is seen as the slope times the horizontal change, $\Delta V = m\Delta H$, and then interpreting this in the case of a plane to obtain the basic idea of vertical change on a plane, symbolically represented by $\Delta z = m_x \Delta x + m_y \Delta y$. This is essentially the idea inspiring the genetic decomposition presented. A possible virtue of this approach is that the notions of plane, tangent plane, the differential, and the vertical change in a directional derivative are all explained and inter-related by this simple geometric idea, thus potentially helping students build a coherent schema for the differential calculus of functions of two variables. But, this remains to be investigated.

Researchers have identified challenges students face when modeling dynamic situations. This report discusses the results of semi-structured clinical interviews with ten prospective secondary mathematics teachers who were provided with a dynamic image of a growing and shrinking cone. We asked the students to graph the relationship between the surface area and the height of the cone. We identify four themes in the students' solution approaches and discuss the implications of these approaches. Specifically, we discuss the themes with respect to relationships between the students' solutions and their images of the growing and shrinking cone, including the extent that they leveraged this image to determine their solutions.

Keywords: Modeling; Problem Solving; Cognition

The authors of the Common Core State Standards for Mathematics (CCSSM) (National Governors Association Center for Best Practices, 2010) argued students should have the opportunity to construct and compare a multitude of relationships including those that have constant rates of change and those that have varying rates of change. They also identified modeling and reasoning quantitatively as two practices that should permeate students' mathematical experiences. These policy calls are in line with researchers who have identified students' *quantitative* and *covariational reasoning*–students conceiving situations as composed of measurable attributes that vary in tandem–as critical to numerous K-16 concepts (Ellis, 2007; Johnson, 2015a; Moore & Carlson, 2012; Thompson, 2011). These same researchers have argued that much is to be learned about how students approach dynamic situations, including the extent that these approaches are rooted in constructing structures of quantities and relationships between these quantities. Further, researchers have called for increased attention to exploring students' activities as they make sense of situations where they conceive of multiple quantities covarying (Castillo-Garsow, Johnson, & Moore, 2013; Thompson, 2011).

We discuss ten prospective secondary mathematics teachers' (heretofore referred to as students) solutions to a task in which they graphed a relationship between the surface area and height of a cone as the cone changed in size (but maintained a constant slant-angle). Using our analyses of the students' activities in semi-structured clinical interviews (Clement, 2000), we illustrate four themes in their solution approaches. With respect to these themes, we discuss how they used their images of the situation to determine a relationship between the surface area and height of a cone. Collectively, these themes provide glimpses into students' thinking as they construct relationships between quantities in what we intended to be a three-dimensional context.

Literature Review and Motivation

Saldanha and Thompson (1998) described covariation to include, "imagistic foundations for someone's ability to 'see' covariation" (p. 298). By 'see' covariation, we infer Saldanha and Thompson did not mean that covariation and quantities are independent of the mind or merely perceptual objects. Instead, we interpret them to refer to someone constructing and re-constructing a dynamic situation to the point that they envision it as entailing measurable attributes and an understanding or anticipation of how these attributes change in tandem. Additionally, we characterize a sophisticated image of covariation to include the capacity to 'replay' one's image of the dynamic situation while holding in mind how these attributes are changing in tandem. In this regard, how students operate and reason in what they come to understand a covariational situation is directly tied to their images of that situation.

Students' images are important for their construction of mathematical objects (Izsák, 2004; Thompson, 1994). Focusing on students' images in applied problems, Moore and Carlson (2012) examined students' activities for the purpose of determining distinguishing features of students' images with respect to the formulas and graphs that the students produced when modeling and representing situations with covarying quantities. Most relevant to the present work, the authors noted that despite the students' creations of mathematical products that an observer might deem incorrect with respect to the intended situation, these mathematical products were consistent with the *students'* images of the situations. For instance, on a task that included a box with varying base dimensions, some students envisioned a box with fixed base dimensions. As a result, these students determined a volume formula that captured a base with fixed dimensions. Based on their findings, the authors (Moore & Carlson, 2012) argued that researchers and educators should give more attention to students' images of problem contexts including determining how these images play a role in the mathematical products students construct.

Theoretical Perspective

We leverage tenets of radical constructivism by approaching knowledge as actively built up by the individual in ways that are idiosyncratic to that individual and fundamentally unknowable to another individual (von Glasersfeld, 1995). Hence, we approach quantities as personally constructed measurable attributes (Steffe, 1991). Likewise, relationships between quantities are constructed by the individual, with these relationships being influenced by the individual's understanding of each quantity and their image of the relevant situation (along with other potential influences). It follows that we do not assume that students see situations that we provide them with in the same way that we do or intend for them to do (Thompson, 2011). For instance, a student may imagine a cone growing smoothly as a video suggests, growing in discrete snapshots corresponding to adding to the cone in sections, or physically changing in some other fashion (e.g., stretching the cone as if it is made of malleable rubber).

Although we take the stance that students' knowing and thinking is fundamentally unknowable to us as researchers, we can make inferences about students' thinking based on our interpretations of their words and actions. Steffe and Thompson (2000) referred to such inferences or models as *the mathematics of students*. Our goal was to characterize students' images of a situation and the mathematical products they created based on our inferences of their activities when given a dynamic situation as described in the following sections.

Methodology

We conducted a series of three semi-structured task-based clinical interviews (Clement, 2000) with ten students (eight female, two male). The students were enrolled in a secondary mathematics teacher education program at a large university in the southeast United States. At the time of the third interview–the interview we focus on here–these students had completed their first content course in the secondary mathematics education program, as well as at least a full calculus sequence and two additional mathematics courses (e.g., linear algebra, differential equations, etc.) with a grade of C or better. Some students had completed several additional education and mathematics courses.

The interviews consisted of a series of tasks and problems with many tasks asking the students to construct and represent a relationship between quantities in a dynamic situation. Each interview was videotaped and these videos were digitized for analysis. Two members of the research team were present at each interview, and for each interview, the interviewers took field notes and discussed observations and insights afterwards. Upon completion of the interviews, members of the research team viewed the videos and selected instances of student activity that revealed insights into the students' thinking. The research team then met to discuss their observations and used an open (generative) and axial (convergent) approach (Strauss & Corbin, 1998) to construct tentative themes we observed across students. Upon further analysis, themes were refined by comparing and contrasting different students' activities. Through this process of constructing, refining, and re-refining, the research group reached a consensus on themes that characterized the students' activities on the cone problem.

Task Design – The Cone Problem

At the start of the interview, we presented students with a video of a growing and shrinking cone with a fixed slant angle. The height of the cone increased and decreased at a constant rate with respect to the video playback (Figure 1). We then gave the students the following prompt, "Watch the video, which illustrates a cone with a varying height. Sketch a graph of the relationship between the height of the cone and the outer surface area of the cone."

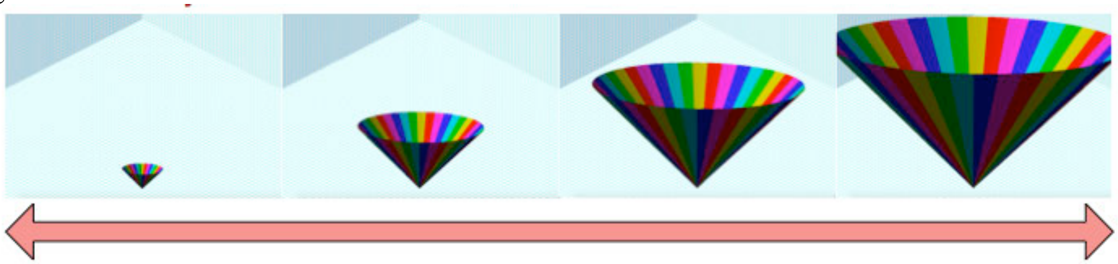

Figure 1: Dynamic Image of Cone

Saldanha and Thompson (1998) described a student's activity as he considered the relationship between two similar quantities (e.g., length)–a car's distances from two fixed points as the car traveled along a straight line. We extended this type of situation to involve the covariation of two quantities of different attributes: length and surface area. We also designed the task so that the situation lent itself to reasoning about amounts of change between the two quantities (e.g., for successive equal changes in height, the outer surface area of the cone increases and the change in the outer surface area also increases). We consider Saldanha and Thompson's (1998) task to be much more complex (imagistically) in this regard. We also note that we designed the task so that the students would not have a memorized formula readily at hand, although we hypothesized that students may attempt to construct or recall such a formula.

Results

We organize the students' solution approaches to the cone problem into four themes (Table 1). In what follows, we describe these themes including the relationships between students' images of the situation and their solution activity.

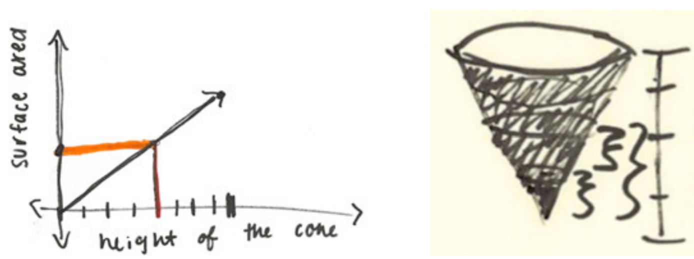
Predetermined Relationship

Students classified in the "Predetermined Relationship" theme used their initial image of the situation to dictate all further actions and conclusions. These students quickly came to a conclusion about the relationship between height and surface area based on some imagistic or physical aspect of the cone (e.g., the cone growing and shrinking in a 'smooth' or 'constant' manner). Instead of further analyzing the situation in an attempt to justify their claimed relationship, the students assimilated all

Table 1: Student Solution Approach Themes

Theme Name	Theme Description	Students
Predetermined Relationship	The student uses some imagistic aspect of the situation to reason about the relationship of the quantities. No fundamental changes of image occur from his/her initial observation.	Polly, Alice, Roz
Formula Values Determine Relationship	The student derives a formula to obtain specific numbers to determine and investigate the relationship between the quantities.	David, Kate, Terrence
Formula Structure Determines Relationship	The student derives a formula and uses properties of the formula to determine the relationship.	Angela, Audrey
Images of Covariation Determine Relationship	The student uses their image of the situation to determine the directional change and amounts of change of the two quantities under consideration.	Caroline, Trish

subsequent actions and products in terms of their initial claim. For instance, if the students determined a formula, they described the formula in terms of their initially stated relationship between the quantities; the students did not intend the formula to be for testing or verifying their relationship. Most notably, the students maintained their initial conclusions even when we directed them toward particular aspects of the situation or their activity that we thought would contradict their initial conclusions.



(a) (b)

Figure 2: Roz's Solution to the Cone Problem

For example, after concluding the relationship was linear and drawing a graph to reflect that relationship (Figure 2a), Roz drew the 3-D cone in a way that identified (from our perspective) amounts of change of surface area for successive equal changes of cone height (Figure 2b). When asked to describe how the changes in surface area for each successive height were changing, she responded, "going off this idea that it's a constant change in surface area," and then described that for equal changes in height, there was an equal change in surface area. Roz maintained that the surface area changed by constant amounts, even after the interviewer repeatedly prompted her to identify and shade different sections that represented the change in surface area. This response illustrates that Roz already had a pre-determined linear relationship in mind when reasoning with her picture of the situation (Figure 2b) to identify and explain how the changes in surface area varied.

Formula Use

We identified two themes in which students constructed formulas to model surface area (but not always in relation to only the height of the cone) and used their formulas to reason about the relationship between height and surface area. We make two distinctions between these students' solutions based on how they used their formula to make conclusions about the relationship.

Formula Values Determine Relationship. Some students used formulas to compute numerical values. Students in this theme constructed an initial image of how the quantities were related (e.g., both the surface area and height *increase* as the cone grows), but were then perturbed by whether the quantities covary at a constant or changing rate of change. Each student then moved to determine a formula by which they could calculate paired (height, surface area) values. As no actual values were given to the students to describe the cone, the students created hypothetical values. After determining a formula, each student calculated the area for several specified values of height, with these height values increasing in equal increments. Each student then determined the relationship by comparing her or his calculated values (e.g., determining the difference between successive surface areas). We note that despite each student creating a different, technically incorrect formula, all students in this theme concluded (accurately) that the changes of surface area increased for equal changes of height.

David is one of the students who engaged in this type of reasoning. After watching the video, David conjectured that the surface area is increasing at an increasing rate with respect to height. Having difficulty using the situation or a diagram to justify his conjecture, he created a formula to compute surface area. David used the height, h, and average radius, $r_{ave,}$ (which he described as half the radius) of the cone in combination with his prior knowledge of surface area (SA) of a cylinder to derive $SA = 2\pi(r_{ave})h$. He assumed the height and radius were equal to get the final formula, $SA = 2\pi(h/2)h$. After first trying to use this formula to determine changes of surface area for arbitrary equal changes of height, he moved to using specific (numeric) height values to compute surface area values (Figure 3). He then computed differences in surface area values to conclude that the changes of surface area increase for equal changes of height.

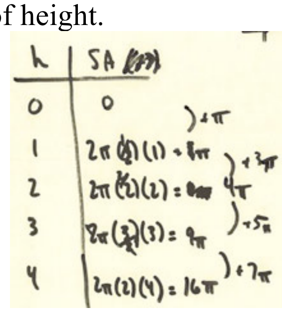


Figure 3: David's Solution to the Cone Problem

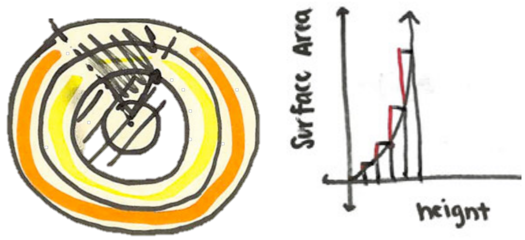
Formula Structure Determines Relationship. Whereas students grouped in the previous theme used their formulas to calculate and compare numerical values, students classified in this theme inferred how the quantities covaried based on the structure of their formulas. Specifically, the students determined a surface area formula with a multiplicative relationship between the quantities (i.e., height times height or height and radius of the base multiplied together with an assumption that the height and radius were proportionally related) and thus concluded that as height increased, surface area increased at an increasing rate.

To illustrate, after watching the video, Angela concluded that the surface area of the cone increased as the height increased. She then created a 2-D image to represent surface area by drawing a circle with a wedge removed (Figure 4a). Angela wrote the formula $A = \pi r^2$, where r represents the radius of her circle (or, equivalently, the slant height represented by x). Although she understood that the formula would not produce accurate surface area values without further information or modification, she reasoned that the formula was correct in its general structure and drew a graph (Figure 4b) that she associated with that formula. She claimed, "I know that since this is r-squared that it's going to be, the surface area is going to be a quadratic…path of a parabola" After using a linear function to relate the radius of the circle (or, equivalently, the slant height) to the cone's height, she further justified her graph by noting that the quadratic nature of her modified formula (*A= 'some quadratic in h'*). She added, "I know what a parabola looks like and I know it's increasing at an increasing rate." Although Angela drew several diagrams to reason about an increasing surface area (see Figure 4a), she did not use these diagrams to describe *changes* in surface area for equal changes in height. Rather, Angela relied on the quadratic nature of the formula for surface area to make conclusions about the graph and relationship; she reasoned with a formula structure-covariational relationship association.



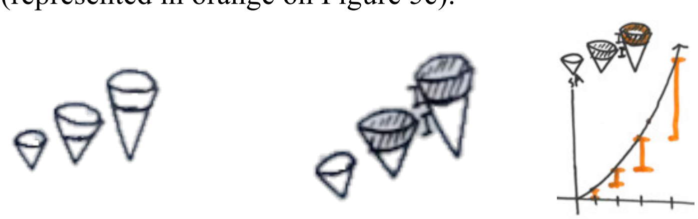
(a) (b)

Figure 4: Angela's Solution to the Cone Problem

Images of Covariation Determine Relationship

The students classified in this theme relied solely on their image of the situation to determine how the surface area and height of the cone covaried. The students maintained a 3-D image of the situation, and they were the only students to exclusively leverage a 3-D image of the situation to describe the rates of change of surface area and height of the cone. Specifically, Caroline and Trish imagined the surface area and height increasing continuously. Each student also imagined changes of surface area as successive strips for equal changes of height. The students used this image of the changes of surface area to compare successive changes in surface area.

As an example, after reading the prompt, Caroline drew three cones corresponding to equal changes in cone height (Figure 5a) and used these diagrams to determine how the quantities covaried. Caroline stated, "When you add some height, you add an extra strap around it [*re-draws 2nd cone bigger than 1st, draws strap with bottom of the strap at the height of 1st cone, seen in Figure 5b*]. Then you add some height, then you add a strap above that [*re-draws 3rd cone, bigger than 2nd with strap starting at height of top of 2nd cone seen in Figure 5b*]." She continued, "And if I were drawing these, to scale, this [*shades in strap in 3rd cone*] would have more surface area then this [*shades in strap in 2nd cone*]. So that means for equal changes in height [*marking changes of height in her diagram see in Figure 5b*], the change in surface area increases." Caroline used this reasoning to conclude that the surface area increases at an increasing rate with respect to height, and she produced a graph to reflect this relationship. Further, she identified how changes in surface area were represented on her graph (represented in orange on Figure 5c).



(a) (b) (c)

Figure 5: Caroline's Activity and Solution to the Cone Problem

Discussion

We identified themes in the students' activities that provide insight into ways these students modeled a dynamic situation. These themes are not intended to be evaluative or exhaustive; we do not claim preference of one theme over another, and there are many other possible solution approaches to this task. By comparing the students' activities across these themes, we note differences in how students' solution approaches are related to and influenced by their images of the situation. Three of the ten students (classified in the first theme) focused on a particular physical phenomenon of the situation (the constant or smooth growth of the cone), and they generalized properties of this phenomenon to the relationship between height and surface area. Five of the ten students relied on values produced from (second theme) or the attributes of (third theme) a formula to describe the relationship between the quantities. Although these five students leveraged an image of the situation that was attentive to the quantities of height and surface area, their use of this image was primarily static (e.g., using a fixed state to determine a rule). Only two of the ten students (fourth theme) used their images of the situation exclusively and continually reconstructed these images to reason covariationally.

We were surprised that only two of the ten students relied exclusively on leveraging images of the situation to represent amounts of change. Many students (e.g., Roz, Angela) engaged in activities that we believed had the potential to support them in reasoning emergently about the relationship (e.g., drawing diagrams and shading), but such activity was often assimilated in terms of previously made conclusions. This result was especially unexpected considering that in previous interview tasks several of the students classified in the first to third themes modeled relationships in dynamic situations by strictly leveraging images of the situation. One possible explanation for this result is that these students had learned the formula for the surface area of a cone in their prior school experiences. Hence, the students aimed to remember or to derive this formula rather than attempt to use images of the situation to construct the relationship.

Future Research

Several students' initial images of the situation relied on the video showing a constant change of height with respect to (implicit) time (first theme). Thus, we ponder how these students would engage in a task in which the cone's height grows at a non-constant rate or the students are able to control how the height varies. Additionally, several students persistently attempted to derive a formula for the relationship with their subsequent actions relying on their formula. Future researchers might be interested in comparing how students engage in situations that lend themselves to formulas and situations that do not. This would give insight into how students reason and rely on formulas and the consequences of such reliance, especially with respect to nuances in students' covariational reasoning (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Johnson, 2015b).

Although some students maintained viable images of the quantities in the situation (from our perspective), they had difficulty reasoning about and comparing corresponding changes in the quantities. Moreover, even when we directed the students to consider how changes in the quantities might be identified in the context of the situation, some students identified what we perceived to be increasing amounts of change, yet argued that these amounts of change were equal. We envision that further investigation into students' images of change (Castillo-Garsow et al., 2013) would help explain these seemingly contradicting activities.

The study reported in this paper is part of a larger study on the roles of examples in learning to prove. We focus here on manifestations of students' productive use of examples for proving in the course of exploring conjectures and proving or disproving them. In this context, we define productive use of examples for proving as students' utterances that indicate that working with examples led them to realize and gain insights into some aspects of the key ideas for proving (or disproving) the conjecture. There were a total of 39 participants (12 middle school, 17 high school, and 10 undergraduate students). Each took part in an individual one-hour task-based interview. We identified 77 cases of productive use of examples, 41 based on an interviewer's provision of example(s) and 36 based on students' spontaneous generation of examples. These cases serve to characterize students' strengths that are not directly fostered in school.

Keywords: Reasoning and Proof

Proof and Proving in Mathematics Education

It is commonly agreed among mathematicians and mathematics educators that mathematical proof and proving are at the heart of mathematics, and that the activity of mathematically proving is dauntingly difficult even for most good undergraduate students. A continuing concern in mathematics education is that students do not sufficiently understand the nature of evidence and proof in mathematics and that they struggle with providing logically sound justifications and arguments to support the validity of mathematical conjectures or claims (e.g., Healy & Hoyles, 2000; Kloosterman & Lester, 2004; Knuth, Choppin, & Bieda, 2009). This concern has been guiding numerous studies, as it reflects a deficiency in one of the key elements of mathematics and mathematical practice (e.g., Harel & Sowder, 2007; Knuth, 2002; Sowder & Harel, 1998). Consequently, there have been calls for proof to play a more central role in mathematics education, by researchers (e.g., Ball, Hoyles, Jahnke, & Movshovitz-Hadar, 2002), as well as reform initiatives (the *Common Core State Standards for Mathematics* and the NCTM *Principles and Standards for School Mathematics*). However, despite these calls, research continues to indicate that students' understanding of proof is far from being satisfactory (Harel & Sowder, 2007; Healy & Hoyles, 2000).

A major source underlying students' difficulties in understanding proof and proving is related to their treatment of examples (e.g., Healy & Hoyles, 2000; Zaslavsky, Nickerson, Stylianides, Kidron, & Winicki-Landman, 2012). There is evidence that an inhibiting factor in students' proving (at all levels) is an over reliance on examples. They often infer that a general claim is true for all cases on the basis of checking just a number of examples that satisfy this claim. This tendency has been recognized as a stumbling block in the transition from inductive to deductive arguments, and the progression from empirical justifications to proof (e.g., Fischbein, 1987). This tension between empirical and formal aspects of proving suggests that understanding the logical relations between examples and statements is a non-trivial task that is critical for proving. However, this kind of understanding is not usually explicitly addressed in the course of learning mathematics, in general, and learning to prove, in particular.

There have been attempts to help students learn the limitations of examples for proving in order to reduce their tendency to infer from examples more than is logically valid (e.g., Sowder & Harel, 1998; Stylianides & Stylianides, 2009; Zaslavsky et al, 2012). While these attempts address the limitations of examples for proving, they overlook the potential of example-based reasoning strategies in enhancing conjecturing and proving. In fact, less attention has been given to facilitating students' ability and inclination to build on the potential strengths of using examples for proving. More specifically, there is scarce research on using examples generically, i.e., in a way that allows to see the general through the particular, make sense of a mathematical statement, and gain insight into all or some of the main ideas of its proof (e.g., Knuth, Kalish, Ellis, Williams, & Felton, 2011; Leron & Zaslavsky, 2013; Mason & Pimm, 1984; Rowland, 2001). Mason and Pimm's (1984) terms of *generic example* and *generic proof* capture the essence of what we mean by using examples generically. Accordingly, "A generic example is an actual example, but one presented in such a way as to bring out its intended role as the carrier of the general." (ibid p. 287); and a "generic proof, although given in terms of a particular number, nowhere relies on any specific properties of that number." (ibid p. 284). Example-based reasoning strategies encompass this way of thinking with and through examples.

We believe that students' failure to engage productively in example-based reasoning strategies, to think about examples generically, and to analyze examples when engaging in activities related to proving, accounts for many of the difficulties they encounter in learning to prove. Our study stems from the stand that students should learn to use and analyze examples analytically and generically, not only in order to gain a better understanding of the conjectures (or statements) that they explore but also in order to learn to develop proofs (or dis-proofs) of these conjectures.

Very little research has focused on the nature of middle school, high school, or undergraduate mathematics students' thinking about and use of examples in generating, making sense of, and proving mathematical conjectures. Alcock and Inglis (2008) argue that such studies are needed in order to effectively develop instructional practices that foster the development of students' learning to prove. We aim at better understanding the nature of example use across grade levels, and in particular, how example use may support students' reasoning and proof development.

Zaslavsky (2014) distinguished between three settings of example use: spontaneous example use, evoked example production, and provisioning of examples. The spontaneous setting highlights what may come naturally to learners and experts, and how productive their choices and what they make of them are. The evoked example production allows us to study what choices learners make when pushed to use examples and also how productive they are. This setting has a strong diagnostic power, as it may evoke students' strengths as well as their weaknesses with respect to exemplification and proving. The provisioning of examples by a researcher allows us to examine what learners see in these examples, and in what ways they are able to build on the given examples to gain insights about how to justify or prove a claim. This setting also may shed light on possible mis-matches between intentions (of a teacher/researcher and a learner). In our study, we distinguish between example uses that involve student generated examples and those that involve researcher provided examples.

The Study

The study reported in this paper is part of a larger study of the roles of examples in learning to prove. Its purpose is to better understand the roles examples play in the development, exploration, and justification of mathematical conjectures, with the overarching goal being to help students appreciate the need to prove and to learn to prove. In this portion we focus on ways in which students use their own examples or examples provided by the researchers to support their claims about the validity of mathematical statements and conjectures. More specifically, we examine cases in which the use of examples can be considered productive for proving. For productive use of examples for proving we consider indications of gaining insights from an example or set of examples about the main idea(s) of a proof. It can be manifested, for instance, by a shift from no clue why a conjecture works (or doesn't work) to an articulation of an idea why. Some of the manifestations of this type of example-use may be seen as generic proving (Leron & Zaslavsky, 2013).

Data Collection

This study was based on individual task-based interviews with 12 middle school (MS) students, 17 high school students (HS), and 10 undergraduate (UG) mathematics majors. The interviews lasted approximately 1 hour and were comprised of a series of tasks in which participants were given the opportunity to conjecture and prove.

Task 2: The Sum of Consecutive Integers

Part 1:
This question involves consecutive numbers. For example, 2, 3, and 4 are consecutive numbers, but 2, 3, and 8 are not consecutive numbers.
Tyson came up with a conjecture about consecutive whole numbers that states: If you add any number of consecutive whole numbers together, the sum will be a multiple of however many numbers you added up. *At this point the interviewer suggests that the participant give an example of how the conjecture works for 5 consecutive whole numbers.*

Tyson thinks that this conjecture will always be true no matter how many consecutive numbers you use or which consecutive numbers you choose. So he thinks that if you add any 3 consecutive numbers, the answer will be a multiple of 3, or if you add any 6 consecutive numbers, the answer will be a multiple of 6, and so on.
Do you think the conjecture is true for any set of consecutive numbers, not just when you pick five consecutive numbers?

Part 2:
Let's come back to the Question 2 [i.e., Part 1 above] conjecture that the sum of five consecutive numbers is a multiple of 5.
At this point the interviewer says while writing the example: Another student had an idea of how to explain it. For the five consecutive numbers 5, 6, 7, 8, and 9, she decided to write the sum as (7-2)+(7-1)+7+(7+1)+(7+2), and writing it that way helped her to explain why the sum must be a multiple of 5. How do you think that helped her see why the conjecture is true for any five consecutive numbers?

The interview protocol for middle and high school participants included 8 tasks total each, and the one for undergraduate participants included 7 tasks total. Three tasks were shared across all participant populations. In this paper we focus mainly on one of these three shared tasks (Task 2 above): The Sum of Consecutive Integers Task. Similar versions of this task served researchers in other studies (e.g., Tabach et al., 2011). For several reasons (mainly due to time constraints, and protocols' modifications done after a number of interviews had been conducted), not all students got to engage in all the tasks that were included in the final interview protocols.

Data Analysis

While we started out looking for example-uses and focusing on whether each example-use was productive for proving, other categories emerged as we were analyzing the data, thus, in part, we used a grounded theory approach to analyze participant responses. The units of analysis were the tasks (except for Task 2, for which we coded each part separately). For each participant, we coded his or her performance on each task according to several categories (productivity, example-source, proof-exhibition). We began by identifying cases in which we observed productive and non-productive example-use for proving. For example, in task 2 part 1, if a participant was able to use many numerical examples to determine that Tyson's conjecture was true only for odd numbers of integers but was not able to produce a legitimate argument as for why this was the case, we considered this "non-productive" for proving (although this activity was clearly productive for conjecturing). In order to be categorized as "productive" for proving, a participant had to use examples to make an argument that showed not only *that* Tyson's conjecture was true only for odd numbers of integers, but *why* this conjecture holds or does not hold, based on the parity of the number of integers involved. Instances of productive example use included participants' use of examples to generate an argument, and were related to a shift in their ability to provide a valid justification that would hold for any other such case.

Additionally, we looked at the source of the example, and distinguished between cases in which an example was provided by the student (spontaneously) or by the interviewer (non-spontaneously). This distinction is important as cases in which productive example-use was based on provided examples, may have pedagogical implications in the classroom.

For each participant we coded his or her performance on each task as productive (P), non-productive (NP), or indecisive. There were two main reasons for considering a case indecisive: (i) if a student came up with a proof but it was unclear whether the examples were helpful in reaching the proof; or (ii) if it was not clear whether an argument qualified as proof. Altogether, 222 cases were analyzed, of which 24 were indecisive.

We also coded cases according to whether or not a proof was exhibited (even a partial or informal one), and whether or not examples were used. When examples were used, we distinguished between cases that included just examples generated by the students (Exp. by St.) and cases where examples were provided also or solely by the interviewer (Exp. by Int.). Note that for those who completed Task 2 Part 1 with a full proof that the conjecture holds for all odd numbers and does not hold for even numbers, and used the same reasoning as in the prompt for Part 2, did not receive the second part (to eliminate redundancy).

Findings

Scope of Productive Example-Use for Proving

The findings in Table 1 include all cases that were coded either as productive or as non-productive (excluding the 24 indecisive cases). There were a total of 198 cases, 62 MS, 89 HS, and 47 UG. Of the 198 cases, 77 (39%) included productive use of examples for proving. Of these, more than half (41) the cases were based on examples provided by the interviewer.

Table 1: Distribution of Cases by Example-Use and Productivity for Proving in all Tasks

Grade Level	**Came up with a Proof** (or partial proof)			**No Proof**			**Total**
	Productive (P) Use of Examples for Proving		No Exp. (NE)	**Non-Productive (NP) Use of Examples for Proving**		No Exp. (NE)	
	Exp. by St.	Exp. by Int.		Exp. by St.	Exp. by Int.		
MS	10	13	2	27	10	0	**62**

HS	11	18	2	37	17	4	**89**
UG	15	10	3	12	4	3	**47**
Total	**36**	**41**	**7**	**76**	**31**	**7**	**198**

In terms of productivity, middle school and high school students performed similarly, as 37% of MS cases and 33% of the HS cases exhibited productive use of examples for proving, while the undergraduate students exhibited considerably more productive use of examples (53%).

Table 2: Productive and Non-Productive Example-Use in Task 2 (the Sum of Consecutive Integers)

Grade Level	Task	Productive (P) Use of Examples for Proving		Non-Productive (NP) Use of Examples for Proving		Total
		Exp. by St.	Exp. by Int.	Exp. by St.	Exp. by Int.	
MS	**Part 1**	4	0	6	0	**10**
	Part 2	0	4	0	2	**6**
HS	**Part 1**	4	0	13	0	**17**
	Part 2	0	7	0	5	**12**
UG	**Part 1**	5	0	3	0	**8**
	Part 2	0	5	0	1	**6**
Total		**13**	**16**	**22**	**8**	**59**

In table 2 we present the findings related to Part 1 and Part 2 of Task 2. Looking at the task as a whole, for this task there are larger differences between the extent of productive use of examples for proving between the three groups: MS – 50% (8 of the 16 cases), HS – 38% (11 of the 29 cases) and UG – 71% (10 of the 14 cases).

Figure 1 examines the trajectory of students who completed both parts of Task 2, and for which none of their performances was indecisive (this reduced the total number of cases in Table 2 by 15).

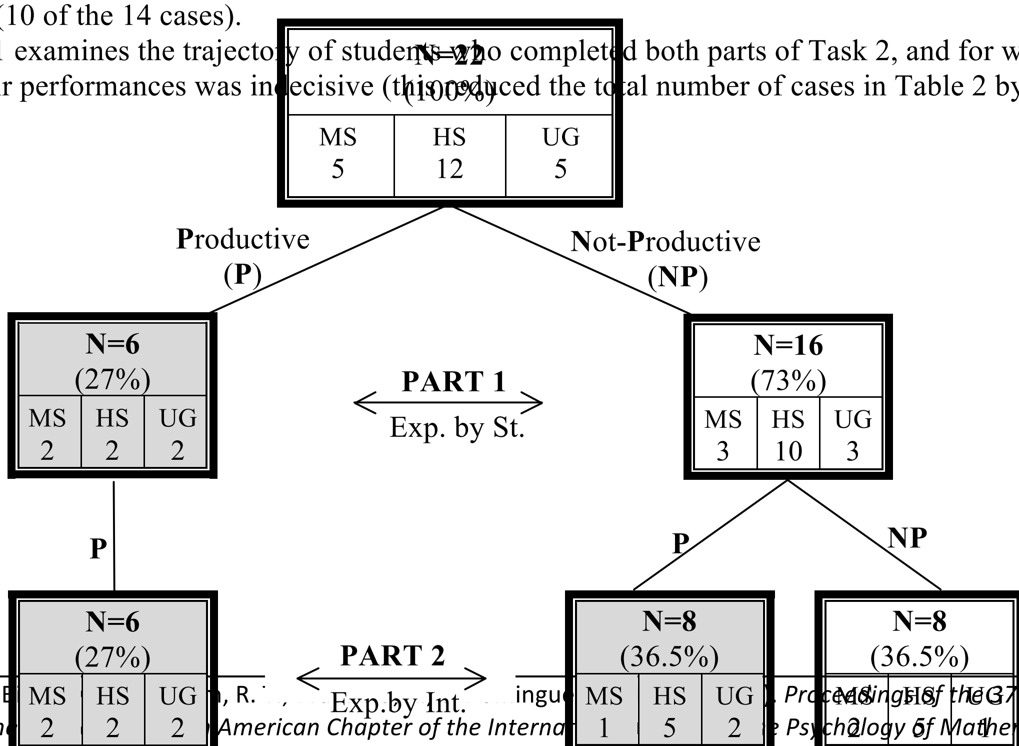

Figure 1: Paths of productive and non-productive uses of examples in Task 2
(Excluding cases that were indecisive or incomplete; N – no. of students)

All of the cases that dealt with Task 2 were cases in which examples were explicitly used. In Part 1, the examples were generated by the students, while in Part 2 – a generic example was provided by the interviewer. Not surprisingly, students who used examples productively in Part 1, on their own, were also able to use the generic example productively. However, interestingly, half of the students who were not able to use examples productively in Part 1, were able to reason productively with the generic example provided by the interviewer in Part 2.

Characteristics of Productive Use of Examples for Proving

We turn to two cases that convey what productive use of examples for proving may look like.

Case #1: A HS student's use of his own examples productively. In Part 1 of Task 2, Sam tries three sets of examples: 1 + 2 + 3 + 4 +5 ; 2 + 3 + 4 + 5 +6 ; 3 + 4 + 5 + 6 + 7. He calculates the last two sums, and immediately is able to make an argument in support of the truth of the conjecture for any five numbers with the following observation:

"I tried a few examples, and then I realized that, well, if you add 1 to every number, then you're ultimately adding 5, because there's 5 numbers. And if the first- and the first- and if the first example 1, 2, 3, 4, 5 is- equals a multiple of 5, then by adding 5 to- to every case, it'll stay a multiple of 5." [10:43 - Time Stamp]

In other words, Sam is able to present a pseudo-inductive argument that emerges from the observation that the conjecture is true for a base case (1+2 +3+4+5), and the mechanism by which this sum changes from this case to the "next" case (where "next" is defined as increasing each term in the sum by 1) does not change the divisibility property of the sum with respect to 5. By looking at the sequence of his three examples Sam is able to both see and utilize modular reasoning when considering the divisibility properties of this sum, as increasing a number by multiples of 5 does not change its remainder (in this case, zero) upon division by 5. As Sam puts it: "if you subtract 5 from a multiple of 5, it'll still stay a multiple of 5."[13:00]

Sam is able to take advantage of the generality of this observation by answering a question that he himself had posed earlier in the interview, namely, whether negative integers were allowed in Tyson's conjecture. He is able to leverage his reasoning about the modular distribution of integers that are divisible by 5 into a correct claim that Tyson's conjecture works just as well for negative integers as it does for positive. In other words, Sam was able to extend the domain of the conjecture by creating an argument that relied solely on three numerical examples. In this case we do not consider each one of his three examples in isolation as "generic," as that clearly does not reflect his thinking. However, we consider all three seen in conjunction with each other as one generic example, as the insight that Sam gained from these examples was located in the relationship between them.

Sam is able to use this insight to create a legitimate argument for why Tyson's overall conjecture is incorrect for four consecutive integers. He reasons: "I thought of a number like 4, which is 1, 2, 3, 4, which adds up to 10. And then it's not a multiple of 4, so, and… even if you add or subtract from that, it'll always be uh, it won't be a multiple of 4."[16:40] In effect, he argues that his base case is a counter-example, and this counter-example does not just hold for the particular example of 1 + 2 + 3+4, but in fact holds for *any* four consecutive integers. Although he does not explicitly discuss remainders, we can interpret his argument as noticing that the remainder upon division by 4 is invariant under increasing a number by multiples of 4.

Case #2: A HS student's use of an interviewer's example productively. In Part 1 Isaac is clearly operating empirically, as he chooses a wide range of examples and uses them for verifying *that* the conjecture is true (e.g., for 5 numbers), without being able to offer a logically valid explanation of *why* it is. He explains that it is because "I did a bunch of trials that go really far into the depths of numbers, including negatives which kind of sealed the deal for me, because negatives are really different from positives."[24:26]

During the second part of this task, the interviewer presented Isaac with a generic example, rewriting 5 + 6 + 7 + 8 + 9 as (7-2) + (7-1) + 7 + (7+1) + (7+2). Immediately, Isaac is able to see the generality within this particular example and apply it to a generic argument. Isaac uses this argument to explain why it must work for any odd number of consecutive integers, and also why it must not work for an even number of consecutive integers. He also produces a parallel algebraic representation, which is the first time that he has done so within this task. Perhaps this is due to the visual salience of the invariance of the 7's in the representation provided by the interviewer. Isaac's immediate response to the interviewer's prompt is reproduced below:

"Okay, so I can see now- this is pretty good proof for why it's, uh, for why it has to be a multiple of 5 or just a multiple of an odd number in general. Or, uh, so um, um the thing with this is, what happens-- ... Um, these numbers cancel each other out. The 2 cancels the 2, the 1 cancels the 1. And you just end up getting 7+7+7+7+7 and, um, and the reason this wouldn't work with an odd- with an odd pair, like if you added- if you added a, uh, 10 [The interviewee wrote +10 at the end of 5+6+7+8+9] to this and then you- and then you added plus 7 plus 3 [The interviewee wrote +(7+3) at the end of the (7-2)+(7-1)+7+(7+1)+(7+2)], then these would cancel out. Then you would be left with (7×5) + (7+3) plus... Yeah, plus (7+3), which would just give you, um, 3- 3 numbers off of what you want. So, yeah. And I guess you could do it with an equation, using *x*... (x-2) + (x-1) + (x) + (x+1) + (x+2) + (x+3). These cancel each other out, these do it as well, and this is just left there as a kind of like, almost like it ruins the party or something. So, yeah."

He later uses the word "symmetry" to explain this argument. In other words, Isaac was initially "stuck" and the generic example provided by the interviewer helped Isaac create a deductive argument as for why Tyson's conjecture was only true for odd numbers of integers.

Concluding Remarks

While the vast majority of studies on students learning to prove focus on their difficulties and suggest ways to address these difficulties, our study identifies numerous cases of students treating examples generically on their own. Moreover, these cases capture shifts from not being able to explain why a mathematical statement is true (or false) to being able to see clearly why it must work in general. Thus, the findings add to our understanding of processes by which students may learn to prove, and at the same time suggest that for some students under certain conditions this may come (almost) naturally with minimal interference. In other words, these cases could be inspiring for teachers who want to build on students' strengths.

STUDENT CONCEPTIONS OF WHAT IT MEANS TO BASE A PROOF ON AN INFORMAL ARGUMENT

Dov Zazkis
Arizona State University

Matthew Villanueva
Rutgers University
mattvill@rci.rutgers.edu

In this paper we explore how students construe what it means for an informal argument to be the basis of a formal proof and what students pay attention to when assessing whether a proof is based on an informal argument. The data point to some undergraduate mathematics students having underdeveloped conceptions of what it means for a proof to be based on an argument. These underdeveloped conceptions limit what students pay attention to during informal-to-formal comparison tasks and may have adverse effects on students' ability to use their own informal arguments to construct proofs.

Keywords: Post-Secondary Education; Reasoning and Proof

Introduction

The constructs we use throughout this paper revolve around the observation that proofs are expected to be written in a verbal-symbolic representation system but may not be generated wholly within that system. Following Weber and Alcock (2009) we refer to reasoning that stays solely within this system as syntactic reasoning, and reasoning that falls outside of it as semantic reasoning. Similarly, we conceptualize a formal proof as a deductive argument that establishes the result to be proven and conforms to the norms of the representation system of proof. This is a characterization of the end product, not the reasoning that led to it. Additionally, we conceptualize an informal argument as a deductive argument that establishes the result to be proven, but does not conform to the norms of the representation system of proof. We refer to the use of informal arguments to inform the construction of formal proofs, or more generally the process of using semantic reasoning to inform syntactic reasoning, as formalization.

Research relevant to formalization can be partitioned into two non-disjoint categories. The first category focuses on the role of semantic reasoning in informing proof productions. The second category examines the semantic-to-syntactic formalization process needed to use semantic reasoning to generate a formal proof.

Research falling into the first category has illustrated the important role that semantic reasoning can play in proof generation. Various types of semantic reasoning have been shown to inform proof generation (Gibson, 1998, Sandefur, Mason, Stylianides, & Watson, 2013, Zazkis, Weber, & Mejia-Ramos, in press). This first body of work has perpetuated the recommendation that students should use semantic reasoning during proof construction. This recommendation has gained considerable traction in mathematics education (e.g., Garuti, Boero, & Lamut, 1998; Raman, 2003).

A second set of studies has focused on the formalization process itself. This research has provided evidence that mathematics majors struggle to use semantic reasoning to inform proof generation (Selden & Selden, 1995; Alcock & Weber, 2010; Zazkis et. al., in press).

These two sets of studies point to a discrepancy between researcher recommendations (that students should generate proofs using informal arguments) and students' behavior and abilities. In order to better understand this discrepancy we examine what mathematics majors pay attention to when attempting to determine if a formal proof is based on an informal argument and how these determinations compare to normatively correct interpretations.

In order to operationalize these notions we consider a formal proof to be *based on* an informal argument if there is a mapping between these two chains of inferences that has two properties: (1) it is meaning preserving to the extent allowed for by the rules of the verbal-symbolic system, and (2) corresponding inferences (or chains of inferences) appear in the same order. We use the acronym FBI-judgment, to refer to student judgments of whether Formal proofs are Based on Informal arguments.

The Study

We are interested in what it means for a proof to be based on an informal argument from a mathematics major's perspective. Thus we create a model of what mathematics majors pay attention to when making FBI-judgments and use this model to create a plausible explanation for why these students may have difficulty with formalizing informal arguments. In particular, we want to illustrate how prioritizing a particular subset of attributes when making informal to formal comparisons influences how students view what it means for a proof to be based on an argument and by extension, affects their ability to formalize.

Participants

Participants were pursuing undergraduate degrees in mathematics at a large state university in the Northeastern United States and had completed a proof based second course in linear algebra, an introduction to proof course, and an introductory analysis course. Thus, the eight participants were familiar with reading and writing proofs in a variety of mathematical contexts. Participants were selected to have roughly equal amounts of A, B, and C grades represented.

Procedure

The second author conducted one-on-one clinical interviews with each participant that lasted between 90 and120 minutes. This involved presenting participants with both informal arguments and proofs and engaged them in a series of comparison tasks. More specifically, he presented participants with triples that consisted of one informal argument and two formal correct proofs, only one of which, from our perspective, was based on the argument.

The informal argument in each triple was presented in the form of a video. Each video lasted approximately 30 seconds and involved the first author justifying the result with a combination of verbal argumentation, graph generation and gestures. The two correct formal proofs in each triple were presented in written form.

At the beginning of each one-on-one interview participants were told that they would be shown triples. They were told that they were to understand and compare the three parts of the triples, but that they did not need to validate correctness. In the first round of the interview participants were shown each of the three triples one at a time. They watched the video and read the two proofs out loud. After participants verified that they felt they understood the result, they were asked to make side-by-side comparisons of what they noticed in terms of similarities and differences between the three parts of the triple. This was done with each of the three triples. Note that during the first stage only the participants' impressions and what they noticed was elicited.

The second stage involved revisiting each triple and judging whether each of the proofs in the triple was based on its informal argument, how confident they were in their assessment and on what information they based their conclusion. Students were not informed that, from the researchers point of view only one of the proofs in each triple was a formalization of the informal argument. This made it possible for participants to conclude that neither or both of the proofs in each triple were based on the informal argument.

Analysis

A set of minimum criteria, which was agreed upon prior to the interviews, was used to determine whether student FBI-judgments were consistent with mathematical norms. We were also interested in what students paid attention to when making FBI-judgments. Each interview was transcribed and grounded theory (Strauss & Corbin, 1990) was used to categorize interviewee responses in terms of what they paid attention to during FBI-judgments.

Materials

We briefly mention that Task 1 involved proofs that $\int_{-a}^{a} \sin^3(x)\,dx = 0$, for all real numbers a, and Task 3 involved proofs that the derivative of a differentiable even function is odd. For space reasons we discuss only Task 2 in detail. To clarify our discussion each step in the informal arguments is labeled with an "I2," each step in the formalization of this argument is labeled with an "F2," and each step in the distractor proof is labeled with a "D2."

<table>
<tr><th colspan="2">If a sequence (a_n) has a limit, it is unique.</th></tr>
<tr><td>Informal argument</td><td>Proof F_2 (Formalization of informal argument)</td></tr>
<tr><td rowspan="3">(I_2-1) If the limit wasn't unique then we could have two limits, say L_1 and L_2.
(I_2-2) But we control the size of the ε-neighborhood around these.
(I_2-3) and if we make it small enough these two ε-neighborhoods are going to not overlap.
(I_2-4) So when we get far enough down the sequence we're going to be both in here [pointing an neighbor hood around L_1] and in here [pointing an neighbor hood around L_2].
(I_3-5) But since we can't be in two places at the once we get a contradiction.
</td><td></td></tr>
<tr><td>Proof D_2 (Distractor)
(F_2-1) Toward a contradiction assume the sequence (a_n) does not have a unique limit.
(F_2-2) Then there exists L_1 and L_2 such that $\lim_{n\to\infty} a_n = L_1$, $\lim_{n\to\infty} a_n = L_2$ and $L_1 > L_2$. $\Big\}$ (I_2-1)
(F_2-3) Let $\epsilon = \frac{L_1-L_2}{2} > 0$. By definition there exists an N such that if $n > N$ then $|L_1 - a_n| < \epsilon$ and $|L_2 - a_n| < \epsilon$.
(F_2-4) $|a_n - L_1| < \epsilon \Rightarrow a_n > L_1 - \epsilon = \frac{L_1+L_2}{2}$
$|a_n - L_2| < \epsilon \Rightarrow a_n < L_2 + \epsilon = \frac{L_1+L_2}{2}$ $\Bigg\}$ $(I_2-2/3)$
(F_2-5) But then for $n > N$ we have that $a_n > \frac{L_1+L_2}{2}$ and that $a_n < \frac{L_1+L_2}{2}$ which is impossible. $\}$ $(I_2-4/5)$</td></tr>
<tr><td>(D_2-1) Toward a contradiction assume the sequence (a_n) does not have a unique limit.
(D_2-2) Then there exists L_1 and L_2 such that $\lim_{n\to\infty} a_n = L_1$, $\lim_{n\to\infty} a_n = L_2$ and $L_1 \neq L_2$.
(D_2-3) By definition for every $\epsilon > 0$ there exists a N such that if $n > N$ then $|L_1 - a_n| < \epsilon/2$ and $|L_2 - a_n| < \epsilon/2$.
(D_2-4) Consider $n > N$.
$|L_1 - L_2| = |L_1 - a_n + a_n - L_2|$
(D_2-5) $\leq |L_1 - a_n| + |a_n - L_2|$ via the triangle inequality
$= |L_1 - a_n| + |L_2 - a_n|$
(D_2-6) $< \epsilon/2 + \epsilon/2$
$= \epsilon$
(D_2-7) So $|L_1 - L_2| < \epsilon$. Since ϵ can be made arbitrarily small $L_1 = L_2$, contradicting the assumption that the limit was not unique.</td></tr>
</table>

Figure 1: If a sequence (a_n) has a limit, it is unique.

Unlike F_2, D_2 is not intrinsically an argument by contradiction. The contradiction was artificially added to proof D_2 to make D_2 and F_2 superficially similar. F_2 starts off assuming, toward a contradiction, that the limit is not unique (I_2-1 and F_2-1) and because of this we may choose two limits, L_1 and L_2 (I_2-1 and F_2-2). Although the assumption that $L_1 > L_2$ (F_2-2) does not explicitly appear in the informal argument, it is implied by the accompanying diagram. Next I_2-2 and I_2-3 argue that the ε-neighborhood around L_1 and L_2 can be made small enough to not overlap. In proof F_2, this "not overlapping," is achieved by choosing ε to be exactly half the distance between L_1 and L_2 (F_2-3), and then showing this choice of ε places a_n both above and below the midpoint (F_2-4) for all n sufficiently large. Finally, both Proof F_2 and the informal argument end by arguing that being in two places at once leads to a contradiction (F_2-5 and I_2-4/5). In the proof this is done formally by arguing that a term in the sequence, a_n, cannot be both above and below the mid point. Proof D_2 demonstrates that any two limits of a sequence can be made arbitrarily close to each other, and thus must be equal, but does not rely on the "two places at once" idea.

Results

A top-level view of the connections the participants made relative to our pre-agreed standards and hence, from our perspective, made normatively correct FBI-judgments for normatively correct reasons can be found in Table 1. As can be seen from the table, the first task was relatively unproblematic for the students in this study. The other two tasks were more difficult. Only 2 of the eight students met our minimum standard on both parts of task 2 and none of our students met our minimum standard on both parts of task 3.

These data point to mathematics majors' difficulties with FBI-comparison tasks. The ability to recognize the final product of formalization is crucial. Without this a student cannot recognize when the formalization process is complete and thus cannot effectively formalize.

Table 1: Student FBI-judgments relative to the minimum standard

	Task 1	Task 2	Task 3
Met criteria for D-I judgment	7/8	5/8	2/8
Met criteria for F-I judgment	8/8	3/8	1/8
Met both F-I and D-I criteria	7/8	2/8	0/8

A model of what students pay attention to when making FBI-judgments

In our analysis we identified four different aspects of arguments/proofs that students focused on when making FBI-comparisons. Two of the foci outlined below are adaptations of Pedemonte's (2007) structural distance and content distance constructs. The reframing of these constructs was necessary because the focus of Pedemonte's research is different from our own. The four foci of comparison are described below:

(1) Structural foci involve noticing global similarities and differences in which inferences follow from one another (i.e., structure). We conceptualize this as an adaptation of Pedemonte's (2007) notion of "structural distance" to a FBI-comparison context. In a broad sense structural foci can be seen as an attempt to evaluate what kind of relationship exists between the structure of an informal argument and the structure of a formal proof.

(2) Content foci involve noticing which specific elements (i.e., inferences, assumptions, data and claims) are present or not present within both an argument and proof. This can be seen as an attempt to evaluate the relationship between the content of an informal argument and the content of a formal proof. This focus can be seen as an adaptation of Pedemonte's (2007) notion of "content distance" to an FBI-comparison context.

(3) Methodological foci involve noticing the proof method used (e.g., contradiction, contrapositive, induction, construction, etc.) as well as the role this method plays in the proof.

(4) Holistic foci involve noticing similarities and differences in terms of goals, style purpose or overarching idea. These comparisons focus on proofs and arguments as a whole and overlook specific structural, content and methodological details.

Here we show that prioritizing one of the four foci of comparison in lieu of others has detrimental effects on students' ability to make informal to formal comparisons. It is important to note that these foci are not necessarily static. Some students may shift foci when moving to a different task.

Content foci. Next we discuss content foci. This involves paying attention to the assumptions and inferences within a proof/argument, but largely overlooking the roles and structure of these elements within a proof. Here the focus is localized to specific steps in the proof. In other words, the details of a proof are examined, but the bigger picture is ignored. We illustrate this focus with an excerpt of S8's work on Task 2. In the excerpt below S8 is asked to compare D_2 and F_2:

Int: Any… any other differences you can see? Looking at the proofs again?
S8: Umm… L_1 is defined to just not be equal to L_2 in proof D_3 and in proof F_3, they say L_1 is greater than L_2.
Int: I, I guess, … do you consider those significant differences? The ones that you mentioned?
S8: Yea, yea definitely. Those are significant differences.

The assumption that $L_1>L_2$ is not explicitly made in the I_2, however, it is implied by the accompanying diagram. Following the above excerpt S8 proceeded to use the fact that the $L_1>L_2$ assumption is part of proof D_2 and not F_2 as a justification for why the distractor proof is based on the informal argument while the formalization proof is not. In focusing in on a particular piece of content which is present in only one of the proofs he overlooks the bigger picture and consequently, makes an FBI-judgment that is in conflict with the normatively correct interpretation. Hence, we contend that prioritizing content in leu of structure is also insufficient for making normatively correct FBI-judgments.

S8's assessment is consistent with his content foci. He is looking for specific inferences that are present in the proofs in order to compare them to the informal argument. Thus, his expressed de facto conception of what it means for a formal proof to be based on an informal argument involves the formal proof using similar assumptions and similar inferences to the informal argument. Within this conception, a difference in assumptions used is sufficient evidence that a proof is not based on an informal argument.

Methodological foci. It is useful to note that our anticipation of methodological foci influenced our task design. Methodological foci were the motivation for making proof D_2 artificially a proof by contradiction. If we had not artificially made D_2 a proof by contradiction students may have concluded that D_2 was not based on I_2 solely based on the fact that I2 is a proof by contradiction without working to make other connections. Thus our task design intentionally discouraged surface level methodological foci. However, one participant did notice this feature of D2:

S7: Wait, what? … There is no point in this [D_2] being a proof by contradiction. That is completely redundant I could have just crossed this out here, "Assume it does not have a unique limit." You can cross that out.

Our task design intentionally prevented superficial methodology based assessments but left the tasks open to deeper assessments like the one in the excerpt above. Since only one of the participants noticed this feature of D_2 , we argue that artificially adding or removing particular methodologies from proofs has the potential to lead students to make incorrect FBI-judgments. That is, if we used a direct proof as a second distractor in place of F_2, we anticipate that the majority of students in our study would have incorrectly used "only one of these is a proof by contradiction" as a justification for why D_2 was based on I_2. This highlights the limitations of a strictly methodological foci.

Holistic foci. The final foci we discuss involves examination of holistic traits. The word trait here is construed broadly and may include attribute such as elegance, efficiency, style, pedagogical purpose or overarching idea. In short, this is intended to capture any treatment of a proof as more than the sum of its parts. Proofs have purposes and can be qualitatively compared to both each other and to the general genre of proof writing.

First we begin by discussing the work of S1 on task 1. The excerpt below begins after S1 reads proof D_1 (He has already read proof F_1).

S1: I feel like D_1 was kind of lamer than the other one
Int: Lamer?
S1: This one [F_1] was a little prettier, it was… I mean over here, we had uh, we were using that it was… this [D_1] felt very… brute force

S1 treats the two proofs in task 1 as aesthetic entities and does not solely focus on the internal (line-by-line) workings of the proofs. He expresses the belief that elegant proofs are more desirable than brute force proofs and judges D_1 as less desirable. Later in his interview, when he was asked to compare F_1 and D_1, he discussed the two proofs relative to the genre of proof as a whole.

S1: Okay, what do they have in common? Clearly they have the goal in common, but the guy on the left, proof D_1, proof D_1 felt more like uh… I don't really know if there's an actual distinction in the math world between a "prove something" and a "show something," but if there was, this [D_1] definitely feels like, you know, just show that it's 0. But this [F_1] was like a really… this felt like it had more behind it here… whereas this [D_1] was like, let's just evaluate it and see where that takes us. Okay? Which is fair, you know? It just doesn't give you any insight into why that's the case.

S1 expresses the belief that proof D_1, does not provide any mathematical insight regarding why the result holds. It is simply an exercise in implementing well-established calculation techniques. Implicitly, he expresses that he often looks for what insights he can gained from presented proofs, in this case he did not find any.

However, one cannot effectively make FBI-judgments by focusing on holistic attributes of a proof in lieu of other attributes. For example, there may be multiple elegant arguments that justify a result. Thus, elegance alone is insufficient for making comparisons.

Multi-focus comparisons. In the previous subsections we argued that prioritizing only one of the foci of comparison in lieu of others was insufficient for making normatively correct based on judgments. In this section we illustrate what comparisons that utilize all four foci look like and how they may yield normatively correct FBI-judgments. To clarify we are arguing that balancing ones attention to these foci greatly increases the likelihood that a student consistently generates correct FBI-judgments but does not guarantee normatively correct judgments.

Below we examine S7's immediate reaction after reading proof F_2 for the first time:

Int: General impressions.
S7: F2 is just literally the proof version of I2…. Uh, so the idea behind this is that, okay if we are trying to show that this sequence has a unique limit, which we want to show that it can't have two limits. So we suppose there is two limits, basic proof by contradiction. So both are proofs by contradiction. And the contradiction occurs when epsilon is small enough. Here they show it intuitively but it's pretty clear from the picture that what they use was a number that's less then half way in between. Here [F_2] is that function, the average. So once we have the. It's not the average it's close enough so that it doesn't even reach the average. And that way the two have no overlap. And then by definition of sequence it should eventually get far enough that it's in this region always and once you get far enough it's in this region always but then it's therefore always in both these regions once it passes that specific end that we defined. And that's the contradiction. Which is what they said here. When we get small enough down we can't be in both but it has to be in both.

It is important to emphasize that S7 realizes that F_2 is based on I_2 before he is asked to make any kind of comparison. The above is simply his initial response. The part of the interview where he will be specifically asked FBI-questions occurred 30 minutes later. Also, he immediately jumps into the comparison when he states that both the proof and the informal argument have the same idea behind them (holistic foci). He then shifts to discussing how this idea manifests itself in terms of structure of both I_2 and F_2 (structural foci). He notes that both the proof and informal argument are necessarily arguments by contradiction with the contradiction in both cases being that you cannot be in two places at once (methodological foci). This is then related to the specifics of the proof, with being both above and below the midpoint of L_1 and L_2 corresponding to being in two places at once in the informal argument (content foci). S7 makes all four types of comparisons, does this without any specific prompting to make a comparison and relates the four types of comparison foci in his discussion.

We believe that the fact that S7 saw the relationship between I_2 and F_2 before he was asked to compare them to be particularly important. Mathematics is often discussed metaphorically as a language. Here S7 recognized that the informal argument and proof were metaphorically telling the same story. This is akin to being shown two paragraphs that tell the same story in two different languages, both of which one is fluent in. The fact that the same story has been presented twice, as well as the multitude of parallels between its two presentations is salient even without being asked to compare the two paragraphs.

On the other hand, if one is learning the second language and is asked the same question the comparison is very different. The comparison becomes an exercise in finding parallels between the words and phrases used, as well as, the order in which these appear. In this case one is likely to grasp onto only a fraction of the similarities and differences between the two paragraphs and make a determination based on only this subset. This is analogous to what we observed students doing when they prioritized one of the foci over others.

Discussion

This paper contributes to the literature on proof and proving both methodologically and theoretically. First, from the perspective of theory, this paper introduced a four-part model of the aspects of arguments/proofs students focus on when attempting to determine whether a particular argument is based on a particular proof. The components of this model are content foci, structural foci, methodological foci and holistic foci. We illustrated that comparisons where students prioritized one of these categories of comparison in lieu of others were prone to incorrect or incomplete conclusions regarding whether a proof was based on an informal argument. Furthermore failure to see the rich connections between informal arguments and proofs point to students having under developed conceptions of what if means for a proof to be based on an informal argument. These underdeveloped conceptions account for difficulties students have with generating proofs based on informal arguments (e.g., Zazkis et. al., in press) and in understanding the connections between informal arguments and proofs presented in lecture (e.g., Lew et al., 2014). These underdeveloped conceptions also account for some of students' resistance to generating informal arguments during proof production.

Methodologically, the triples method introduced in the study is a valuable research tool for those interested in research on the connections between informal arguments and formal proofs. Examining how students compare and contrast ready-made informal arguments and formal proofs provides valuable insights regarding what they notice when making FBI-judgments. In turn, what students' notice during FBI-judgments provides a valuable lens into how they conceptualize formalization and how they might view formalizing their own informal arguments. This method was able to reveal that students' conceptions of what it means for a proof to be the basis of an informal argument are not as rich as an expert conception—often only encompassing a fraction of the connections that exist between informal arguments and formal proofs.

In this paper we report the interview questions used in a study of middle school students' mathematical problem solving behaviors which were chosen based on Vygotsky's concept formation theory and Berger's appropriation theory. We discuss the task design/selection process along with the findings associated with the use of these tasks so to provide new direction for gauging research on mathematical problem solving.

Keywords: Research Methods; Problem Solving; Geometry

Introduction

Improving the teaching and learning of mathematical problem solving relies heavily on development of a theory of mathematical problem solving, which is currently missing from the field (Schoenfeld, 2007). As Schoenfeld articulated, the focus of mathematics education researchers interested in mathematical cognition may need to shift on building theoretical capacity that may account for human decision making in the course of problem solving (2013). We posit that progress towards building such a theory might demand greater attention to theorizing instrument design and task development in conducting research on mathematical problem solving, an area currently absent from the field. Discussions surrounding tasks have frequently focused on defining problems: a question where an individual does not have a ready- to-use approach to find the answer (Wilson, Fernandez, & Hadaway, 1993). Agreement exists that whether a question is a problem depends on the individual working on the task (Schoenfeld, 1985). This description has imposed constraints on researchers' ability to theorize specific principles of instrument design/selection when undertaking research on mathematical problem solving. Existing studies have generally selected questions based on the targeted subject area and whether the question is appropriate for the participants in the study, referring to the participants' educational background as a standard to determine whether a question is beyond their capability or not (e.g. Elia et al., 2009; Kuzle, 2011). These efforts, although useful in providing a profile of expert problem solvers, do not provide a coherent perspective on instrumentation as a methodology.

In a larger study of middle school students' mathematical problem solving behaviors, we used research-based assessment to capture students' ways of knowing by unpacking the relationship among mathematical concepts, cognitive behaviors, and metacognitive behaviors as evidenced during clinical interviews. We reported the findings from the pretest instrument in the study, which suggested that Vygotsky's concept formation theory could serve as an effective framework for designing novel assessments to provide researchers with more precise tools to articulate intricacies of students' understanding of mathematical concepts (Zhang, Manouchehri, & Tague, 2013). In this paper we will report on theoretically based criteria for design of tasks to be used in our research on mathematical problem solving. We will report findings related middle school students' performance on a selected sample of these tasks so to provide direction for future research on mathematical problem solving.

Theoretical framework

As a starting point in our task design, two issues were of particular concern: (1) establishing theoretical capacity that would allow us to document and analyze both cognitive and metacognitive behaviors of the participants in the course of their problem solving; (2) selecting a specific mathematical concept so to develop appropriate tasks surrounding it. To address the first issue we incorporated two theoretical perspectives to design/select interview questions used in this study: Vygotsky's (1962) concept formation theory and Berger's (2004) appropriation theory. Vygotsky's theory proposes a framework for an individual's concept development within a social environment, while Berger's theory proposes an interpretation of Vygotsky's theory in the domain of mathematics by adjusting certain stages. Both theories break down any concept development into three phases: heap, complex, and concept. In the heap phase, the learner associates a sign with another because of physical context or circumstance instead of any inherent or mathematical property of the signs. In the complex phase, objects are united in an individual's mind not only by his or her impressions, but also by concrete and factual bonds between them. In the concept phase, the bonds between objects are abstract and logical. For the purpose of the study we also decided to focus on the concept of Area due to its critical role in school mathematics. Hence, research-based formation stages for the concept of area were assembled as illustrated in Figure 1.

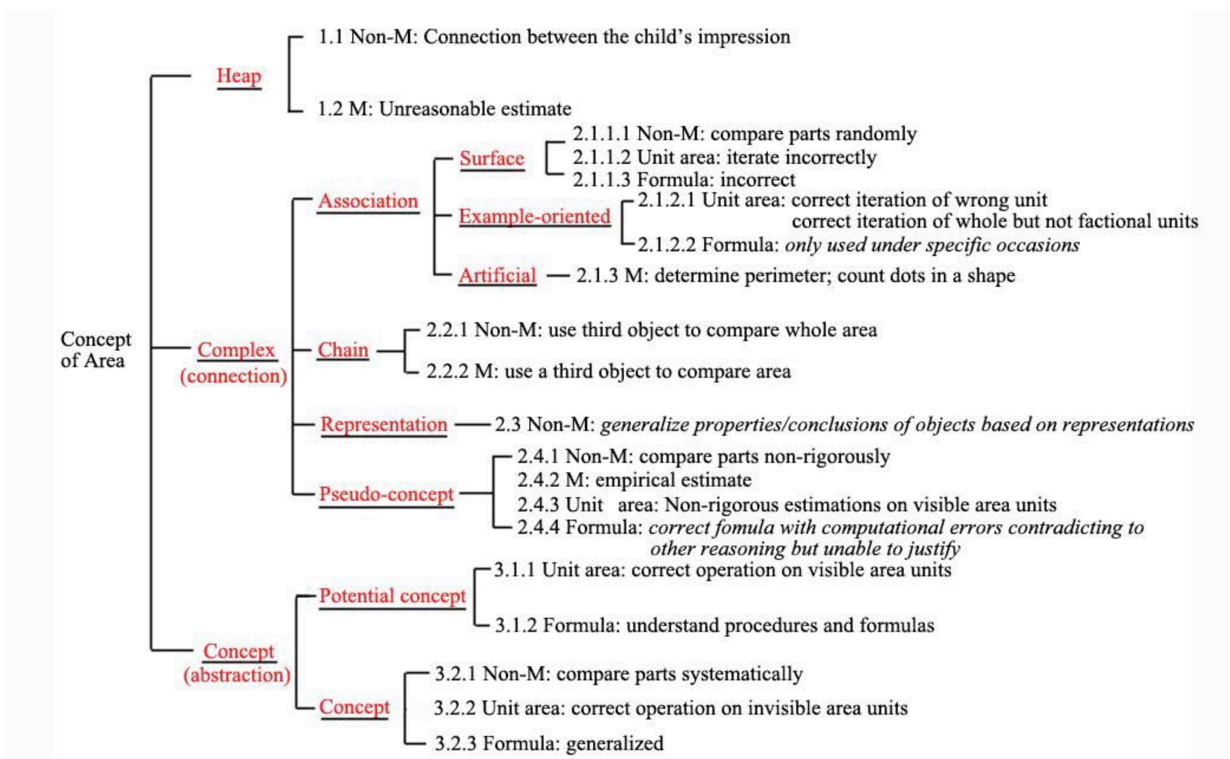

Figure 1. Developmental Stages of the Concept of Area

This structural model served as our primary analytical tool for qualifying the students' work as well as the tasks selected to be used in study. This model was further refined upon a short pilot study in which responses to tasks were obtained from 44 middle school students. The students were asked to responds to five items. Upon analysis of their responses we considered revisions of some of the tasks so to assure ambiguities that could lead to irrelevant answers were removed. Analysis of the relationship among mathematical concepts, cognitive and metacognitive behaviors emerged from the interview results based on our final selection of items which were used in in-depth interviews with five middle school students. The current report is based on our findings of these interviews.

Methods

Participants

Five individuals from a population of 44 sixth grade students were selected to participate in interviews. The original group of 44 were enrolled in three distinct class periods of an algebra course taught by the same teacher. All three classes had been observed by the lead author for 6 months prior to data collection. A pretest was administered to the 44 students. The process of determining and classifying the pretest responses is described as the following. 1) Two authors independently reviewed all responses to identify and document enacted approaches and coded developmental stages associated with each approach based on an earlier version of the developmental stages framework. Notes were compared for consistency in coding. 2) Students' approaches that were ambiguous or non-anticipated were discussed. The framework was adjusted based on the analysis of these responses; five more stages were identified and added to the original framework. 3) Based on the analysis we built a reference list of detected stages for each student to inform participant selection. Each individual's developmental status revealed in the responses was categorized as "overall low" (all responses were rated as Heap and non-Pseudo- concept Complex stages), "varied" (responses were rated across Heap to Concept stages), and "overall high" (Reponses were rated as Pseudo-concept Complex and Concept stages).

Participant selection was deliberate. The following criteria guided our choices: 1) willingness to be involved in the study and had signed the consent forms; 2) the participants would need to represent a range of different developmental attributes pertaining to the target concept. This data was collected through the students' pretest responses; 3) the participants would need to be comfortable with thinking aloud. Five individuals met these criteria: Shana exhibited a *low* status, Andy exhibited a *high* status, Sandy, Allen, and Ivan exhibited *varied* status.

Data collection

The five participants were interviewed individually. Each interview consisted of two parts: During the *background interview* part the participants' mathematics background information, their beliefs about mathematics, and their views on the value of mathematics for their lives were elicited. The second part, *problem solving session* the participants worked on specific mathematical tasks. During the problem solving sessions, interviewer interventions were limited to eliciting clarifications, explanations, or justifications, when needed.

Instrument design

F ive problems were used during the interviews. All problems were related to the concept of area and allowed the participants to tackle the tasks from different stages of concept development. The problems could potentially cover a wide range of concept stages. Peripheral concepts were integrated in several problems in order to enable some degree of interactions between different concepts (e.g. transformational reasoning and variable), since we believe authentic problem solving should involve more than one concept yet the number of concepts needs to be controlled for a deeper analysis on the behaviors acting upon them. When selecting tasks, concept stages along with the corresponding exemplar approaches that could be elicited by each problem were predicted by the authors. An example of this conceptual mapping is shown in Table 1.

Table 1. Predicted stages and exemplar approaches

<table>
<tr><td colspan="2">Compare areas problem
Which of the regions shown below has the largest area? How would you order them?
</td></tr>
<tr><td>Predicted stages</td><td>Exemplar approach</td></tr>
<tr><td>Surface Association Complex – Formula</td><td>Using an incorrect area formula</td></tr>
<tr><td>Chain Complex</td><td>Fitting the circle and the triangle into the square</td></tr>
<tr><td>Potential Concept - Formula</td><td>Using a correct area formula</td></tr>
</table>

Data analysis

Data collection consisted of four phases. First, each participant's key cognitive behaviors during each problem solving episode were mapped and documents. Second, a summary of observed concept stages and metacognitive behaviors during the episode were catalogued and noted. Detailed analysis of the individual's problem solving behaviors according to the relationship among concepts, cognitive behaviors, and metacognitive behaviors was constructed. Finally, cross analysis of the observed concept stages, metacognitive behaviors, and the relationship between them concluded the analysis phase. This process was followed for each of the five tasks used.

Results

The larger study analyzed the participants' performances on each interview question from four perspectives: 1) each participant's point of entry, including identified task elements/objectives and his/her initial approach, 2) types of approaches the study participants used, 3) concept stages revealed when working on the problem, and 4) metacognitive behaviors revealed from the participants during the problem solving episode.

To focus on the research question in this paper, we only report on: 1) each participant's point of entry, including identified task elements/objectives and his/her initial approach, 2) types of approaches the participants used, and 3) concept stages revealed. The problem in Table 1, Compare Areas problem serves as an illustrative example of research-based tasks used in the larger study reported elsewhere (Zhang, 2014).

Point of entry

In the Compare Areas problem, one task element and one task objective are essential to solving this problem: the variable a that represents the equal length of sides and diameter, and the comparison of the areas, respectively.

Table 2 summarizes the task elements/objectives (i.e. key conditions and goals to solve the question) identified by each participant and by the interviewer before each of the participants started solving the problem. Initial approaches adopted by each participant are also outlined.

Table 2. Summarization of initial response/approach adopted by each participant

Participant	Task elements or objectives identified by the participant	Task elements or objectives highlighted by the interviewer	Initial approach
Shana	Equal measure of sides and diameter	NA	The circle and the triangle could fit into the square. Sandy	Just area	The *a* meant equal measure of sides and diameter	Computed the areas by formulas.
Ivan	NA	NA	The circle could fit into the square (verbal conclusion); the triangle had the same area as the circle since the three vertices of the triangle “pokes out.” Andy	Around is the circumference.	The *a* meant equal measure of sides and diameter	Computed the areas of the square and the triangle by formulas.
Allen	The area inside	NA	The circle and the triangle could fit into the square. 
Among the five participants, Sandy’s understanding of variable greatly influenced her initial behaviors. She focused on the actual amount of area instead of the condition that the lengths of the sides and the diameter had the same measures. This prevented her from adopting either a visual or a numerical approach to start tackling the problem. Allen, whose understanding of variable was restricted, chose to ignore it so to avoid confusion. Ivan overlooked the variable; his later behaviors

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

were influenced by this element rather than at the beginning. Interestingly, Shana (who was assessed as low concept development) was the only participant who explicitly identified the task element of equal measure, whereas the others were either confused by the information, overlooking it, or needed to be reminded by the interviewer.

Documented approaches

Table 3 illustrates the approaches that the participants used when solving the Compare Areas problem.

Table 3. Approaches adopted by the participants solving the Compare Areas problem

	Approach	Description	Example from interview
1	Fit into the square	Showed the circle and the triangle could fit into the square.	2	Formula	Used area formulas to compute the areas.	Assigned a number to *a* and used the measure of the side of the triangle as its height.
3	Unit squares	Drew and count unit squares to approximate the area.	4	Compare leftover	Transformed the leftovers of the circle and the triangle into manageable shapes for comparison.	
The third approach was adopted when a specific area formula (i.e. the area formula of circles) was not available to Andy who used the second approach as his initial heuristic. The fourth approach was usually adopted when the participants, who used the fit-into-the-square approach as their initial approach, were prompted to further compare the areas of circle and triangle.

Revealed concept stages

When designing the interview instrument, the researchers had predicted six concept stages that could be revealed in this problem: 1) *Surface Association Complex – Formula* wherein a student uses an incorrect formula, 2) *Artificial Association Complex* where perimeter is compared instead of area, 3) *Chain Complex - Non-measurement* wherein the circle and the triangle can fit into the square, 4) *Pseudo-concept Complex - Formula* where visual reasoning contradicts to computational answers, 5) *Potential Concept - Formula* where a number is plugged into a formula, and 6) *Concept – Formula* where variable *a* is plugged into the formula to reach a generalized answer. Among these stages, 1, 3, and 5 were revealed during the interviews, while 2 was observed during the identification of task objectives prior to one participant's initial approach.

Table 4 summarizes the concept stages of Area concept revealed from the five participants when solving this problem. The approaches associated with each stage as used by them are noted as well. The stages listed in italic are the ones predicted to be revealed by the researcher.

Table 4. Concept stages of area and associated approach revealed by participants

	Revealed concept stage	Associated approach
	Surface Association Complex – Non-measurement	Compare leftover
	Surface Association Complex – Formula	Formula
	Chain Complex	Fit into the square
	Pseudo-concept Complex - Non-measurement	Compare leftover
	Potential Concept – Unit area	Unit squares
	Potential Concept - Formula	Formula
	Concept - Non-measurement	Compare leftover

All other stages were observed when the participants sought an alternative way to either refine or complement their initial approaches. The participants' problem solving behaviors were much more novel during this process (thus less predictable) than their behaviors during the initial attempt (i.e. using fit-into-the-square or formula approach).

Discussion

The study results suggested that metacognitive behaviors of the participants are closely linked to their perceived level of complexity of the task and whether they found it appropriately challenging. That was the case regardless of the participants' level of development pertaining to the concept under study (in our case, area, for instance) or their personal preferences for particular strategies. That is, when a task was perceived as too challenging, it was treated as enigma. This limited our capacity as researchers to access cognitive or metacognitive behaviors of the participants. The same occurred when the problem was perceived as trivial. Because of this, we argue that description of what constitutes a problem (in the context or problem solving) needs to be more precisely defined. The common description "whether a task is a problem depends on the individual" (Schoenfeld, 1985) too broad to inform research instrumentation when studying mathematical problem solving. We posit that benchmarks for selection/design/ development of appropriate problems, according to the concept formation stages specific to those embedded in the task, can enable researchers to more adequately elicit student problem solving. This issue is particularly critical if inferences are to drawn regarding the individuals' understanding of a concept in presence of their mathematical problem solving performance.

Since existing literature does not provide a guide that can inform task design/selection for research purposes, focused scholarly efforts towards construction of such a theoretical platform are needed. Towards that goal several key issues merit elaboration, among many include: 1) task elements and objectives that are essential to understanding the problem in light of learning progression, 2) specific concept stages as entry points to the tasks, 3) desired concept stages embedded in solutions, and 4) potential shifts/paths between concept and its associated concept stages.

Discussion of task elements need to identify conditions under which a problem may suit different populations according to their experiences with the concepts involved. Naturally, if the problem solver has had limited or no experience with a particular concept their interpretation of the task or what is expected as an appropriate answer may not match those of the researchers. Discussion of specific concept stages as entry points granted by the tasks allows the researcher to use the same task with different populations who may not share the same concept developmental status. Such an elaboration allows us to determine whether the task might be too challenging/impossible to solve given a specific concept developmental stage. A description of potential shifts and paths can serve as an aid for the interviewers/researchers to gauge their interventions during the interviews (potential prompts/probing questions when observing problem solving process). These descriptions mainly determine the capacity of a task. If a task allows only one entry point and one desired stage for the solution, it mostly assesses whether an individual knows the procedure or not, which is commonly used in proficiency tests. The development a detailed theoretical model of task design is a necessary tool towards development of a theory of mathematical problem solving.

DEVELOPMENT OF VERTICALLY EQUATED PROBLEM-SOLVING MEASURES

Jonathan D. Bostic

This manuscript describes initial research on the process of vertically equating two problem-solving instruments: one for sixth-grade students and another for seventh-grade students. We connect this study to research aimed at developing measures to assess students' problem-solving performance as framed by the Common Core State Standards for Mathematics. Rasch modeling results indicated that three of the four anchor items worked as planned. Thus, scores on the seventh-grade measure indicate students' performance on seventh-grade content but also their performance on sixth-grade content-focused items.

Keywords: Problem solving; Assessment and Evaluation; Middle School Education

The Common Core State Standards for Mathematics (CCSSM; National Governors Association, Council of Chief State School Officers, 2010) highlight problem solving in some fashion across grade-level Standards for Mathematics Content (SMCs). Furthermore, problem solving is found in several titles and descriptions of the Standards for Mathematical Practice (SMPs). Assessments should address the depth and focus of instructional standards (Wiliam, 2011). Thus, new assessments are needed that reflect the call for problem solving expressed in the CCSSM. Our first objective for this study is to briefly describe psychometric results of a new assessment for seventh-grade students. The second objective is to explore the vertical equating process with respect to this assessment and a previous one for sixth-grade students.

Related Literature

Problem Solving and Problems

We draw upon Lesh and Zawojewski's (2007) notion of problem solving as a process including "several iterative cycles of expressing, testing and revising mathematical interpretations – and of sorting out, integrating, modifying, revising, or refining clusters of mathematical concepts from various topics within and beyond mathematics" (p. 782). Problem solving occurs only when learners work on a problem. Schoenfeld (2011) characterized a problem as a task such that (a) it is unknown whether a solution exists, (b) the solution pathway is not readily determined, and (c) more than one solution pathway is possible. Problems are unique from exercises. Exercises are tasks intended to promote efficiency with a known procedure (Kilpatrick, Swafford, & Findell, 2001). The CCSSM emphasize problem solving in the SMCs and SMPs, hence teachers are expected to engage students in problem solving during everyday instruction.

Researchers have suggested that students should experience non-routine word problems as part of their regular mathematics instruction (Boaler & Staples, 2008; Matney, Jackson, & Bostic, 2013; Palm, 2006; Verschaffel et al., 1999). These word problems ought to be open, realistic, and complex (Matney et al., 2013; Verschaffel et al., 1999). An *open* problem can be solved using multiple strategies and offer problem solvers numerous entry points to the task. A *realistic* problem allows an individual to draw upon his/her experiential knowledge and also fosters engagement through a connection to the real world. Finally, a *complex* task supports perseverance and sustained reasoning, which are highlighted in SMPs #1 and 3. Our research draws upon established ideas for problems and problem solving, as well as prior published work in developing CCSSM-focused mathematics assessments (Bostic & Sondergeld, in press, 2015), to highlight the pilot testing process as well as preliminary findings of a second measure, the Problem Solving Measure for seventh grade (PSM7). We used Rasch modeling (also known as one-parameter item-response theory) and vertical equating while developing the Problem Solving Measure for sixth grade (PSM6) and PSM7 in order to create a sound system for measuring students' problem-solving of items addressing the CCSSM across two grade levels.

Assessment: IRT and Vertical Equating

Oftentimes assessments are delivered as incidents independent of future or previous testing. This is acceptable if the goal is to assess student skills at a single point in time. However, if the purpose of testing is to measure student growth across grade levels then multiple assessments must be given, each related to their appropriate grade level content standards. How then might teachers and researchers determine student growth in learning if the content is different at each grade level? One solution is vertical equating (or scaling) (Wright & Stone, 1979). Vertical equating can only be done when investigating a single unidimensional construct such as problem solving (Lissitz & Huynh, 2003). An attempt to measure student growth from one year to the next using two linked assessments requires common items (called anchors) on both measures (Wright & Stone, 1979). These anchor items are typically moderate in difficulty from the lower level assessment, and placed on the higher-level assessment to be evaluated for change in item difficulty (or displacement). If the items remain at approximately the same difficulty level (within ±.40 logits – or log odds units) on the higher-level test then they are acceptable anchors that will work well in linking different grade level tests (Kenyon, MacGregor, Ryu, Cho, & Louguit, 2006). There is no standard for the number of required anchor items when vertical equating. It is more important to ensure anchor items are of high quality (displacement within range of ±.40 logits) than to have a greater quantity of poorly functioning anchors (Pibal & Cesnik, 2011). In fact, Pibal and Cesnik showed that as few as three anchor items can work well to vertically link tests together provided they are of high quality.

Method

Building upon prior research related to developing the PSM6, we created a problem-solving measure to address the seventh-grade SMCs. The aim of this paper is to provide evidence for vertical equating of scores between the PSM6 and PSM7. Our research questions are (a) Is the PSM7 psychometrically sound? (b) What psychometric evidence suggests that scores on the PSM6 and PSM7 might be vertically equated?

Instrumentation

PSM6. Previously peer-reviewed work by Bostic and Sondergeld (in press, 2015) discusses the validity and reliability of the PSM6. It has 15 items, three from each domain of the CCSSM (i.e., Expressions and Equations (EE), Geometry (G), Number Sense (NS), Ratio and Proportions (RP), and Statistics and Probability (SP)). Two sixth-grade classroom teachers, one mathematician holding a Ph.D., and two mathematics educators with terminal degrees reviewed the items for connections with the SMCs and SMPs, developmental appropriateness, and use of complex, realistic, and open problems. This review panel was also tasked with considerations about bias on the measure. Results of the review indicated that the items addressed the SMCs and numerous SMPs, were developmentally appropriate, all tasks could be solved with at least two strategies, drew on real-life contexts, and were sufficiently complex to be considered problems. A group of sixth-grade students representing different ethnicities, socioeconomic backgrounds, and cognitive abilities (as measured by classroom grades) volunteered to serve on a second review panel to examine the PSM6 for potential bias. The review panel consisting of adults and children found no bias that might impact students' performance.

Data for the PSM6 were collected from 137 sixth-grade students located in a Midwest state. None of the respondents were English Language Learners. Test administration took approximately 75 minutes. Students' responses were scored as correct and incorrect. These scores were used to examine the psychometric properties of the PSM6 using Rasch modeling for dichotomous responses (Rasch, 1980), which is also called one-parameter Item Response Theory (see Bond & Fox, 2007).

PSM7. Development of the PSM7 followed a similar process as the PSM6. The aim of this manuscript is to share the process of vertically equating scores across grade levels on the PSM6 and PSM7. To meet that aim, we selected tasks from the PSM6 that represented core ideas of sixth-grade mathematics and were of moderate difficulty for sixth-grade students. For our study, four total items from the PSM6 were selected as anchors on the PSM7: two items addressing the EE domain and two items addressing the RP domain. These items were within one standard deviation of the mean item difficulty for the PSM6 as well as the one standard deviation of respondents' mean (making them average difficulty items). EE and RP draw upon the number fluency ideas that are central to support the progression pathway to algebraic reasoning and thinking that is at the core of CCSSM content development across grade levels (Smith, 2014). Therefore, items addressing this content were deemed acceptable content for both grade levels.

Data Collection and Analysis

Four-hundred and eighty-seven students located in a Midwest state completed the PSM7. Seventh-grade students took approximately 80 minutes to complete 19 items, four of which were the items for vertical equating purposes. Responses were scored as correct and incorrect. These data fueled the quantitative analysis using Rasch modeling for dichotomous responses. Rasch methods are often viewed by many social science researchers as the best method for instrument development and refinement because they convert ordinal data into conjoint, hierarchical, equal-interval measures that place both person abilities and item difficulties on the same scale allowing them to be directly compared to each other (see Bond & Fox, 2007). Winsteps Version 3.74.0 (Linacre, 2012) was used for all Rasch analyses. Psychometric evaluation of the PSM7 in terms of its reliability and validity evidence were conducted similar to that which was previously done for the PSM6. Assessment of anchor item functioning and displacement was also performed.

Results

Psychometric Findings

Unidimensionality is a fundamental quality of measurement. Items with negative point biserial correlations, infit mean-square (MNSQ) statistics falling outside 0.5 – 1.5 logits, or outfit MNSQ statistics greater than 2.0 logits are not meaningful for measurement (Linacre, 2002), and should be removed from a test as they do not contribute to a unidimensional latent trait. No items on the PSM7 had negative point biserial correlations (.06 – .65). All items fell within Rasch MNSQ fit parameters for infit statistics (.76 – 1.25). Only one item had an outfit statistic greater than 2.0 (.10 – 3.13). Item reliability was high at .98 suggesting strong internal consistency for items. Further, item separation was high (6.90) and item measures ranged from 3.03 to 4.69 indicating a meaningful variable (i.e., problem-solving ability) was created. Collectively, these statistics suggest all items worked together to form a unidimensional measure capable of assessing a wide range of problem solving abilities among seventh-grade students.

Vertical Equating Findings

Of the four items used as anchors from the PSM6 to the PSM7, three fell within the appropriate range for displacement (-.06 – .18). One RP item had a displacement of -.43 and was thus deemed unacceptable for anchoring purposes. Therefore, three of the PSM6 items will remain on the PSM7 assessment during further testing administrations for linking purposes.

Conclusions

Overall, the PSM7 showed acceptable psychometric properties during its first administration. We were able to develop a continuous construct of problem solving assessed across two grade levels by using Rasch modeling methods and vertical equating. This construct aligns problem-solving items on two tests with appropriate grade level SMCs. It allows evaluation of a student's sixth-grade problem-solving skills while providing an opportunity to assess a student's growth in competency when moving into grade seven. Such linked measures like the PSM6 and PSM7 respond to calls for assessments to reflect the depth and focus of standards, especially new ones adopted across multiple regions of the USA.

STUDENT RECORD KEEPING FOR COGNITION AND COMMUNICATION

Anthony Fernandes	Dan Heck	Johannah Nikula
UNC Charlotte	Horizon Research	Educational Development Center
afernan2@uncc.edu	dheck@horizon-research.com	jnikula@edc.org

This study explores how the records that students make during problem solving assist their cognition and communication. Grounded in the problem-solving literature and cognitive load theory, we examine the records that 14 middle grades students make as they solve geometry problems in one-on-one task based interviews. We identify features of record keeping that assist the students with cognition and communication and discuss the implications of this work.

Keywords: Cognition; Geometry; Middle School Education; Metacognition

This paper investigates how records students generate during problem solving assist in their cognition and communication. Solving mathematical problems and communicating thinking are fundamental parts of learning and doing mathematics (NCTM, 2000; NGA & CCSSO, 2010). Helping students learn and use strategies for solving mathematical problems and communicating their thinking are essential elements of successful mathematics instruction.

In this paper we describe a study of *record keeping* (RK) that middle school students used to help them think about a problem and then communicate their thinking. We were guided by the following research question: How do middle-grades students use record keeping during problem solving for cognition and communication?

Record Keeping

In reviewing the literature we found diverse terminology that intersected with our idea of record keeping. For our purposes, *record keeping* (RK) is the act of capturing pieces of information developed during the process of solving a mathematical problem in a manner that allows the problem solver to retrieve this information later. Such pieces of information include: important aspects of the problem statement, additional information possibly needed for solving the problem, characteristics of possible solutions, ideas about solution strategies, and/or partial solutions. The record could be physically inscribed or electronically captured, and it might take various forms including words, symbols, equations, drawings, or diagrams. Its defining characteristic is that RK secures information external to the mind of the problem solver; it does not take the form of a mental note.

Theoretical Perspectives

Our study was guided by foundations in problem solving (Polya, 1957; Schoenfeld, 1992) and Cognitive Load Theory (CLT) (Sweller, 2003). CLT is a learning and instructional theory based on the temporary and limited nature of working memory and the permanent and essentially unlimited capacity of long-term memory (Sweller, 2003). Working memory draws on long-term memory, but can only store about seven chunks of information and process only two or three chunks of information at a time. If these limits are exceeded, working memory gets overloaded.

From a CLT perspective, problem solving can generate a high cognitive load for students due to the information that needs to be stored and processed simultaneously. Literature on problem solving suggests that a means of reducing this load is to offer heuristics that students can use, including writing an equation to describe the problem situation or drawing a diagram.

Using equations, diagrams, and other external representations as records during problem solving can serve two purposes (1) bolster the capacity of working memory by offloading part of students' thinking onto the environment (Tabachneck-Schijf, Leonardo, & Simon, 1997), and (2) focus attention on key quantities and relationships needed to solve the problem (Zhang, 1997). Successful problem solvers are adept at working with a representation that captures the essential relationships needed to solve the problem (Diezmann & English, 2001; Nunokawa 1994). Expert problem solvers also construct many more visual representations than novices do during problem solving (Stylianou & Silver, 2004). Once created, diagrams can be useful for facilitating communication for students. Multistep explanations are generally challenging to describe, and also hard for listeners to follow (Hufferd-Ackles, Fuson & Sherin, 2004).

Modes of Inquiry

We conducted 14 one-on-one problem-solving and interview sessions with middle school students to understand how RK helped them in cognition and communication. The sessions lasted about 45 minutes each while the student worked on three challenging geometry tasks. The sessions were videotaped and the students' written work was also collected. After the students worked on the problems, the researcher asked follow-up questions.

Analysis of student work and interviews involved detailed examination of each student-generated record, specifically describing the record created, how it was used in problem solving, and the student's reasoning related to the record. A combination of emergent codes and codes based on the literature were used to analyze data from the sessions. The research team together created and shared analytic memos describing how each student's RK aided cognition and communication. Two main themes supported by multiple examples arose from this analysis – *RK fosters exploration and supports persistence* and *RK for communication aids recounting and referencing*. We discuss these two themes drawing on examples from one student's work on the Shelf task (Fig 1). In this task the students were given a cross-section of Joseph's bedroom with some pertinent measurements and were asked to find the length of the shelf.

Results

RK for cognition fosters exploration and supports persistence

RK featured prominently during the initial stages of work on problems when the students did not seem to have a clear approach to a problem and were exploring various avenues. In such cases they drew on prior experiences like using the numbers provided to do some initial computation, and labeling or marking figures. Based on these initial results, the students may have continued with their approach or may have abandoned it and tried something new, in either case gaining some traction on the problem. Below we illustrate how Carol, an 8th grader, initially engaged in exploratory RK which eventually led to a successful solution of the Shelf task.

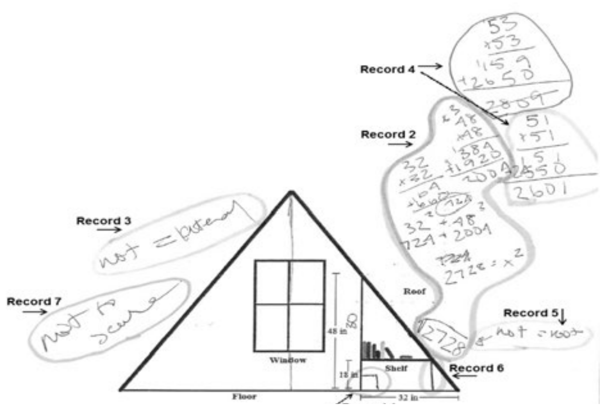

Figure 1: Record Keeping for Shelf

Carol began the task by marking a right angle (Record 1, Fig. 1) which prompted her to explore the use of Pythagoras' theorem. She made several records to determine (incorrectly, due to computational errors) the length of the hypotenuse of the key triangle is the square root of 2728 (Record 2, Fig 1). After observing that evaluating this square root would involve further calculations, she explored other properties of the triangle. Using her pen as a measuring device she observed that the triangle in the figure was not equilateral and made a note – "not = lateral" (Record 3, Fig. 1). Returning to the Pythagorean approach, she tried to find a whole number square root of 2728 (Record 4, Fig 1). While making these calculations, she realized that no whole number, when squared, could have 8 in the units place. Carol wrote “not = root” (Record 5, Fig 1) to remind herself of this fact. At this point she asked if the figure is drawn to scale and was told that it was not necessarily. After using her pen to make measurements near the 18 inches mark and a segment she had drawn before (Record 6, Fig 1), Carol wrote “not to scale” (Record 7, Fig 1).

Carol next turned the paper over and proceeded to create a scaled drawing of the figure. She noted 4 as a common factor of 32 and 48 and made equally spaced dots representing 4 inch intervals along both the vertical and horizontal parts of the diagram (Record 8, Fig 2). She used this approach, making several additional records (Records 9-12, Fig 2), to determine the length of the shelf as 20 inches.

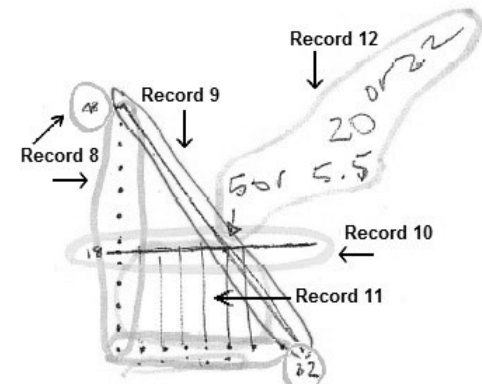

Figure 2: Record Keeping for Shelf

In our analysis of the interview with Carol, we note that her RK supported two approaches – one numerical and one diagrammatic. In the numerical approach she used Pythagoras’ theorem and attempted to work out the length of the roof. Through her calculations she noted that this would not be a whole number and thus decided to try a diagrammatic scaling approach. Carol began by trying to determine if the original figure was drawn to scale. When she discovered that the figure was not necessarily drawn to scale, she was motivated to create a scaled figure, leading to an approach that yields the solution. At each step, her RK such as “not to scale”, “not = lateral”, and “not = root” acted as signposts that guided her towards another approach that eventually led to a successful solution. By offloading her work and keeping track of the dead ends, Carol was able to use her RK to attempt possible approaches to the task, but set them aside when she found them unproductive and considered other approaches.

RK for communication aids recounting and referencing

The records that the students generated usually mediated their interactions with the researcher during the session interviews. The records served to remind students of the work they had done and also grounded many comments and gestures that students used to communicate their thinking to the researcher.

In Carol’s explanation of her work on the Shelf task, she used the records to walk the researcher through a chronology of her thinking, including all of the ultimately not successful work to find the length of the roofline of the shelf structure, and to find the length of the shelf via comparative measurement with known values. She gestured to each record to draw the researcher’s attention to the calculations she completed and parts of the diagram she had marked as she related each episode of her work. In this way, the records provided Carol a set of prompts for the chronology and points of reference for the researcher as the audience.

Carol’s culminating diagram (Fig 2) served to ground her numerous gestures as she explained how she determined the number of dots that would represent the length of the shelf. Carol gestured repeatedly to Records 8-11 when describing the diagrammatic scaling method she used to solve the problem, using her pen as a pointer to indicate the dots and their meaning as measures used to count by 4 inch increments both vertically to locate the height at which the shelf would be set, and horizontally to determine its length. Pointing to the records also emphasized the estimating decision that Carol made about whether the end of the shelf that intersected the roof corresponded to 5 or 5.5 dots (20 or 22 inches) horizontally.

With the diagram as the background, Carol was able to point to various parts and combine these gestures with her speech to develop a coherent explanation that the researcher was able to follow. The diagram as a record was vital to this interaction; without access and reference to it the researcher would not have understood the thinking behind Carol's approach.

Discussion

In our data we found that RK effectively supported both the students' cognition and communication. Based on the analysis of their records the students experimented with various approaches to the problem. In some cases, the records brought to the fore an approach that they used to successfully solve the problem. We conjecture that RK allowed the students to first offload their thinking onto the paper to free up more of their working memory. Further, by having the records in front of them, the students were able to draw on pertinent information from their long-term memory to solve the problem.

Besides aiding the students' cognition, RK proved useful in communicating their thinking. The students used their existing records or sometimes generated records to ground their interaction with the researcher. We conjecture that by providing a constant outlet for the students' ideas, the RK prompted students to explore further, consequently exhibiting more persistence in their problem solving.

Given the benefits we have outlined for RK, the larger goal of our study is to understand what features of mathematics task presentation promote RK that aids students' cognition and communication. Further, we are interested in deriving principles for designing tasks to promote useful RK, and general development of students' RK strategies for problem solving.

OPTIMIZATION PROBLEMS IN FIRST SEMESTER CALCULUS

Renee Y. LaRue
West Virginia University
rlarue1@mix.wvu.edu

Nicole M. Engelke
West Virginia University
nminfante@mail.wvu.edu

Optimization problems require students to use a combination of calculus and pre-calculus skills to solve word problems, which are historically challenging for students. Although they are often able to learn strategies for arriving at the correct answer, the goal is for students to understand how and why these strategies work. Using Tall and Vinner's (1981) concept image as our theoretical perspective, we examine barriers to students' understanding of the role of the optimizing function as they are in the orienting and planning phases of Carlson and Bloom's (2005) Problem Solving Framework.

Keywords: Problem Solving; Modeling

Most standard optimization problems in first semester calculus require students to read and interpret a problem, set up an appropriate function to model the situation, differentiate the function to find critical values, prove the critical values give a maximum or minimum, and answer the specific question from the problem. White and Mitchelmore (1996) observed that students were more successful at solving such problems when the function is already given than when they must construct the optimizing function first. Here we examine barriers to constructing an optimizing function and to understanding the significance and meaning of the answer.

Literature Review

As part of a larger study, White and Mitchelmore (1996) presented students with one of four versions of two standard optimization problems. There were significantly more correct answers to the versions given explicitly than there were to the versions given in the form of a word problem, requiring the students to define the variables themselves, supporting research stating that a weak concept image of variable often plays a role in students' difficulties with calculus (Clement, Lochhead, & Monk, 1981; Kaput, 1987; Malisani & Spagnolo, 2009; Orton, 1983). There is a large body of literature devoted to student understanding of functions (Dubinsky & Harel, 1992; Sfard, 1992; Vinner & Dreyfus, 1989). Eisenberg (1992) and Even (1998) found that students are often reluctant to consider the graphical representation of a function, and when they do, they frequently have trouble interpreting the information correctly.

Theoretical Perspective

Carlson and Bloom's (2005) problem solving framework allows us to describe students' activity as they solve optimization problems. The framework is divided into four phases: orienting, planning, executing, and checking. In the orienting phase, the student deciphers the problem and assembles the tools he or she thinks may be required. In the planning phase, the student uses conceptual knowledge to determine an appropriate course of action, which is then implemented during the executing phase. Finally, during the checking phase, the problem solver goes back to the original problem to see if the answer makes sense.

In this paper, we will focus on the concept images that are evoked while the students are in the orienting and planning phases of Carlson and Bloom's (2005) Problem Solving Framework. Tall and Vinner (1981) define concept image as "all the cognitive structure in the individual's mind that is associated with the given concept" (p. 1). This cognitive structure may be incomplete, incorrect, or logically inconsistent and may have very little to do with the formal mathematical definition of the concept. Tall and Vinner (1981) address the possibility of logically inconsistent components of the concept image by defining the “evoked concept image.” When the two conflicting parts of the concept image are simultaneously evoked, the individual experiences confusion known as cognitive conflict, often leading the student to resolve the conflict, developing a better understanding of the concept, and other times leaves the student feeling uneasy and frustrated but ultimately unable to address the conflict.

Methods

Data was collected through semi-structured interviews, which were video recorded and transcribed for analysis. We began with a small pilot study with three second semester calculus students during Spring 2014 (Arthur, Brent, Carl) and collected data two more times with first semester calculus students during the Summer 2014 (Franz, Sam, Tracy, Lars) and Fall 2014 (Ashod, Brandi, Cy) semesters. All three iterations of the interviews involved the students solving optimization problems and answering some questions about related prerequisite material. For the first interview, we gave three problems, but scaled back to two problems for the second and third interviews to allow time for more detailed, focused questions. In the second and third interviews, we explored students’ beliefs about the relationship between perimeter and area of rectangles (for example, does an increase in perimeter guarantee an increase in area?).

In the interest of space, here we only present the results from Question 1, which was common across all interviews. The students’ responses to subsequent questions reflected reasoning similar to their responses to Question 1. Question 1 was: *A rectangular garden of area 200 ft^2 is to be fenced off against rabbits. Find the dimensions that will require the least amount of fencing if a barn already protects one side of the garden.*

Results and Discussion

One of the three second semester calculus students and four of the seven first semester calculus students were able to solve Question 1 without intervention from the interviewer. Three of these five students solved the problem as though the barn did not exist, but when they became aware they had forgotten the barn, all three expressed surprise and disgust that they had neglected that detail, indicating that it was likely due to inattention.

The other five students were eventually able to solve the problem as well, but they all needed help, in the form of leading questions, hints, or explicit suggestions to try a different approach. The assistance was given with the intention of continuing through the interview to assess the students’ understanding at as many phases of the process as possible.

Why Do We Need This Function?

All of the students were aware that they needed to construct some function that could be differentiated, and they all knew they needed to do something to eliminate one of the variables. Beyond that, seven of the ten students demonstrated that they did not have a well-developed concept image for the optimizing function. We would like their concept images to include the following: 1) The optimizing function should be a single variable function representing the quantity we would like to maximize or minimize and 2) Our goal is to find the absolute maximum or minimum of this function.

Franz and Tracy had Property 1, but not Property 2; they knew they were supposed to differentiate a function representing perimeter, but neither knew why. Franz said, “It’s just a standard thing that we do,” and Tracy said, “I honestly don’t remember why that works, I just know that it does.” Arthur, Carl and Tracy all attempted to differentiate an expression for area at first, indicating that Property 1 was not part of their evoked concept image.

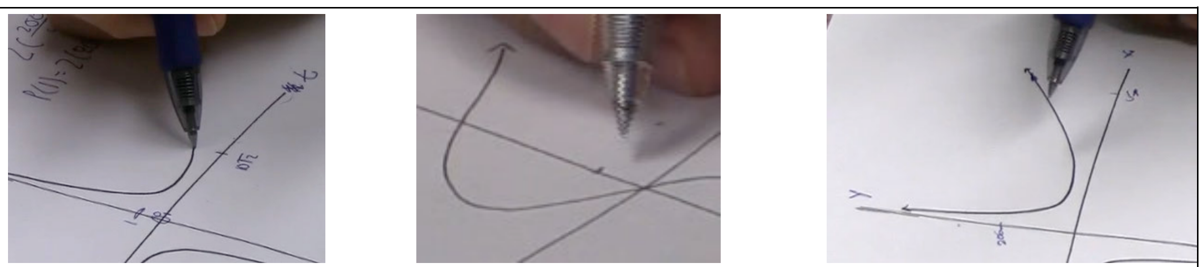
Ashod, Arthur and Cy became very focused on the key word, “dimensions” in the problem and discussed using the perimeter only as a means for finding dimensions, not the maximum or minimum. These three students did not display evidence that Property 2 was part of their evoked concept image; instead, they were simply using the perimeter equation because it provided a convenient way to find dimensions. Consider Ashod's response, "Basically what we would do is we solve for either variable to plug it in to find the perimeter of this. That's, to find the perimeter which would give us the dimensions of it." We use the terms function and equation intentionally here, because these students were focused on the perimeter equation as something they could use to solve for something, rather than as something they would need to differentiate. Their initial evoked concept image for area and perimeter limited them to equations or formulas, rather than expressions that could be thought of as functions.

Franz, Tracy and Lars demonstrated a lot of difficulty with thinking of these equations as functions, implying difficulty with Property 1. Franz wrote, "$2x + y =$ " with nothing written to the right of the equal sign. When asked about it, he said, "I don't know what it's equal to now. I think, uh..." and then gave up. After moving on from her initial attempt to use the area equation, Tracy wrote "$\text{minimize materials} = 2y + x$" which seemed like a good first step, but when it came time to express perimeter as a function that could be differentiated, she did not know what to do. Even after the interviewer suggested she use the letter *M* to represent "amount of material," she remained hesitant, saying, "Even then, I don't think that'd help me. That's just adding another variable." Lars had a similar problem.

How is This Function Related to This Graph?

Only one of the ten students mentioned the graph without being prompted, supporting Even's (1998) observation that students resist transitioning to different representations of functions. Cy said, "It's weird to, like, make the jump from numbers into a graph sometimes. In some situations, the numbers are really just a stand-in for the work I'm doing in my head with graphs, but in this situation, it's more, the numbers are all I really ever thought about this."

It is possible to solve optimization problems without considering the graph, so we do not fault the students for avoiding the graphical representation. However, we would like the students to be able to correctly interpret and identify key information on the graph of the optimizing function, even if they would not automatically use it. We noticed some of the pilot study students having trouble with this, so we asked pointed questions of the other seven students.



Brandi solved Question 1, found $y = 10\sqrt{2}$, and marked it here.	Franz solved a different question, found $w = 2\sqrt{3}$, and marked it here.	Ashod solved Question 1, found $x = \sqrt{200}$, and marked it here.

Figure 1: Students Labeling Graph

When they marked the point in the domain corresponding to the critical point, these students did not place it below what was clearly the absolute maximum or minimum of the graph. Even though they were able to find the correct answer, being unable to correctly place it on the graph suggests that the students either do not know what the answer signifies or that the significance of the answer does not play a dominant role in their minds as they are solving the problem. When these students were in the planning phase of the problem solving process, they did not plan ahead based on the goal of finding the absolute minimum of the optimizing function, rather, they were just looking for a function to differentiate without thinking about why.

Conclusion

All of the interviewees were eventually able to solve Question 1, generally considered to be an easy optimization problem, but their incomplete concept images for the optimizing function signal poor understanding of the optimization process. Variables, function notation, and the role of the optimizing function are important to the construction of an optimizing function. Several students did not display evidence of working towards the goal of constructing an optimizing function with Property 1, evidenced by their unwillingness or inability to use appropriate function notation. For many students, the evoked concept images of the role of the derivative when constructing an optimizing function appeared to be limited to the knowledge that the derivative was useful, and that setting the derivative equal to zero would somehow lead to the correct answer, demonstrating that Property 2 was not part of their evoked concept image for the optimizing function. We need to allow students to explore the role of the optimizing function while they are in the orienting and planning phases of the problem solving process to facilitate better understanding of the entire optimization process. We suggest an increased emphasis on constructing the graph of the optimizing function and activities exploring the optimizing function, such as sketching several rectangles with the appropriate area, but different perimeters.

STUDENTS' REASONING OF LOGICAL EQUIVALENCE BETWEEN AN IMPLICATION AND ITS CONVERSE

KoSze Lee
University of North Florida
ko-sze.lee@unf.edu

This study examines students' reasoning of logical equivalence between an implication and its converse. In particular, it focused on the cognitive schemes underlying students' logical comparison of both implications. Past research found that students experienced difficulties in these tasks. From 120 justifications written by 60 Singapore Secondary Three students, a hierarchical ordering of five types of logical comparison schemes was derived. The schemes ranged from disregarding the order of antecedent and consequent to comparing syntax, truth values, and counterexamples. Research for instructional support on logical equivalence is needed.

Keywords: Reasoning and Proof; Advanced Mathematical Thinking; Problem Solving; Number Concepts and Operations

This study examines students' reasoning of logical equivalence between two mathematical propositions, specifically, an implication and its converse since implication is at the heart of mathematical reasoning (Durand-Guerrier, 2003). Students' competence in determining the logical equivalence between an implication and its variants (e.g., converse or contrapositive) is a key aspect of mathematical proving (Epp, 2003; Stylianides, Stylianides, & Philippou, 2004). It is the first step towards building their knowledge of proof strategies and ability to discern valid and invalid proof methods. However, little attention is given to this aspect in proof instructions.

Research had shown that students experienced difficulties in understanding the logical nonequivalence between an implication and its converse (Hoyles & Küchemann, 2002). They encountered the most struggle in interpreting an implication as a bi-conditional ("if and only if") and regarded the implication and its converse as equivalent. However, it remained unclear what cognitive schemes were underlying their reasoning about logical equivalence between implications. Understanding their schemes is a first step to inform the role of logical reasoning instruction in proof instructions (Epp, 2003).

Theoretical Framework

Reasoning of logical equivalence between propositions is grounded in logical reasoning of propositions. One aspect of logical reasoning in mathematics concerns the reasoning of mathematical objects in relation to the truth or falsity of mathematical propositions, and in particular, implications. A mathematical implication is an open sentence of the form "If P then Q" where the antecedent P and the consequent Q are propositions themselves. Since the counterexamples satisfy the antecedent but not the consequent, the order in which the mathematical propositions appear as the antecedent and the consequent in the syntax will determine what constitute as counterexamples. Variants of the implication can be generated by means of negating and/or changing the order of the mathematical propositions in the syntax,(e.g., "If *not* P then *not* Q," "If Q then P," and "If *not* Q then *not* P.")

Durand-Guerrier (2003) proposed that students' should adopt an understanding of the implication as generalized conditionals. Based on this epistemic stance, two propositions are logically equivalent when students determine mathematically that the set of example that satisfies and the set of counterexamples that falsifies each proposition are the same.

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

Logical comparison schemes

Just as students hold schemes of mathematical proofs in proving conjectures (Harel & Sowder, 2007), they also hold logical comparison schemes when determining the logical equivalence between propositions. A student's logical comparison scheme is a cognitive scheme underlying one's process of constructing mathematical justifications to determine whether two or more mathematical propositions are logically equivalent. One type of logical comparison scheme may be characterized as logical reasoning errors due to students' interpretation of the "if-then" syntax based on its everyday meaning (Epp, 2003). However, other schemes that students may demonstrated remain unclear. The research question pursued by this study is: what types of logical comparison schemes do students use to determine the logical equivalence between an implication and its converse?

Method

The data of this study came from the written work of 60 Singapore Secondary Three (equivalent to U.S. 9th Grade, 14 to 15 years old) student, who participated in a larger study about logical reasoning and mathematical proving. The students in this study were taking double mathematics classes at that grade, one introduced basic contents in algebra, trigonometry, arithmetic, rate and proportion, and graphs while the other emphasized algebraic thinking and computations, quadratic and trigonometric functions and graphs, and basic calculus.

Each student attempted one logical equivalence tasks for two separate occasions. In the logical equivalence tasks, students were presented with both an implication (e.g., "Joe says: If the product of two whole numbers is even, then their sum is odd") and its converse (e.g., "Eva says: If the sum of two whole numbers is odd, then their product is even.") spoken by fictitious characters and asked to decide whether both propositions were expressing the same mathematical idea and were logically equivalent. Two different versions of the tasks using similar implications were given to each student. In each version, one of the pair of propositions is mathematically true (Eva's) while the other is falsifiable by counterexamples (Joes'). Every student attempted one version during the first occasion and the other during the second version. In between the occasions, students worked on a set of self-paced training materials that provided work-examples of implications of different logical combinations and mathematical proofs.

Coding and Analysis

A total of 120 students' written justifications were analyzed. A set of external codes was initially generated based on past research, for example, students' scheme of interpreting an implication as a bi-conditional statement (Hoyles & Küchemann, 2002), by analyzing their writing and mathematical reasoning. Generally, students' responses included use of examples and use of mathematical arguments based on properties and inferences followed by a conclusion about the logical equivalence. The type of justification used could be distinguished by its linguistic features. New codes were then generated and then refined based on emerging distinctions between students' justification approaches. Based on the extent to which students demonstrated sophisticated reasoning and their consideration of the examples and counterexamples associated to the implications, a hierarchical order of the coded categories was also developed as a result. 20% of (n = 12) students' written justifications were randomly selected for inter-rater reliability scoring. A second coder, who was a high school mathematics teacher, coded each justification. Seven justifications were coded as "others" since the students either misinterpreted the task or provided irrelevant responses (inter-rater reliability - 79.2%).

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

Findings

Students' logical comparison schemes consisted of four types. Each scheme was demarcated by distinctive characteristics of logical reasoning. They were then ordered hierarchically based on the extent to which examples and counterexamples were considered in their logical reasoning.

Table 1: Students' logical comparison scheme for the implication and its converse

Scheme (Level)	Students' justifications about a pair of an implication and its converse
Order-irrelevance (0)	Conclude that the pair of implications is the same because: • The order of the antecedent and consequent in the syntax did not matter • Both propositions are referring to the same pair of symbolic equations though in different order • Examples are constructed to satisfy the pair exist though one of them may be falsified by counterexamples
Syntax Comparison (1)	Conclude that the pair is different because different mathematical objects were referred by different antecedents
Truth Comparison by examples (2)	Conclude that the pair is different because one is shown true using examples and the other is shown false using counterexamples
Truth Comparison by Proofs (3)	Conclude that the pair is different because one is proved true using deductive proofs and the other is shown false using counterexamples.
Counterexample Comparison (4)	Conclude that the pair is different because their general counterexamples to the implication and its converse are different

At level 0, students exhibited an "Order-irrelevance" scheme underlying their justifications in support of both the implication and its converse being logically equivalent. To that extent, an implication could be interpreted as either a bi-conditional statement (if and only if) or a conjunction proposition ("…and…"). They arrived at this logically invalid conclusion via three verification approaches: syntax, symbolic, or example. In the first approach, students compared the mathematical ideas expressed in the antecedents and consequents of both implications. In the second approach, students re-formulated the mathematical ideas expressed in the antecedent and consequent using systems of equations and variables for comparison. In the third approach, students justified that both implications were the same as if the task was demanding them to verify the propositions and constructed the same or different examples.

At level 1, students exhibited a "Syntax Comparison" scheme underlying their justifications for concluding that both the implication and its converse are logically nonequivalent. They arrived at this logically valid conclusion by comparing the mathematical ideas in the antecedents of the pair and noted that they were different. At level 2, students exhibited a "Truth Comparison by Example" scheme underlying their justifications for concluding the implication and its converse being logically nonequivalent. They arrived at this logically valid conclusion by comparing the truth values of both implications to determine one was true and the other was false. Typically, students constructed a counterexample and concluded that Dewey's (or Joe's) implication was false but used only examples to reason that Gabriel's (or Eva's) implication was "true," the latter of which exhibited an Empirical-based proof scheme (Harel & Sowder, 1998).

At level 3, students exhibited a "Truth Comparison by Proofs" scheme underlying their justifications to reach a conclusion of logical nonequivalence. Similar to the "Truth Comparison by Example" scheme, students compared the truth values of the implication and its converse. Instead of using examples to show one of the implications was true, they constructed a deductive proof. However, such a scheme might be invalid for tasks involving two true but logically nonequivalent implications, such as an implication and its inverse. At level 4, few students exhibited a "Counterexample Comparison" scheme underlying their justifications to arrive at a conclusion of logical nonequivalence. Contrary to the prior two "Truth Comparison" schemes, students did not compare the truth values of the implication and its converse. Instead, they analyzed and compared the kind of counterexamples needed if each implication were false. This usually led to a description of different general counterexamples for each implication. Students would then conclude that the implication and its converse were logically nonequivalent.

Discussions and Conclusions

How do students reason about the logical equivalence between a mathematical implication and its converse? This study revealed various logical comparison schemes underlying students' determination of their logical equivalence. These schemes involved students' proof schemes reported in past studies (Harel & Sowder, 1998), which implied that students' logical comparison schemes were closely knitted to their proof schemes. Also, the schemes assumed a hierarchical order according to the extent of validity in their logical reasoning in terms of the examples, counterexamples, and inferences made.

The above findings exposed the superficiality of students' logical reasoning of variants of implications: little emphasis is given to the counterexamples when analyzing the logical equivalence between implications and propositions. Students need instructional support on how to conceptualize logical equivalence by considering the different cases and the counterexamples related to the implication and its variants. It is important to teach logical reasoning from a semantic point of view, that is, to analyze the examples and counterexamples (Durand-Guerrier, 2003). This is the epistemic first-steps for understanding alternative but equally valid proof methods. Further research on students' logical comparison involving contrapositive and other logical propositions are thus required towards this purpose.

MATHEMATICIANS' ASSESSMENT OF PROOFS WITH GAPS DEPENDING ON THE AUTHOR OF THE PROOF

David Miller

There is little research on mathematicians' assessment of mathematical proofs. The current paper contributes to this literature by reporting on professors' assessment of two mathematical proofs depending on whether a student or colleague authored the proof. By interviewing nine professors, we investigate mathematicians' perceptions of gaps in proofs depending on who authored the proofs. We also investigate whether mathematicians evaluate the gaps in the proofs differently depending on the author and their consistency in this judgment.

Keywords: Reasoning and Proof, Advanced Mathematical Thinking

Proof plays a significant role in the advanced mathematics courses that mathematics majors complete. Proof is the dominant form of pedagogical explanation that professors use to convey mathematical insight to their students (Lai & Weber, 2014; Weber, 2004) and it is the primary way in which professors assess student performance (e.g., Weber, 2001). However, the important issues of how the professor chooses to present proofs in instruction and how they evaluate the proofs that their students present are under-researched areas in undergraduate mathematics education (Mejia-Ramos & Inglis, 2009 and Moore, 2014).

In this paper, we address these issues by exploring the permissibility of gaps in a proof. As proofs would be impossibly long if every logical detail is included (Davis & Hersh, 1981), it is common for mathematicians' proofs to contain gaps (Fallis, 2003) and it is understood that the reader of the proof might have to construct a sub-proof to bridge these gaps when checking the proof for correctness (Selden & Selden, 2003; Weber & Mejia-Ramos, 2011). Mathematics majors' proofs may also contain gaps (cf., Selden & Selden, 2003), perhaps because mathematics majors are uncertain of what requires justification. The goal of this paper is to address four related questions: What are mathematicians' perceptions of gaps in proofs given by professors during lecture? What are mathematicians' perceptions of gaps in the proofs that their students submit for credit? Do mathematicians evaluate gaps differently in these two contexts? How consistent are mathematicians in their judgment?

Related Literature

There is evidence that mathematicians are not uniform in their judgment on how they evaluate gaps in students' and mathematicians' proofs. With regard to student proofs, Inglis and Alcock (2012) and Weber (2008) presented mathematicians with a student-generated proof that contained what Selden and Selden (2003) called "the gap" (because the proof was valid except for a large gap) and asked the mathematicians to judge if the proof was valid. Across the two studies, 14 mathematicians evaluated the proof as invalid, five as valid, and one said he could not judge without further context. Some participants in Weber's (2008) study remarked that the proof would be invalid for students but valid if it were written by a mathematician, as less justification is required in a non-classroom context. These results are consistent with the qualitative study by Moore (2014), who also found mathematicians were not consistent with their evaluations of student-generated proofs and further, that whether a gap in a proof was significant depended on the understanding of who wrote the proof.

With regard to mathematicians' proofs, Inglis et al (2013) presented 110 mathematicians with a proof containing a gap and found substantial variation in their judgment of how the gap affected the validity of the proof. With proof presentation, mathematicians expressed a tension in deciding how much detail should be provided in a proof (Lai & Weber, 2014). Presenting too much detail can mask the more important ideas in a proof and deny students the learning opportunities that arise as they construct sub-proofs, but presenting too little detail can leave students' confused. In a survey asking if bridging a particular gap in a proof improved its pedagogical quality, about 40% of the mathematicians claimed it would while roughly the same number thought bridging the gap made it worse (Lai, Weber, & Mejia-Ramos, 2012).

Methodology

Participants

Nine mathematicians in either pure or applied mathematics who currently work as members of a Research I level University near the East Coast agreed to participate in this study.

Materials and Procedure

Participants met individually with the first two authors for their interview. The interview was broken up into two phases: 1) assessment of three proofs and 2) general open ended probing questions. For the first phase, the interview was further broken up into to two contexts. In **context A**, we told the professor that a colleague had written the proofs in an introduction to proof class on the board during lecture or as a solution handed out to students, and in **context B**, the students in your introduction to proof class hand the proofs in for homework.

The interview began with Context A. The participants were given the first proof and sufficient time to read the proof before discussing it with the interviewers. The interviewers asked the participants the following questions and to explain their reasoning.

1) Do you think that this proof is correct?
2) How would you rate the pedagogical quality or appropriateness of this proof?

This procedure was repeated for two more proofs (third proof won't be discussed for brevity). For Context B, the participants were given the proofs in same order. For proof 1, after sufficient time to re-read the proof, participants were asked two questions and to explain their reasoning.

1) Do you think that this proof is correct?
2) If grading this proof on a 10 point scale, how many points would you give it?

If the participant stated that the proof was correct, but did not give it a score of a 10, then the interviewers probed further for their reasons. At this point, the interviewers gave the participant another student proof for proof 1 without any obvious gaps, and asked the same two questions as before. The participants were given an opportunity to reassess the way they scored the first proof that had a gap and, if the first proof was reassessed, the participants were probed about the reasons for the changes. Next the participants were given both student versions of the second proof and asked the same questions for each proof.

The Proofs

Proofs 1 and 2 from Context A (proofs with gaps) are:

Proof 1. If n^2+1 is a prime number greater than 5, then the digit in the 1's place of n is 0,4, or 6.

Proof: Suppose that n^2+1 *is a prime number greater than 5. Thus* n^2+1 *is odd. Then* n *is of the form* $10k+0, 10k+2, 10k+4, 10k+6,$ *or* $10k+8$. *Then* n^2+1 *is of one of the following forms:*

$$(10k+0)^2+1=100k^2+1=10(10k^2)+1;$$
$$(10k+2)^2+1=100k^2+40k+4+1=10(10k^2+4k)+5;$$
$$(10k+4)^2+1=100k^2+80k+16+1=10(10k^2+8k+1)+7;$$

$$(10k+6)^2+1 = 100k^2+120k+36+1 = 10(10k^2+12k+3)+7;$$
$$(10k+8)^2+1 = 100k^2+160k+64+1 = 10(10k^2+16k+6)+5.$$

The only choices for n*, then, are those numbers with 1's digits of 0, 4, or 6.*

Proof 2. There exists a sequence of 100 consecutive integers, none of which is prime.

Proof: We will show that 100 consecutive integers $101!+2, 101!+3, 101!+4, \ldots, 101!+101$ *contain no primes. Since both terms of* $101!+2$ *contains a factor of 2, 2 is a common factor of* $101!+2$ *and thus* $101!+2$ *is not prime. We can do this for each number in the list. Thus, the sequence of 100 consecutive integers given above contains no primes.*

We refer the reader to the results to see the majority of the gaps in each proof.

Results

Context A

All but one of the participants evaluated Proof 1 as correct, but they had comments about the pedagogical quality or appropriateness of the proof. In referencing the pedagogical quality of the proof, many comments were directed that some of the gaps should be filled or time in class should be spent explaining how to bridge the gap. For example, if presenting this proof Professors A, C, F, and G said they would note the gap from n^2+1 being odd to n being even and Professors B, D, E, G, and H stated that there should be some explanation of why n can take on the stated forms. Professor C and G suggested that their colleague could have said something about why those cases exhaust all possibilities and Professors A, C, D and G pointed out that there should be some explanation of why we can dismiss the forms ending with a 2 and 8.

All of the participants evaluated Proof 2 as correct, and participants had a variety of comments about the pedagogical quality of the proof. Several had comments about the statement that the numbers in the sequence has a common factor. For example, Professors A, F and H stated (or implied) that there should be a general formula showing there is a common factor for each term of the sequence, Professor B said there should be motivation on why we choose this specific sequence, Professor C commented that there should be a few more examples of why it can be factored and should be motivated, and Professor G emphasized that this sequence is only one possible sequence. Professor B thought that the pedagogical quality of the proof would be improved if it had stated a more general sequence involving $k!$. We see that participants focused on different aspects of the proof and there was not a consensus on any one aspect. Hence, at least for these proofs, the mathematicians noted that although gaps in a proof were not sufficient to render them invalid, in these contexts, they found them pedagogically undesirable and were reasonably consistent with their judgment.

Context B

In this context, participants were to assess the proofs with respect to their students producing them for an assignment. During the interview, the participants were asked to grade the proofs on a 0 to 10 scale. All participants were given proof 1 (with gaps – proof 1(A)) and asked questions, followed by the same proof (without gaps – proof 1(B)). This was followed by giving both versions of proof 2 (with and without a gap) and asking the participants questions. All participants assessed the proofs on a 0 to 10 scale (Table 1).

Table 1: Mathematicians' Assessment of Proof with Gaps Authored by Students

	Prof A	Prof B	Prof C	Prof D	Prof E	Prof F	Prof G	Prof H	Prof I	Average
Proof 1(A)	6	9	8	9	9	7	10	6	8	8.00
Proof 1(B)	9	10	10	10	10	9	10	9	9	9.56
Proof 2(A)	10	10	8	10	10	8	10	8	10	9.33
Proof 2(B)	10	10	10	10	10	10	10	10	10	10

The lower average grade and overall scoring on proof 1(A) reflected that this proof had a number of gaps at various places in the proof, causing participants to assess it more critically than proof 2, which only had one obvious gap. When the majority of these gaps were filled in on proof 1(B), most participants were convinced that the proof was completely correct by giving it a 10. This data provides evidence that professors are more critical of students' proofs that have gaps in their reasoning, even if they are not large gaps. In contrast, the grading shows that mathematicians' were not too concerned (grading wise) about proof 2(A) not having a general formula that $\mathbf{101}! + \boldsymbol{j}$ has a common factor of $\boldsymbol{j}$ and were okay with the statement "We can do this for each number in the list." Even though mathematicians' did say that it would be better for the students to spell this out, they did not feel like they needed to take off points because it was evident from the written proof that the "student understood." We found that with Proof 1, most participants would deduct points from Proof 1(A) even though they judged it to be valid. There was substantial variation with how many points they would deduct for this proof as well as if they would deduct any points with Proof 1(B).

PRESERVICE MIDDLE SCHOOL MATHEMATICS TEACHERS' CONCEPTIONS OF PROOF

Merve Arslan | Gözde Kaplan | Çiğdem Haser
Middle East Technical University

Keywords: Reasoning and Proof; Teacher Education-Preservice

Developing students' understanding of proof has become an important task of mathematics educators (Hanna & de Villiers, 2008). Teachers' competence in creating opportunities for their students and enhancing their experiences with proof is considerably affected by their own conceptions of proof (Knuth, 1999). Therefore, this study investigated junior preservice middle school mathematics teachers' (PST) conceptions of proof through their responses on a written task where conceptions of proof referred to conceptions of what made an argument a mathematical proof (Knuth, 1999).

Data were collected from 32 PSTs enrolled in Elementary Mathematics Education program at a Turkish public university. PSTs took algebra and geometry courses, however, geometry courses did not include proof practices. Two mathematical statements (one algebra and one geometry) and three mathematical arguments which were trying to prove these statements were presented for each statement. PST's were asked to determine whether given arguments were valid proofs for the statements or not and explain their reasoning. Their responses were deductively coded according to Cobb's (1986) sources of conviction as *authoritarian* or *intuitive*, where the former addressed an outside authority (such as a book) as the source and the latter an individual's "uncritical belief" (Almeida, 2001, p.56) for "a proposition [which] makes intuitive sense, sounds right, rings true" (Cobb, 1986, p.3). Participants' emphasis on the distinction between empirical and general arguments was validated by the literature, as *generality* was considered as an important criterion of proof (Balacheff, 1988).

Findings showed that PSTs mainly relied on *intuitive* and *authoritarian* reasons and general terms in the argument while explaining their reasoning for accepting an algebraic argument as a proof. Some participants stressed that mathematical proofs should not be exemplifying specific cases. PSTs employed *intuitive* reasons and idea of *generality* in geometry task. However, they did not mention *authoritarian* reasons.

PSTs relied on similar reasons for evaluating both algebraic and geometric arguments. They were able to transfer their understanding of proof formed in algebra courses to the case of geometry. Not relying on *authoritarian* sources of conviction in geometry task might be due to the lack of experience of a geometry content course in which they would learn about authorities' practices and preferences. Mathematics content courses could be enhanced to have more influence on PSTs' conceptions of proof.

ONE MATHEMATICS TEACHER'S ARGUMENTATIVE KNOWLEDGE CONSTRUCTION IN AN ASYNCHRONOUS GRADUATE COURSE

Due to perceived "convenience," 100% online courses (synchronous and asynchronous) are progressively becoming more popular, particularly among professionals interested in advancing their education. In-service teachers are no exception. In asynchronous courses one of the most commonly used ways in which students interact with each other is via discussion board posts. Marttunen and Laurinen (2001) argued that since learners have more time and flexibility to formulate their arguments, asynchronous experiences such as discussion board posts might better facilitate knowledge construction.

In this poster presentation, a partial report of a larger study, we will share one in-service mathematics teacher's knowledge construction process based on the analysis of his posts on the discussion board in a graduate level online geometry course. In the larger study, we used Vinner's (1997) framework to identify pseudo-conceptual and pseudo-analytical thought processes of participants in this course. Kevin (pseudonym), the focus student of this poster presentation, showed predominantly pseudo-analytical thought processes in his coursework through the 8-weeks semester. To better understand his knowledge construction process and identify repeated practices, we used Weinberger and Fischer's (2006) framework to analyze his engagement on the discussion board. According to this framework there are four dimensions that may "extend and refine our understanding of what kind of student discourse contributes to individual knowledge acquisition" (p. 73): participation, epistemic, argumentative, and social mode of co-construction.

Our preliminary results show that in the participation dimension Kevin is one of the most active participants. However, in epistemic dimension his activities often fell into the category "construction of inadequate relations between conceptual and problem space" (Weinberger & Fischer, 2006, p. 74). He tends to argue "simple claims" and within social modes dimension he often "accepted the contributions of the learning partners in order to move on with the task" (Weinberger & Fisher, p. 77). In this presentation, we will share excerpts in each category and propose some strategies to engage learners in focused activities that will enable them to develop relations between prior knowledge and problem space with grounded claims.

CONSTRUCTING PROBLEM-SOLVING STRATEGIES DURING COLLABORATION WITH PEERS OF EQUAL AND MORE ADVANCED KNOWLEDGE

Sarah A. Brown
University of Wisconsin-Madison
sbrown23@wisc.edu

Martha W. Alibali
University of Wisconsin-Madison
mwalibali@wisc.edu

Keywords: Problem Solving; Elementary School Education; Cognition

Past research has suggested that when two students who have partial but complementary knowledge of a concept work together, they can build a more advanced understanding of the concept (Ames & Murray, 1982). Schwarz, Neuman, and Biezuner (2000) suggest that this effect is most prevalent when the two students have different strategies and when they discuss their disagreement. The current study investigated how collaboration with more advanced peers and similarly skilled peers affects students' problem solving in the domain of mathematical equivalence, specifically with problems of the form 3 + 4 + 5 = 5 + __.

Eight pairs of second and third graders completed an individual pretest of four problems prior to working together to solve two additional problems. Finally, participants completed an individual, four-problem posttest. Of the eight pairs, four consisted of one partner who solved all pretest problems incorrectly (i.e., was nonequivalent) and one who solved most of the pretest problems correctly, and four consisted of two partners who were both nonequivalent at pretest.

Three (75%) of the four participants paired with a more skilled peer solved at least one problem correctly at posttest. In comparison, four (50%) of the eight participants paired with a peer of similar ability solved at least one problem correctly at posttest. When a participant adopted a correct strategy, the generation of that correct strategy occurred during collaboration. In all nonequivalent-nonequivalent pairs, if one student improved, so did his or her partner. This suggests that particular aspects of the interactions led to learning.

We investigated how the sole equivalent-nonequivalent interaction that did not lead to learning differed from the other equivalent-nonequivalent interactions. We found that this particular interaction was unusual in that the two children barely spoke.

Next we investigated how two interactions between two nonequivalent students led to learning for both partners. In three of four collaborations, one of the partners read all or part of the problem aloud, possibly highlighting the atypical location of the equal sign. This led to the generation of a correct strategy. In two of these partnerships, both students adopted the correct strategy, but in the third, the more dominant child dismissed the correct strategy in favor of an incorrect one. When neither student read the problem, the pair did not generate a correct strategy.

In sum, pairing a nonequivalent student with a more advanced peer was more beneficial than pairing two nonequivalent students together, but two nonequivalent students frequently did generate correct strategies during collaboration when they read the problems aloud. Ongoing work examines whether this pattern holds in a larger sample.

IDENTIFYING AND PRIORITIZING UNKNOWNS IN MATHEMATICAL MODELING

Jennifer A. Czocher

According to the Common Core State Standards for Mathematics (CCSSM), mathematical modeling serves as an essential link between classroom mathematics and decision making in everyday life (National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010). Learning to do mathematical modeling presents challenges to students and educators because it requires coordination of mathematical and real world knowledge sources. Successful modeling requires students to identify and prioritize unknown information when constructing a specific model, such as those presented by open beginning and/or open middle problems. As such, it is important to understand student thinking during mathematical modeling tasks, especially when they are open to interpretation.

Open-beginning questions are defined as those which have no clear starting point and which do not cue a method of solution (Monaghan, 2009). Open-middle problems are those that can be solved in a variety of ways and which may have missing or ambiguous data (Sheffield, 2006). Where standard word problems tend to begin with an idealized, real-world situation that is couched in mathematical terms (Gould, Murray, & Sanfratello, 2012), open-beginning and open-middle questions challenge the student to assemble a strategy using his or her own mathematical toolkit, problem solving skills, and knowledge of the real world situation.

Using a process view of Mathematical Modeling (Blum & Leiβ, 2007), we explored how students identified and prioritized variables and conditions when solving open-beginning and open middle problems. We conducted task-based interviews with high school students. The students readily identified variables and constraints common to school mathematics (Watson, 2008) but had difficulty determining which or how they should be incorporated into a mathematical model and which should be ignored. Moreover, sometimes authentic real-world factors were excluded altogether. Analysis suggests that students may benefit from additional support in prioritizing variables, conditions, constraints, and assumptions so that they may be articulated in a mathematical representation.

STUDENTS VACILLATE BETWEEN THE F-C-S LEVELS OF GENERALITY

José Francisco Gutiérrez
University of California, Berkeley
josefrancisco@berkeley.edu

Keywords: Algebra and Algebraic Thinking; Cognition; Equity and Diversity; Learning Theories

Introduction & Background: Previous semiotic–cultural research on student mathematical reasoning (Gutiérrez, 2013; Radford, 2003) has identified three modes of action—Factual, Contextual, and Symbolic ("F-C-S"), representing different levels of generality—that students appropriate as means of dealing with pattern-generalization problems. The F-C-S framework, in its current formulation, might suggest that students monotonically progress from one mode to the next, yet recent findings indicate this is not necessarily the case. To help clarify the issue, this study asks: How do students *navigate* the F-C-S levels of generality?

Methods: The empirical context is a year-long ethnography of a high-school classroom community, conducted over the 2013-2014 school year. This poster presents the analysis of three students' situated reasoning during one particular pattern-finding problem involving geometric objects called Spiralaterals. Data consist of a 35 min. span of classroom video. I produced and analyzed a detailed transcription of students' verbal, gestural, and other semiotic actions as they referred to mathematical objects and attempted to construct generalizations. All student utterances were coded for their semiotic mode, and I analyzed whether each utterance reflected a generalization *to* a particular mode or merely a reiteration *in* the mode (Gutiérrez, 2013).

Results & Discussion: Students' reasoning *vacillated* between the F-C-S modes (Figure 1).

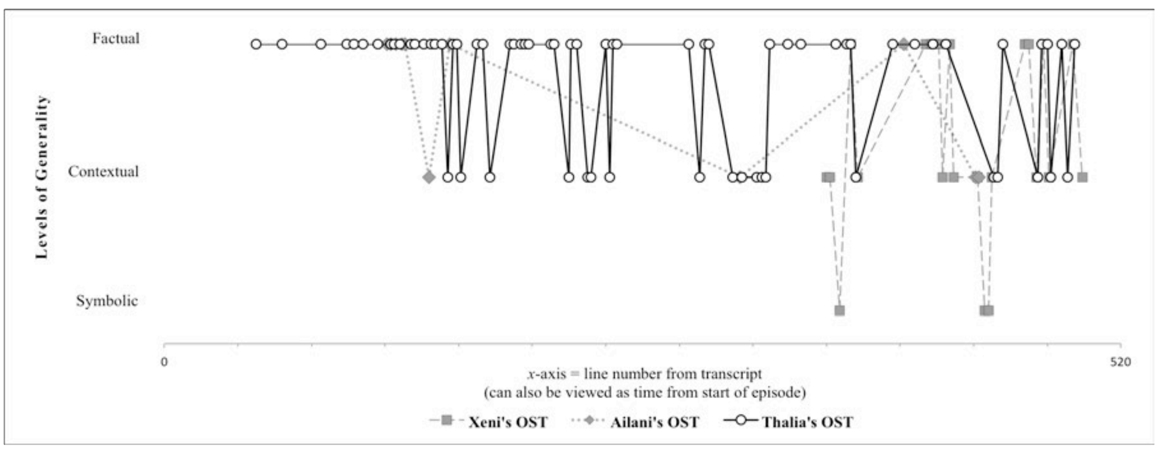

Figure 1. Juxtaposed Student Ostensive Semiotic Trajectories.

Chi-square analysis of total student utterances revealed a difference between the students with respect to their participation within each of the semiotic modes ($X^2(4, N = 103) = 14.78, p<0.01$). The Factual and Contextual modes made up the bulk of sense-making activity and were crucial for all three students' articulating generalizations. However, only Xeni operated in the Symbolic mode, which in situ resulted in a social-mathematical status hierarchy; further studies closely examine this semiotic-linked power dynamic and its impact on student agency and identity.

STEM movement calls for a development of cross-disciplinary education integrating mathematics, science, technology, and engineering. However, a critical issue is that there is no understanding on how each discipline relates to another in K-12 education (Dugger, 2010). Dugger's discussion of STEM education necessitates further studies on interconnectedness between disciplines to build STEM curriculum. This research investigated relationships of cognitive skills used in learning of mathematics and science.

Table 1: Hypothesized relationships between cognitive domains

Linear Regression	Reasoning				Applying		
Model	R1	R2	R3	R4	A1	A2	A3
Dependent (Mathematics)	Analyze	Generalize/ Specialize	Integrate/ Synthesize	Integrate/ Synthesize	Select	Represent	Model
Independent (Science)	Analyze	Generalize	Integrate/ Synthesize	Draw Conclusion	Find solution	Interpret information	Use model

A data analysis began with establishment of theoretical relationships based on descriptions given by TIMSS 2011 assessment framework (see Table 1; Mullis et al. 2009). Assessment data of seventh and eighth graders from 2006 to 2010 in Iowa Tests for Basic Skills (ITBS) were collected. Generalized DINA (GDINA; de la Torre, 2011) was used to generate individual students' probabilities to master cognitive skills, which allows observing relationships of cognitive domains. Based on the results, correlations and linear regression equations were applied to describe relationships (see Table 2).

Table 2: Results of linear regression models

Grade		R1	R2	R3	R4	A1	A2	A3

STUDENTS' REASONING AND SENSE MAKING ON CONCEPTS OF VARIABLES

Ruveyda Karaman
University of Missouri
rk5f7@mail.missouri.edu

William W. Deleeuw
University of Missouri
wwdg24@mail.missouri.edu

Keywords: Reasoning and Proof; Algebra and Algebraic Thinking; Assessment and Evaluation

Algebra has an important role for students' mathematical learning. Expressions and equations are two algebraic contexts that students have to start learning from the 6^{th} grade (CCSS, 2010). Reasoning and sense making about mathematical contexts, including algebraic topics, are very important habits that secondary level students should develop in Algebra classes (Rasmussen et al., 2011). To understand students reasoning and sense making abilities on algebra problems, especially problems asking the behavior of variables in expressions and equations, the relationships between and among equations/expressions, and the effect of varying the value of the variable, I examined 9^{th} grade students responses on conceptual measures. Results revealed several patterns in solution methods that give a clue about the nature of students reasoning and sense making on algebra problems, hence their understanding on the basis of why a computation or algorithm works.

Participants were 300 9^{th}-grade students from different high schools in three states in the U.S. Participants included students with and without disabilities. Data collection consists of assessment forms (concept of variable forms) that Algebra students took at the end of school semester. Conceptual assessments has been linked to the Common Core State Standards, from grade 6 through high school grades. Concept of variable form includes 19 probes with 11 multiple-choice and 8 open-ended algebra problems. As an illustration, an example for multiple-choice item is "Carl simplified $6h - h$. He said an equivalent expression was $5h$. Do you agree with Carl?

A. Agree, because $6h - h$ can be factored as $h(6 - 1)$ to simplify it.
B. Disagree, because h is a common term in both so $h - h$ is 0, that leaves 6.
C. You cannot tell if he is correct because you do not know the value of h.
D. Carl is only correct if h is a positive number." and an example for open-ended item is "Bart said, '$w + 3$ is less than $5 + w$.' Circle one: Always true Sometimes true Never true
Explain your answer." Students responses were scored based on their correct choices on multiple-choice answers and their true, partially true or wrong explanations on the open-ended items. Data analysis focused on the open-ended items to investigate the nature of students' reasoning and sense making on algebraic concepts.

Findings show that students have a pattern of the misconceptions on open-ended algebra problems. For example, more than half of the students think that they cannot compare two expressions (in above question) because they do not know the value of the variable. This study identifies several misconceptions that students have on the concepts of variables, equations, and expressions.

CONSISTENT OR INCONSISTENT STANDARDS? PRE-SERVICE SECONDARY MATHEMATICS TEACHERS' EVALUATIONS OF MATHEMATICAL ARGUMENTS

Yi-Yin Ko
Indiana State University
Winnie.Ko@indstate.edu

Jessie Stark
Indiana State University
jstark4@sycamores.indstate.edu

Keywords: Reasoning and Proof; Teacher Knowledge, Teacher Education-Preservice

Current reforms have called for a stronger emphasis on proof across content domains in secondary school mathematics (Common Core State Standards for Mathematics, 2010). However, many pre-service secondary mathematics teachers (PSMTs) have considerable difficulty determining an argument's validity (e.g., Bleiler, Thompson, & Krajčevski, 2013) and constructing their own proofs (Ko & Knuth, 2009). To date, less attention has been given to PSMTs' criterion used in evaluating the validity of their own arguments and given mathematical arguments for the same problems in the domains of algebra, geometry, and number theory. To address the research gap, this study examines criteria that PSMTs perceive for determining whether or not their own argument and a given argument are convincing and are mathematical proofs in these content domains.

This study had 14 PSMTs from one Midwest University in the United States, all of whom had taken Calculus I, II, III, as well as an introduction-to-proof course. The instrument used in the study included three mathematical statements and six arguments adapted from the existing literature. The participants were asked to complete a two-part semi-structured interview. The first part of the interview focused on PSMTs' own proof productions along with their validations. The second part of the interview focused on PSMTs' validations of given arguments. Our data source included transcriptions of PSMTs' interviews and their written work. To analyze criteria that PSMTs perceived for discerning the validity of their own work and given arguments, we used Knuth's (2002) taxonomies of convincing arguments and mathematical proofs. The results of the study showed that some PSMTs tended to use different criteria to decide if their own arguments and given arguments were convincing and were mathematical proofs. Although all PSMTs had successfully passed an introduction-to-proof course, they still experienced difficulty identifying if a given argument was a mathematical proof across content domains.

CONNECTING COLLEGIATE MATHEMATICS TO SCHOOL MATHEMATICS: PROSPECTIVE SECONDARY MATHEMATICS TEACHERS' CONSTRUCTION OF ABSTRACT MATHEMATICAL CONCEPTIONS

Younhee Lee
The Pennsylvania State University
yul182@psu.edu

Keywords: Advanced Mathematical Thinking; Teacher Education-Preservice; Teacher Knowledge; Post-Secondary Education

Prospective Secondary Mathematics Teachers (PSMTs) have been typically required to take a significant number of collegiate mathematics courses to be qualified to teach school mathematics, but neither was there a strong positive correlation between student achievement and the number of collegiate mathematics courses taken by their teachers (e.g., Begle, 1979) nor did teachers seem to conceive the connections between collegiate mathematics and the mathematics they teach (e.g., Zazkis & Leikin, 2010). This contradictory evidence raises questions about the ways in which PSMTs develop their knowledge in collegiate mathematics.

This study posits that engaging in abstraction process within the context in which PSMTs can actively reflect on their school mathematics knowledge is necessary for PSMTs to connect collegiate mathematics and school mathematics. By adopting a theoretical framework 'Abstraction in Context' (Dreyfus, Hershkowitz & Schwarz, 2015), tasks for teaching interviews were designed so that PSMTs can engage in abstraction process through successions of activities and continuous transformation of their knowledge. The purpose of this study is to investigate PSMTs' abstraction process and their perceived connections in a series of teaching interviews. The data consist of teaching interviews with four PSMTs. Each PSMT participated in five 90-minute interviews in which they constructed and consolidated their knowledge of polynomial ring, irreducible polynomial and the prime factorization of polynomial building on what they had previously known about polynomials and factoring polynomials. The RBC+C model (Dreyfus et al., 2015) was used as an analytical lens to understand how PSMTs constructed abstract mathematical conceptions and connected collegiate mathematics and school mathematics.

PSMTs in this study showed their initial tendency to restrict their conceptions of factoring to the 'factoring by hand' rather than encompassing factoring over complex numbers as well. Through constructing their conceptions of an irreducible polynomial and polynomial ring, it seemed that not only were they able to recognize some applicability of these abstract mathematical notions to school mathematics context but also integrate and unify some school mathematics ideas in a vertically reorganized way.

DEVELOPING MATHEMATICAL PROCESSES THROUGH COMMERCIAL GAMES

P. Janelle McFeetors
University of Alberta
janelle.mcfeetors@ualberta.ca

Keywords: Elementary School Education; Instructional Activities and Practices; Reasoning and Proof; Geometry

Games have been recommended as a way for students to develop a meaningful understanding of mathematical ideas before they move toward abstractions (Diénès, 1971). Ernest (1986) identified three educational uses of games in mathematics class: gaining skill-based fluency, developing conceptual understanding, and refining problem solving approaches. Limited systematic research addresses the use of commercial board and card games that teachers and parents are already playing with their children, which contain opportunities to experience mathematical ideas. The poster addresses the research question: What mathematical learning do students demonstrate through their experiences with games and with each other?

Using Deweyan-inspired action research (Stark, 2014), experience is viewed as activity transformed through thoughtful reflection (Dewey, 1938/1997). The aim, methodologically, is transformative practice by cyclically clarifying meaning of (inter)actions. Theoretically, the dialectic of students' game play and encouragement to *notice* (Mason, 2002) their mathematical thinking in action contributed to understanding their growth in mathematical learning.

Located in two urban elementary schools, 65 students in grades 4 to 6 volunteered to participate. Students explored games such as *Gobblet Gobblers*, *Othello*, *Quartex*, and *Set*. Students' data included photographs, pictorial and written responses to reflective prompts, and individual interviews. Field notes and teacher interviews enriched the data analysis as multiple perspectives were included to assess fit between constructed meaning and experiences.

Results indicate an additional intention of incorporating commercial games in mathematics class: the crucial development of mathematical processes. *Communicating* mathematically was inherent in negotiating and defending specific plays, and was refined as students developed language for moves and saw their peers as an authentic audience. *Reasoning* through informal deductive statements emerged as students convinced themselves and others of best moves. *Visualizing* improved through first physically testing playing pieces on game boards toward an ability to predict moves in advance or find the best spot to place a game piece. Additionally, the students' development within the three processes was interconnected as their ability to see logical moves were verbalized to peers. I will use photographs and children's statements to illustrate these mathematical processes in the presentation. Opportunities for children to develop mathematical processes are imperative if these processes are to be used to understand specific mathematics content. Results of this project respond to two enduring challenges in mathematics education: 1) to provide opportunities for children to experience mathematical ideas so that they can build conceptual understanding through formal instruction; and, 2) to invite parents to re-engage in children's mathematical learning through informal game play at home.

PRECALCULUS STUDENTS' PROBLEM SOLVING PROCESS ON A CALCULUS-CONCEPT TASK

Yuliya Melnikova
Texas State University
y_m26@txstate.edu

Christina Starkey
Texas State University
cs1721@txstate.edu

Keywords: Problem solving; Modeling; Post-Secondary Education; Advanced Mathematical Thinking

Introduction. In 2004, the MAA's Committee on the Undergraduate Program in Mathematics (CUPM) recommended that all mathematics courses should help students develop "analytical, critical reasoning, problem-solving, and communication skills". Calculus persists as a roadblock course and might be the first course in which some students are asked to conceptually reason. To investigate precalculus students' preparedness for the type of reasoning required of them in calculus, this study examined precalculus students' ability to reason given a mathematical modeling task based on calculus concepts which could be solved using previous knowledge and problem solving skills.

Methods. Five STEM major precalculus students participated in the study. During a task-based interview, the participants were asked to graphically represent the height of water in a bottle as a function of the amount of water in the bottle without numerical values, units, and rates given. The interviews were open-coded to explore common themes in the students' reasoning and their ability to work through the task, and coded according to Carlson and Bloom's (2005) problem solving framework to illuminate how students progressed through the problem solving cycle.

Results. Consistent with Carlson and Bloom's (2005) framework, the students repeated the planning, executing, and checking cycle. However, the checking phase was weak, and their problem solving was not as refined as the mathematicians' in Carlson and Bloom's study. All five students recognized the increasing relationship between height and amount of water, and that the shape of the bottle would result in a non-constant rate of change in height. However, students struggled to correctly model the non-constant rate of change graphically; only one produced a correct graph. Two of the students drew concave up or exponential graphs, and the other two drew piece-wise linear graphs. The results show that students had difficulty understanding exactly how the shape of the bottle would affect the rate of change. This could suggest a lack of conceptual understanding, which could hinder the students' success in a Calculus I course. Implications for teaching suggest a need for earlier activities exposing students to nonlinear rates of changes and covariation in order to prepare them for advanced mathematical reasoning.

TEACHERS' AND THEIR STUDENTS' ENGAGEMENT IN MATHEMATICAL PRACTICES

Samuel Otten
University of Missouri
ottensa@missouri.edu

Christopher Engledowl
University of Missouri
ce8c7@mail.missouri.edu

Keywords: Teacher Knowledge; Mathematical Knowledge for Teaching; Reasoning and Proof

Mathematical habits of mind are both a means and an end of mathematics education (Lim & Selden, 2009) and learning can be viewed as the process of coming to participate in these mathematical ways. In the U.S., certain Standards for Mathematical Practice (SMPs) have been codified in the *Common Core State Standards* (2010). To better understand the challenges of enacting these SMPs, we examined the relationship between teachers' own engagement in SMPs and the ways in which they provide opportunities for their students to engage in SMPs. Results take the form of cases of two secondary mathematics teachers—Mr. Forrest and Mr. Mingley—who were similar in terms of exhibiting SMPs while working on mathematical tasks themselves but who were different in terms of the implementation of SMPs with their students.

Data for the teachers' engagement in SMPs consisted of written work and recordings of discourse from eight teachers (grades 5–12), including Mr. Forrest and Mr. Mingley, as they worked on 5 mathematical tasks. Classroom data involved three lesson observations each for Mr. Forrest and Mr. Mingley. Analysis involved identifying instances of the SMPs in both data sets, followed by qualitative coding of patterns within those instances. Within the classroom data, tools from discourse analysis (Truxaw & DeFranco, 2008) were also used to identify the nature of students' participation in the SMPs. The two cases were then constructed by looking across all instances of Mr. Forrest or Mr. Mingley engaging in SMPs during the teacher tasks and characterizing general themes evident in their classroom observation data.

Findings reveal that Mr. Forrest and Mr. Mingley conjectured, generated arguments, and criticized others' justifications. They also used some SMPs in conjunction, such as attending to precision as a way of refining conjectures. Although both teachers exhibited SMPs themselves, there were differences in their students' engagement in the SMPs. In Mr. Forrest's class, his mathematical tasks required students to explicitly engage in SMPs and, during the implementation, the students were held responsible for engaging in SMPs. In Mr. Mingley's class, however, SMPs occurred regularly but typically involved Mr. Mingley preparing opportunities for the SMPs, only to end up directly modelling the SMPs for the students.

This study contributes to the ongoing discussion about implementing the SMPs. Although teacher facility with the SMPs may be a necessary condition for successful implementation, the case of Mr. Mingley shows it is not sufficient. The study also prompts discussion about the potentially complementary opportunities of students (a) witnessing SMPs from a more knowledgeable other and (b) actually engaging in SMPs themselves.

A growing number of researchers have indicated that students' quantitative reasoning is important for their engaging in modeling, problem solving, and generalizing (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Ellis, 2007; Thompson, 2011). More recently, researchers have argued for increased attention to the images students construct when modeling and reasoning quantitatively. Moore and Carlson (2012) illustrated that students' mental images of a situation influenced how they related quantities of that situation. Students often held images of the situation inconsistent with those the researchers expected, but the students' solutions were compatible with the students' images of the situation. Other researchers (Castillo-Garsow, Johnson, & Moore, 2013; Thompson, 2011) argued that students' images of situations and their envisioning how quantities change in tandem are intrinsically related. Addressing the call for more attention to students' images of dynamic situations, we used semi-structured task-based clinical interviews (Goldin, 2000) with 10 students to explore the images students constructed as they made sense of the relationship between the height and surface area of a cone as the cone's height increased and decreased in a proportional relationship with the cone's radius.

In this poster, we characterize the images students relied on when imagining the cone growing and shrinking. Two of ten students solely relied on a general image of the cone changing 'smoothly' with respect to time. The other students developed more sophisticated images with four students using 3D-images, three students using 2D-images, and one student using a combination of the two. We also discuss the implications of the students' images with respect to their determined solutions. Collectively, our results indicate that the students developed idiosyncratic images that greatly influenced how they solved the problem. An implication of our findings is that teachers need to be attentive to students' images of situations in order to support students in reasoning quantitatively as they model these situations.

AN EXPLORATORY ANALYSIS OF PRE-SERVICE MIDDLE SCHOOL TEACHERS' MATHEMATICAL ARGUMENTS

Vecihi S. Zambak
Marquette University
vecihi.zambak@marquette.edu

Marta T. Magiera
Marquette University
marta.magiera@marquette.edu

Keywords: Middle School Education; Teacher Education-Preservice; Learning Trajectories

Calls for increased focus on mathematical argumentation in school mathematics are critical for teacher educators charged with preparing prospective K-8 teachers (PST) to foster mathematical argumentation in their future classrooms. This is because research suggests that middle school years are crucial for students to gain proficiency in creating and critiquing mathematical arguments. Supporting PSTs' strong understanding of what it means to *do* mathematics necessitates that teacher preparation programs place an emphasis on mathematical and pedagogical preparation that facilitates PSTs' strong understanding of mathematical argumentation and proving in school mathematics.

Based on problem-based interviews with 22 K-8 PSTs, we report on PSTs' ability to create mathematical arguments in the context of problems that involve reasoning and generalizing about patterns. The research question was: *How do pre-service middle school teachers reason about change in problem situations that require analyzing patterns and what is the nature of the arguments they create?* We selected this curricular topic because the reasoning about change and patterns is essential for learning concepts related to functions, algebraic thinking, and measurement. Records of the interviews were analyzed qualitatively (Strauss & Corbin, 1998) to first identify the specific problem solution trajectory. Then, using Toulmin's argumentation framework (2003) as a guide, we examined the structure of arguments pre-service teachers generated. Due to the space limitation, in this proposal, we only report the selected results from one task where participants were asked to generalize about the number of matchsticks to make a rectangle made up of R-rows and C-columns.

The vast majority of the PSTs reasoned about this task by first noticing the invariant characteristics of the given structure and focusing on horizontal and vertical change in the number of sticks. In the process of initially limiting the number of rows to only one and "unfolding" the consecutive numbers of columns they were able to develop the correct rule e.g., $4+3(c-1)$, or $4 + 3(r-1)$ if reasoning about change in rows, and later account for change in the second variable arguing that the number of sticks in *any* figure could be determined by a rule $4 + 3 (c-1) + [3 + 2(c-1)] (r-1)$. Overall however, they demonstrated limited ability to justify *why* their rule works. Most of those PSTs who used this strategy did not articulate clear links between the context of the problem and their rules. Instead, they supported the validity of their claims with specific examples (43% used one example, 21% two or more specific cases). Only a few were able to contextualize their rules using specific characteristics of the problem they solved. While in this proposal we only highlight selected findings from one task, this study documents reasoning paths PSTs at the beginning of their teacher education program generate and contributes to the knowledge of PST's ability to create mathematical arguments.

A FRAMEWORK FOR ANALYZING INFORMAL INFERENTIAL REASONING TASKS IN MIDDLE SCHOOL TEXTBOOKS

Maryann E. Huey
Drake University
maryann.huey@drake.edu

Christa D. Jackson
Iowa State University
jacksonc@iastate.edu

Building upon the work of Zieffler, Garfield, DelMas and Reading (2008) and others, we developed a framework for assessing informal inferential tasks in middle school mathematics textbooks. The framework both embodies the key recommendations for developing informal inferential reasoning and captures common trimming attributes, which lower the cognitive demand and opportunities to learn. Researchers believe that introducing inferential reasoning informally will assist students later in developing argumentation structures necessary for understanding formal methods (Wild & Pfannkuch, 1999). Inferential reasoning has long been a key learning goal of statistics education and provides access to viewing knowledge of core statistical concepts and reasoning about data distributions. Tools are needed to assess the fidelity of tasks in alignment with both national and research-based recommendations.

Keywords: Curriculum Analysis; Data Analysis and Statistics; Middle School Education

Background

Inferential reasoning has served as a unifying theme and goal of introductory statistics courses at the tertiary level for a number of years (Konold & Pollatsek, 2002). With the recent emphasis of statistics as a core component of the middle and secondary mathematics curriculum, the role of inference is gaining in prominence (NGA Center & CCSSO, 2010). Current recommendations for middle and secondary statistics education outlined in the *Guidelines for Assessment and Instruction in Statistics Education [GAISE]* report support the introduction of informal inferential reasoning at the middle school level and formalizing inferential reasoning during the secondary years (Franklin et al., 2007). These recommendations are evident in the articulation of the Common Core State Standards for Mathematics (CCSS-M) adopted throughout the United States (NGA & CCSS0, 2010), but not explained in an equally detailed manner. In response, middle school textbook publishers quickly produced curricular materials intended to align with the need for informal inferential reasoning in grade 7. Yet, many teachers, especially at the middle school level, do not have experience teaching informal inference. We argue that guidance is needed on how to assess the fidelity of inferential reasoning tasks contained within these curricular materials. While this may seem to be a narrow focus, inferential reasoning is a key learning goal of statistical education and incorporates knowledge of core statistical concepts and reasoning about data distributions. In this paper, we describe a framework we developed for characterizing informal inferential reasoning tasks based on recommendations of statistics education research, and then share how we analyzed tasks from three widely available seventh grade textbooks.

Informal Inferential Reasoning

In order to define and situate informal inferential reasoning for the purposes of this paper and framework, two broader concepts must be described: statistical inference and statistical reasoning. *Statistical inference* refers to moving beyond the data at hand to make decisions about some wider universe, taking into account that variation is everywhere and conclusions are therefore uncertain (Moore, 2004). *Statistical reasoning* is defined "as the way people reason with statistical ideas and make sense of statistical information" (Garfield & Ben-Zvi, 2004, p. 7). Hence, *inferential reasoning* is the way people make sense of statistical ideas and information with the goal of generating a conclusion that extends beyond the data at hand.

Generally, two types of problems fall under the broad definition of inferential reasoning: (a) generalizing from samples to populations, and (b) comparing samples to determine significant differences in populations (Garfield & Ben-Zvi, 2008). While students can address these problems with formal hypothesis tests, they can also formulate responses based on informal approaches that do not involve set procedures, but rather coordination of prior knowledge, statistical concepts, and the context of the problem. *Informal inferential reasoning* allows students in upper-elementary grades to engage and successfully draw inferences (Stohl & Tarr, 2002; Watson, 2002; Watson & Moritz, 1999).

Informal Inferential Reasoning Task Framework

Building upon the work of Zieffler, Garfield, DelMas and Reading (2008) and others, we developed a framework for assessing informal inferential tasks in middle school mathematics textbooks that both embodies the key recommendations for developing informal inferential reasoning and captures common trimming attributes, which lower the cognitive demand and opportunities to learn (See Table 1). While the recommendations from leaders in statistics education and other disciplines provide a comprehensive list of requirements for inferential reasoning tasks, our framework acknowledges a spectrum within each task dimension (i.e., inference, ill-structured, open-ended, context, and visual representation) that reveals nuances in tasks and ultimately pedagogical choices made by textbook authors and publishers that directly impact students' opportunities to learn

Table 1: Informal Inferential Reasoning Task Framework

Task Dimension	Low (Deterministic) - Limited/No reasoning required	Medium – Some inferential reasoning required	High – Inferential reasoning required
Inference	A population is utilized or the type of the data is unspecified. No requirement is needed to infer beyond data provided.	Sample data is utilized with the acknowledgement of variation.	Sample data is utilized with the acknowledgement of variation, and students are required to infer beyond the data at hand.
Ill-Structured	A prescribed procedure is desired with specified descriptive statistics computations.	A procedure exists that can be adapted in order to coordinate core statistical concepts with a choice of statistical measures.	Coordination of core statistical concepts is required to fully address the task without a prescribed solution path.
Open-Ended	Only one acceptable or "correct" solution exists.	Multiple numerical solutions with similar interpretations are possible or limited numerical solutions exist with a variety of possible interpretations.	Multiple numerical solutions are possible and a variety of conclusions.
Context	The task can be addressed fully by removing the context.	The context is helpful for generating an inference, but not required.	The problem context must be considered in order to generate a viable inference.
Visual Representation	Visual representations are neither provided nor encouraged.	Visual representation are provided or created, but mask the original data.	Raw data is provided and organized in graphical representations.

and reason about statistics. For each task dimension, we created a tiered set of categories based on the level of inferential reasoning required for the task: low (deterministic), medium, and high.

Inference

The first task dimension, inference, relates to how sample and population data are presented and utilized in tasks. Based upon a synthesis of research from educational psychology, science education, and mathematics education, statistics educators recommend informal inferential reasoning tasks require students to:

> 1) make judgments, claims, or predictions about a population based on samples, but not using formal statistical procedures or methods, 2) draw on, utilize, and integrate prior knowledge (formal or informal) to the extent that this knowledge is available, and 3) articulate evidence-based arguments for judgments, claims, or predictions based on samples. (Zieffler et al., 2008, p. 46-47).

A key facet of these recommendations relates to the need for students to experience and think about the differences between complete populations and samples. If a complete population is provided or the source of the data is unknown, then the task does not require inferential reasoning and is reduced to simply computing the differences in measures of center or another statistic of interest to draw a concrete and certain conclusion. Only through sample data is uncertainty introduced, which is the nature of statistics versus a deterministic mathematical problem.

Ill-Structured

Ill-structured tasks require informal reasoning versus applying formal approaches. Reasoning effectively to generate informal inferences requires prior knowledge of core statistical ideas, such as measures of center, variation, skew, outliers, shape of data distribution, and sample size, and an understanding of the relationships between them (Garfield & Ben-Zvi, 2007). Many statistical questions require coordination of both a measure of central tendency, such as mean or median, with a measure of variation such as range, interquartile range, or mean absolute deviation (MAD). In addition, middle school textbooks include tasks that require coordinating and comparing two measures of center, two measures of variation, or other combinations.

The second criterion for this dimension relates to the extent that the task is either well- or ill-defined in nature. Informal approaches to reasoning are needed when problems either do not align with known solution methods or are presented before students possess the knowledge of such methods. One would expect that students possess varying repositories of knowledge, which would result in a diversity of solution strategies when administered similar inferential reasoning tasks. This knowledge might consist of prior statistical knowledge, life experiences related to the context, and informal reasoning skills. As Means and Voss (1996) state, “Informal reasoning assumes importance when information is less accessible, or when the problems are more open-ended, debatable, complex, or ill-structured, and especially when the issue requires that the individual build an argument to support a claim” (p. 140).

When students approach ill-structured problems, they generally progress through four phases: problem structuring, preliminary design, refinement, and detailing (Goel, 1992). As ideas are flushed out in more detail, students become more committed to their solution strategy. The omission of one correct answer or lack of problem constraints is the key factor for encouraging informal reasoning. Watson and Moritz (1999) describe an iterative process that students embarked upon when comparing two data distributions involving: comparing measures of center, then considering other characteristics of the data distribution such as skew or range, and finally coordinating all possible data comparisons together to produce a detailed and integrated response. These steps provide a view into students’ statistical reasoning beyond traditional tasks that are highly structured in nature and seek a predetermined solution. The ranking for this category requires that no prescribed solution path is provided in advance and that students must compare at least two core statistical concepts.

Open-Ended

Open-ended tasks directly connect to the goal of eliciting informal approaches to inferential tasks (Bakker, 2004; Cobb, McClain, & Gravenmeier, 2003; Garfield & Ben-Zvi, 2007; Watson, 2002; Watson & Moritz, 1999). According to Leathman, Lawrence, and Mewborn (2005), open-ended problems “elicit reasoning, problem solving, and communication” (p. 413). Characteristics of high quality, open-ended tasks include the involvement of significant mathematics, the potential to solicit basic to sophisticated responses, and a balance between too much and too little information. Clearly, the bounds of ill-structured tasks and open-ended tasks overlap to some degree as the descriptions of both include common characteristics.

Many teacher-researchers initially introduce open-ended tasks to hone students’ thinking and reasoning about a situation. Through whole class discussion, the open-ended tasks become closed as taken-as-shared meanings develop (e.g. Cobb, 1999). In one study, students were asked to determine which of two ambulance service providers was better and provide justification for their reasoning (Cobb, McClain, & Gravenmeier, 2003). During a lengthy whole class discussion, students determined a process for reasoning about the information provided and agreed upon a final conclusion. Hence, the initially open-ended task became closed through the instructional process of establishing norms for acceptable justification.

By understanding this natural instructional sequence of tasks initially being open-ended in nature and over time becoming close-ended through the course of learning and whole class discussions, we anticipate not all tasks in a textbook would meet this requirement within an instructional unit. As students see relationships between tasks and establish ways of reasoning, the variety of conclusions will decrease with experience. However, if prescribed answers are provided for all inferential tasks, then the textbook is not allowing adequate room for students to engage in informal reasoning. Therefore, open-ended tasks require students to decide what is relevant and what constitutes acceptable justification without prior instruction. For example, if a textbook supports a range of answers as acceptable or incudes a clause, such as “Answer will vary”, then the task is deemed to be open-ended in nature. In addition, high quality, open-ended tasks require some level of justification or explanation to accompany the conclusion based on the selected relevant information. Therefore, we attend to both the open-ended nature of the response and the need for justification.

The Role of Context

The authors of the *GAISE* recommendations (Franklin et al., 2007) state, “In mathematics, context obscures structure. In data analysis, context provides meaning” (p. 7). Hence, the use of context is the norm in statistics education and instructors commonly introduce data sets in relation to some real-world phenomena or situation. However, the way statistics educators use context in their tasks varies substantially. On one hand, several have created problem scenarios familiar to students in an effort to increase accessibility and leverage prior knowledge and experiences (Bakker, 2004; Garfield & Ben-Zvi, 2007; Watson & Moritz, 1999; Watson, 2002; Watson, 2008). For example, Watson created a sequence of tasks based on measures of actual students’ heart rates and arm-span lengths. Creating data sets close to the knowledge and experiences of students helps focus the tasks on the reasoning process.

On the other hand, some researchers advocate tasks based on real-world contexts. Cobb (1999) and Cobb, McClain and Gravemeier (2003) created a variety of real-world contexts such as ambulance response times, success of speed traps, effectiveness of AIDS treatments, battery life spans, SAT scores based on school expenditure, and response time versus alcohol intake. Cobb, McClain and Gravemeier (2003) state that students must find the context of the problem both plausible and important before they will engage in reasoning about the data. In our framework, we attend to the inclusion of context and the role it plays in terms of generating an inference. Because we cannot be certain of which contexts will be either familiar or engaging to students, we focus only on the role of the context in the problem. If the context can be stripped away and/or ignored, the task is coded as low on the framework. If the context facilitates reasoning about the task, but is not needed to generate a response, then it is coded medium. Tasks that require attending to the context and incorporating it are ranked high.

Visual Representations

Visual representations shift students' thinking away from local attributes or summary statistics towards global characteristics and relationships. Tasks involving small sets of data (n<50) encourage the use of dot plots and bar graphs to depict the data distributions (Bakker, 2004; Garfield & Ben-Zvi, 2007; Watson 2002; 2008; Watson & Moritz, 1999). In addition to shifting students' thinking toward the entire distribution versus individual data values, visual representations facilitate coordination of core statistical concepts in a way that is extremely difficult with only summary statistics and little prior experience with statistical reasoning. The most useful representations for novices are graphical displays that reveal the raw data, in addition to organizing it visually, such as dot plots (Franklin et al., 2007). Therefore, we privilege representations that reveal the raw data and do not restrict the students' reasoning.

In the cases where only raw data is provided without a graphical display or a prompt to create a graphical display, the task is coded low. If the task contains graphical displays that mask the original data values (e.g. box-plots), it is coded medium. We acknowledge that box-plots serve an important role in inferential reasoning, by providing a lens in which to view the data that is useful. However, reasoning is restricted to some degree, as characteristics of the original data distribution are hidden from view. Lastly, if the data values are provided or generated by the students and visual representations are either provided or encouraged, the task is coded high.

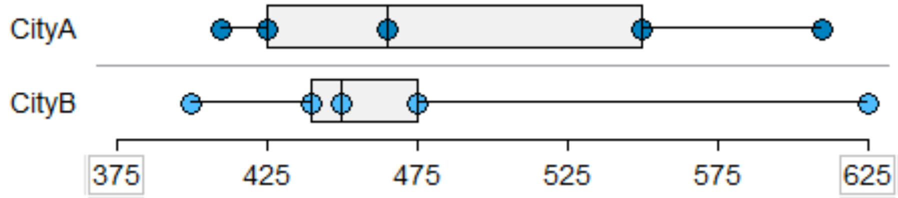
Application of the Framework

Analysis of Teacher Materials

We examined the teacher's editions of three commonly used 7th grade textbooks and identified the chapter(s) on statistics. In the chapter(s), the textbooks often reference examples for students' problems. Therefore, we analyzed the task based on the cited example. We acknowledge that hypothetically the task could be solved in a variety of ways; however, the example implies a set procedure path. In addition, if the answer key requires only a numerical answer, the task was classified as close-ended. Finally, if the task could be completed fully without considering the context, we coded the task low. The purpose of the following section is not to provide representative or typical tasks of the textbooks, but rather to demonstrate how the framework can be applied to a variety of informal inferential tasks found in CCSS-M aligned grade 7 textbooks.

Applying the framework, the task in Figure 1(problems 1, 2, and 3 inclusive), does not meet the requirement for inference since the source of the data is unspecified. One might assume this representation includes all the data of rental costs for each city, as there is no verbiage to the contrary. In regard to the task being ill-structured, prior examples in the textbook provide an approach to this problem of comparing the inner quartiles and the ranges of the box-plots. Since the inner quartile of CityB is smaller than CityA, yet the range of City B is larger than CityA, students will need to decide how to proceed. Therefore, this task is medium in terms of being ill-structured. A specified path exists but can be modified to accommodate coordination of core statistical concepts based on student's discretion. Next, the task is high in terms of being open- ended in nature, as the textbook notes that answers will vary. Depending on the decisions made when comparing CityA to

To answer the following problems, use the box-and-whisker plots of apartment rentals in two different cities.



Rental Cost ($)

1. *Which city has a greater median apartment rental cost?*
2. *Which city has a greater interquartile range of apartment rental costs?*
3. *Which city appears to have a more predictable apartment rental cost?*

Figure 1: Task adapted from Holt McDougal (2012)

CityB, students may arrive at different justifications. The context of the problem does not appear to be needed or facilitate reasoning, so it is rated low. Although a visual representation is provided, the original data is masked, leading to a medium ranking. Overall, we conclude that this task provides some opportunities for students to engage in aspects of informal inferential reasoning, but falls short of requiring all aspects.

The double dot plot below shows the quiz scores out of 20 points for two different class periods. Compare the centers and variations of the two populations. Round to the nearest tenth. Write an inference you can draw about the two populations.

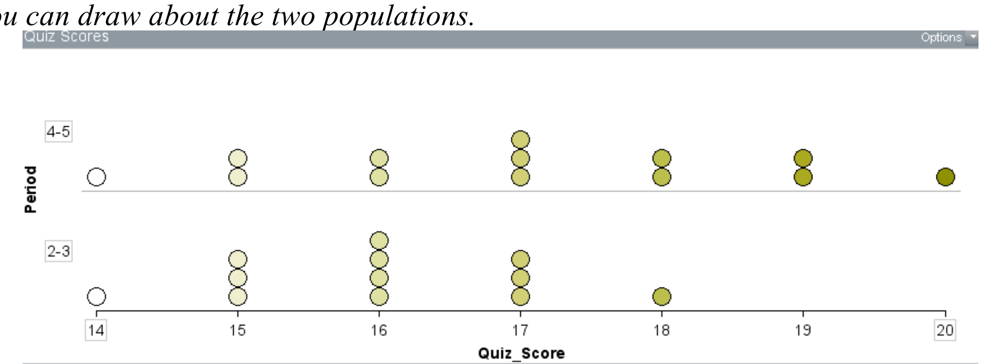


Figure 2: Task adapted from Glencoe (2013)

Applying the framework to this task, we conclude that it does not meet the requirement of an inferential task. The task implies that the dot plots represent the population for the two groups of class periods. In regard to the task being ill-structured, prior examples in the textbook provide a procedure of first comparing mean values and then comparing MADs. Students are steered to conclude that periods 4-5 have a higher mean and a larger MAD or more variation. Therefore, periods 4-5 scored higher on average, but the scores varied more and were spread out. In terms of being open-ended, the task is low because one correct answer is noted in the teacher's edition. In addition, the context is not needed for the problem and perhaps inhibits reasoning by grouping the data of two class periods. Lastly, in terms of visual representation, the task ranks high with the raw data visible and organized in a way that facilitates coordination of core concepts and informal reasoning. Overall, this task ranks low in terms of providing students opportunities to informally reason about inference.

Make a Conjecture *The box plots show the distributions of mean weights of 10 samples of 10 football players from each of two leagues, A and B. What can you say about any comparison of the weights of the two populations? Explain.*

Distribution of Means from 10 Random Samples of Size 10
Means

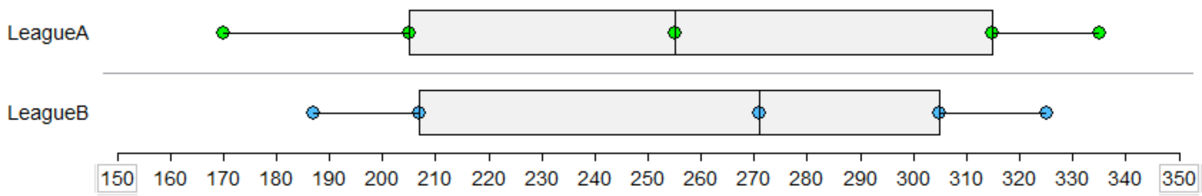

Figure 3: Task adapted from Go Math! (2014)

This task is different from the others as the box-plots are sampling distribution of means, a sophisticated statistical concept that has proven illusive to many tertiary students in introduction to statistics courses. The textbook recommends inferential reasoning with distributions of sample means as a way to reduce variability and make better comparisons, since the means vary less than the original data. Applying the framework to this task, we conclude this task meets the full requirements of an inferential task, as the data are labeled as samples of size 10 and students are asked to generate a conclusion that extends beyond the data at hand. In regard to the task being ill-structured, prior examples in the textbook provide an approach to the problem of comparing the centers of the distributions and looking at the overlapping portions of the inner quartile. Students may or may not understand why this approach works, but it is specified. Hence, we would rank this as low in terms of being ill-structured. Students will note that League B has a higher mean, but the overlapping inner quartiles create ambiguity in terms of which league has higher weight in general. Therefore, the task is close-ended with one correct answer. In addition, the context is not needed for generating the inference. In terms of visual representation, the task ranks medium with a graphic display and no access to the original data. Overall, we would conclude this task does provide some opportunities for students to engage in aspects of informal inferential reasoning, but falls short of requiring all aspects.

Conclusion

With the advent of many new mathematics textbooks claiming to align with national standards and research-based recommendations, tools are needed to assess the fidelity of tasks posed to students. Further, to study the learning effects of first introducing inference through informal approaches followed by formalization, middle school students require authentic experiences with informal inferential reasoning. Without the development and utilization of frameworks based on prior research and educational experiences, we will never know if students have the opportunities to informally generate inferences that later lead to a robust and connected understanding of formal statistics. Finally, we need to hold textbook publishers accountable for providing students with authentic opportunities to sense-make and reason, as outlined by leaders in statistics education.

THE DEVELOPMENT OF INFORMAL INFERENTIAL REASONING VIA RESAMPLING: ELICITING BOOTSTRAPPING METHODS

Jeffrey A. McLean
Syracuse University
jamcle01@syr.edu

Helen M. Doerr
Syracuse University
hmdoerr@syr.edu

This study focuses on the development of four tertiary introductory statistics students' informal inferential reasoning while engaging in data driven repeated sampling and resampling activities. Through the use of hands-on manipulatives and simulations with technology, the participants constructed empirical sampling distributions in order to investigate the inferences that can be drawn from the data. Students' developing reasoning of sampling and informal inference is reported as they move from repeated sampling methods to resampling methods, along with their reasoning of bootstrapping methods and how this reasoning was applied to make informal inferential claims.

Keywords: Data Analysis and Statistics; Modeling

Introduction

Over the past few decades statistics education has become an integral part of the mathematics curriculum at all levels. Influential documents such as the National Council of Teachers of Mathematics standards documents (NCTM, 1989, 2000), the *Guidelines for Assessment and Instruction in Statistics Education College Report* (Aliaga et al., 2005), and The *Common Core State Standards for Mathematics* (National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010*)* have emphasized the importance of statistics education at all levels. Prior to these documents, statistics at the K-12 level was often "the mere frosting on any mathematics program if there was time at the end of the school year" (Shaughnessy, 2007, p. 957).

This relatively new emphasis on the learning of statistics brings with it a new emphasis on how statistics is taught. A trend in statistics education is the shift from a focus on theoretical distributions and numerical approximations to an emphasis on data analysis (Cobb, 2007). Cobb asserted that many statistics curricula are outdated and based on how statistics could be learned prior to the computing power of modern times. The use of probability distributions, such as the normal distribution, were once needed since the conceptually simpler approach of simulations by hand was far too tedious to perform. Technology now allows these simulations to be performed nearly instantaneously. New curricula for introductory statistics courses should emphasize the ideas of data creation, exploration and simulation.

This study investigates students' developing informal inferential reasoning while engaging in a data driven instructional unit. Activities in the unit use both hands-on manipulatives and computer simulations to construct empirical sampling distributions from which students made informal inferences.

Related Literature

Informal inferential reasoning has been defined as "the drawing of conclusions from data that is based mainly on looking at, comparing, and reasoning from distributions of data" (Pfannkuch, 2007, p. 149), "the process of making probabilistic generalizations from (evidenced with) data that extend beyond the data collected" (Makar & Rubin, 2007, p.1), and "the way in which students use their informal statistical knowledge to make arguments to support inferences about unknown populations based on observed samples" (Zieffler, Garfield, delMas, & Reading, 2008, p. 44). Synthesizing these definitions, this study examined the claims that students made about populations of data when examining empirical sampling distributions, and how the students used the distributions of data to support these claims. Researchers suggest the use of informal inference before the use of formal inferential procedures (Zieffler, Garfield, Delmas, & Reading, 2008), such as employing the "three R's: randomize data, repeat by simulation, and reject any model that puts your data in its tail" (Cobb, 2007, p.12). This use of simulation to teach informal inferential reasoning can help students build a deep understanding of the abstract statistical concepts (Burrill, 2002; Maxara & Biehler, 2006). College curricula using simulations have indicated modest improvement in students' understanding of inference (Garfield, delMas, & Zieffler, 2012; Tintle, Topliff, Vanderstoep, Holmes, & Swanson, 2012).

There are two forms of simulations in this study, simulations that construct an empirical sampling distribution by: 1) repeatedly sampling from an available population; and 2) resampling from a sample with an unavailable population. Research involving repeated sampling activities have indicated that *some* students develop "a multi-tiered scheme of conceptual operations centered around the images of repeatedly sampling from a population, recording a statistic, and tracking the accumulation of statistics as they distribute themselves along a range of possibilities" (Saldanha & Thompson, 2002, p. 261). However, many students do not focus on empirical sampling distributions for inference and instead compare a single sample statistic with a population parameter. Students have also shown difficulty distinguishing the difference in strength of conclusions made from a small number of samples versus those made with large amounts of samples (Pratt, Johnston-Wilder, Ainley, & Mason, 2008).

The second form of simulation activities aimed to elicit and develop students' ideas about the resampling method of bootstrapping. Efron (1979) introduced the method of bootstrapping and asserted that the bootstrap was more widely applicable and dependable than earlier resampling methods, while also using a simpler procedure. Bootstrapping begins with drawing one sample of data from a population. Bootstrap samples are then constructed by choosing elements from this one sample, with replacement, and creating resamples which are equal in size to the original sample. A statistic from these bootstrap samples is then aggregated to form an empirical bootstrap sampling distribution. If done with hands-on manipulatives, this sampling process using replacement can potentially provide insight into the approach, but it is also very time consuming. However, technology can be used to simulate this procedure in a short period of time, but the use of technology may obscure the underlying sampling process.

While limited research has been done on student learning of statistics with bootstrapping methods (Garfield, delMas, Zieffler, 2012; Pfannkuch & Budgett, 2014; Pfannkuch, Forbes, Harraway, Budgett, & Wild, 2013), researchers have asserted that bootstrapping may promote student learning of the logic of inference (Cobb, 2007; Engel, 2010, Hesterberg, 2006)). The bootstrapping method has already become part of introductory statistics coursework such as the CATALYST curriculum (Catalyst for Change, 2012). Some textbooks (e.g., Lock, Lock, Lock-Morgan, Lock, & Lock, 2013) introduce the method of bootstrapping to define confidence intervals well before discussing confidence intervals with normal approximation methods. Lock et al. claim that the bootstrapping method has become an important tool for statisticians and that it is also intuitive and accessible for introductory statistics students. The authors further state that bootstrapping capitalizes on students' visual learning skills and helps to build students' conceptual understanding of key statistics ideas. There is not yet research evidence to support these claims, which will be explored in this study.

The research questions guiding this study were: 1) What student reasoning develops as they move from repeated sampling methods to resampling methods? 2) How do students develop their reasoning of bootstrapping methods and apply this reasoning to make informal inferential claims.

Theoretical Framework

The focus of analysis for this study was the models of sampling that the students created while engaged in a model development sequence (Lesh, Cramer, Doerr, Post, & Zawojewski, 2003). Drawing on Lesh and colleagues, in this study, we define models as "conceptual systems … that are expressed using external notation systems, and that are used to construct, describe, or explain the behaviors of other system(s)" (Lesh & Doerr, 2003, p. 10). Teaching and learning from a modeling approach shifts the focus of an activity from finding an answer to one particular problem to constructing a system of relationships that is generalized and can be extended to other situations (Doerr & English, 2003). Students' mathematical models are useful for research since they provide a means for investigating students' developing knowledge (Lesh, Hoover, Hole, Kelly, & Post, 2000). Model development sequences consist of three forms of activities: model-eliciting activities that encourage students to generate descriptions, explanations, and constructions in order to reveal how they were interpreting situations; model-exploration activities that focus on the mathematical structure of their models and often use technology in order to develop a powerful representation system; and model-adaptation activities that transform the models created in model-eliciting activities in order to investigate more complex problems (Lesh et. al, 2003). By using a modelling approach to examine student reasoning, we can view reasoning as dynamic and developing over the course of instruction. Student reasoning may not only change from activity to activity, but many times during an activity. This framework allows us to examine the impact of the activities on the development of students' reasoning.

Design and Methodology

In this qualitative case study, the first author collaborated with two introductory statistics instructors to create an instructional unit that consisted of two model development sequences (Figure 1). This study is part of a larger study that examined the development of informal inferential reasoning through simulation activities and the role of hands-on manipulatives versus technological

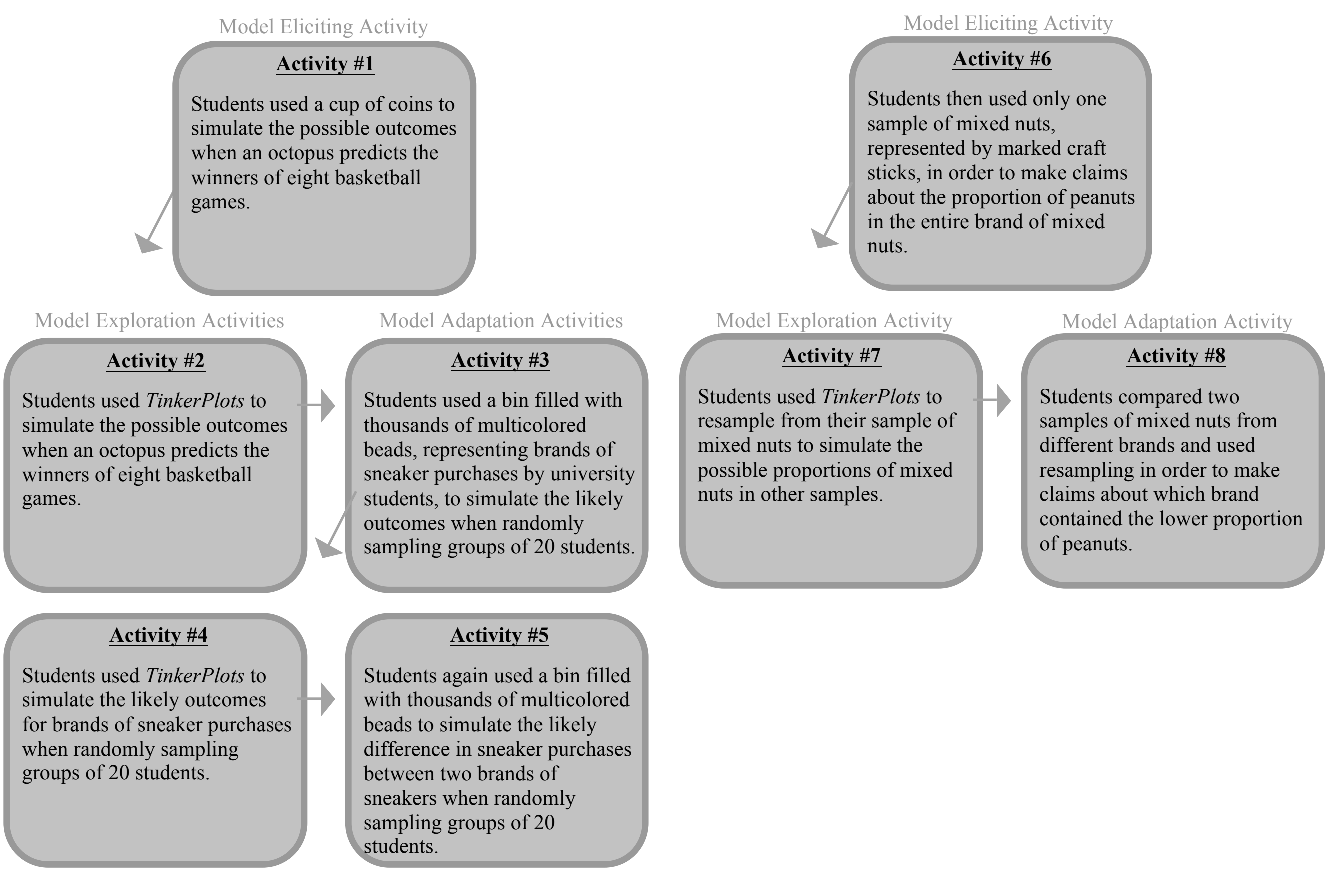

***Figure 1:* Overview of the instructional unit consisting of two model development sequences**

tools with four classes of students at the secondary and tertiary levels. For this study we focus on one group of four students at the tertiary level engaging in the instructional unit. During the unit, the group of students was videotaped and their written work was collected. One student from the group participated in three interviews to discuss her thinking during the instructional unit. The videos, student work, and interview were analyzed with qualitative methods in order to construct the development of the models of sampling used by the participants, and how they were applied to make inferential claims.

The first model development sequence was intended for students to create models that allowed them to draw inferential claims from empirical sampling distributions constructed from repeated sampling from a known population. The second model development sequence no longer had an available population to repeatedly sample from. This put the students in a situation where they needed to extend their models for drawing conclusions by constructing resampling methods to use with the one available sample. Figure 1 provides an overview of the two model development sequences.

Results

We will report the main reasoning, and changes in reasoning, related to the ideas of sampling and informal inferential claims as demonstrated by the four students during the instructional unit. Changes in reasoning occurred both as students progressed through the activities in the unit and also during group and class discussion within the activities.

The first activity in the instructional unit asked the students to determine the likely range of correct predictions made when guessing the winner of eight basketball games. A cup of coins was given to the group as an option to use to draw their conclusions. The group showed an aversion to using the coins to simulate guessing and attempted to calculate the probabilities of each outcome. A class discussion encouraged the group to use eight coins to simulate possible outcomes for the number of correct predictions.

Initial Model of Sampling and Inference

The group simulated the outcomes by flipping eight coins five times. For each group of eight coins they counted the number of heads, which represented a correct prediction. They concluded that because of varying values in their simulations, there is “no definitive answer as to the range of possible outcomes”. This view of one definitive and correct range of possible outcomes was in line with their initial attempts to calculate the probability of each outcome occurring. One student in the group, Megan, was later interviewed to discuss her reasoning in the activity and was still not convinced on the value of using simulations to answer the original question. She had read ahead in the course’s textbook to determine a way of answering the activity through calculations, and constructed a 95% confidence interval with a normal approximation to the binomial distribution.

Second Model of Sampling and Inference

The second activity continued in the same context as the first, but moved on from using coins to simulate outcomes, to the use of *TinkerPlots* (Konold & Miller, 2014). *TinkerPlots* was set up for the students using a spinner with half of the area marked ‘Right’, the other half ‘Wrong’, a window that collected the outcomes simulated by the spinner, and a dotplot that collected the number of correct predictions in each sample. A screenshot of the *TinkerPlots* setup is shown below in Figure 2.

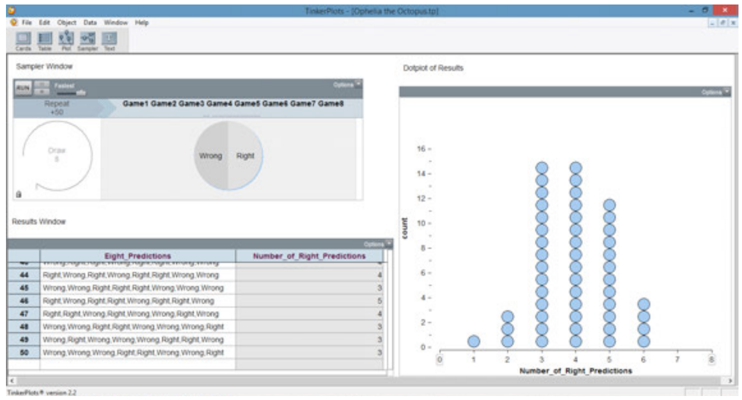

***Figure 2: TinkerPlots* setup for activity #2**

Each group member first used *TinkerPlots* to simulate 10 samples. Together they determined that the outcomes that occurred the most often could constitute a range of likely values. The group discussed how each of their dotplots were slightly different and led them to have varying predicted ranges. After simulating 1000 samples, they discussed how more samples led to each of their dotplots looking very similar and yielding the same intervals of likely values. The group concluded that more samples lead to more accurate predictions. From their dotplots with 1000 samples they determined that between 2 and 7 correct guesses seemed likely. Megan continued to add samples and came to the conclusion that at some point, adding more samples did not change the look of the dotplot. She concluded that the plot was saturated with data.

Third Model of Sampling and Inference

The next two activities involved sampling from a population of university students to determine what number of sneaker purchases out of groups of 20 students were Nikes. This was first done with a bin of thousands of multicolored beads, each color representing the purchase of a certain brand, and then continued in the next activity using *TinkerPlots* to simulate the outcomes. A similar *TinkerPlots* setup was given to the students as before. The spinner was replaced with a mixer containing the same distribution of balls as the beads used as hands-on manipulatives. The students were asked if it was reasonable for Nike to claim that 7 out of 20 student sneaker purchases by the university students were Nikes.

The group used the same methods to construct an empirical sampling distribution as the previous model but the change came with how they drew their conclusions. When using the hands-on manipulatives, all samples except for one showed more than 7 of 20 sneaker purchases were Nikes. A simulation with *TinkerPlots* also showed a majority of the samples falling above 7 out of 20. The students determined an interval of likely outcomes for Nike sneaker purchases and found 7 of 20 to be below the interval. They concluded that Nike should claim that more than 7 out of 20 sneaker purchases at the college were Nikes. They recommended Nike to claim that 10 in 20 purchases were Nikes, which was approximately the center of the distributions.

Fourth Model of Sampling and Inference

The fifth activity was the first time that the students had to deal with the comparison of populations. The context was similar to the previous two activities. Students were asked to investigate if the difference in Nike and Adidas sneaker purchases at a university was the same as the difference in the global sales of 15%, or 3 in 20 students. The same bin of beads was used as in the previous activity, with one color representing Nike purchases and another color, Adidas purchases. The students decided that since they already constructed an empirical sampling distribution of Nike sneaker purchases, they would conduct the same number of samples and count Adidas sneaker purchases. The group chose to calculate the mean values of each distribution and compare them. The means were approximately three purchases apart, which led the students to conclude that the 15% difference in Nike and Adidas global share held true for the college students.

Initial Model of Resampling and Inference

The next change in the students' models occurred during the beginning of the second model development sequence. The first activity put the students in a situation where they needed to extend their models for drawing conclusions by constructing resampling methods to use with the one available sample. The students were told that the manager of bulk food in a grocery store ordered a sample of a new brand's mixed nuts. She plans to order a large shipment of mixed nuts, but has determined that her customers prefer mixed nuts with fewer peanuts. Before she orders, the manager wants to know more information about the percentage of peanuts in this new brand. The students were given a bag of 25 sticks to represent the sample of mixed nuts. Seven sticks were marked with a 'P' to represent peanuts. The remaining sticks were not marked and represented other types of nuts.

The group began by applying a method similar to the previous activities by taking seven samples of five mixed nuts and calculating the average percentage of peanuts. They chose the size of five since it would be easy to take many samples and also to calculate the percentage of peanuts. After some class discussion, they decided to try and take larger samples. Through interactions with the instructor, they found that if they took samples of size 10 in a similar manner to their previous samples, all outcomes were not possible. Since there were only seven peanuts in their original sample, the largest percentage of peanuts in their sample of size 10 would be 70%. After discussing this issue with the class, they decided to take samples of size 10 from their original sample of 25, with replacement. The process of sampling with replacement was more time demanding than sampling without replacement, so the group decided to collect only three samples. They found the average percentage of peanuts in the three samples and concluded that a likely interval for the percentage of peanuts in the population was that average plus or minus an arbitrarily chosen 4%. During an interview with Megan after the activity, we discussed her group's choice of sample sizes of five and 10. She said that larger samples may have provided more accurate results, but would have taken too long to sample with the sticks.

The next activity worked with *TinkerPlots* and gave each group member a different sample of mixed nuts. From these new samples, each member used *TinkerPlots* to collect resamples of 25 mixed nuts (as set up in *TinkerPlots*) and applied similar methods from the first model development sequence to construct a interval of likely values based on the height of outcomes on the dotplot. The group was told the true percentage of peanuts in the brand of mixed nuts, which was a value not included in all of their predicted ranges. Megan chose a much wider range of values than the other students. She concluded that if others did this as well, more of their likely ranges would capture the true percentage of peanuts.

Second Model of Resampling and Inference

The final activity gave the students two samples of mixed nuts from two brands and asked them to conclude which brand had the lower proportion of peanuts. The samples were each of size 25 and contained six and 10 peanuts. Unlike the previous activity comparing sneaker purchases, *TinkerPlots* was available for the students to construct sampling distributions. The group constructed two empirical sampling distributions with 200 samples in each and determined that the first brand likely had 16%-32% peanuts and the second brand had 32%-48% peanuts. These ranges were chosen based on the height of the dotplot for each outcomes. Since the likely interval for the second brand was higher than the other brand's interval (except for the endpoint) they concluded that the second brand is likely to have more peanuts.

During an interview after the activity, Megan and the first author discussed the possibility that both brands had 32% peanuts. Megan concluded that it was unlikely for both brands to have 32% peanuts, but since that was the only value that overlapped between the two likely ranges, she still believed that the second brand was more likely to have more peanuts.

Discussion

The group's model of inference from simulation developed from not drawing a conclusion from simulated data, to using data as evidence to make informal inferences. The first model development sequence was developed as a means for the students to build the necessary tools to draw these informal inferential claims and attempt to apply them to situations in the second model development sequence with an unavailable population. The group constructed some notion of the bootstrapping process by resampling with replacement from their original sample, but did not take resamples that were equal in size to the original sample. The time demanding nature of resampling by hand was noted as one reason for taking smaller sized samples. Immediately after these topics were covered in the class, the course instructor began topics in formal inference. She believed that the students were better prepared for the concepts of confidence intervals and hypothesis testing by participating in the instructional unit. Further research is needed to indicate the connections between the informal inferential models constructed in this study and students' reasoning of formal inference. This study also has implications with the content and design of introductory statistics curricula, and the role of resampling activities on the development of informal inferential reasoning.

This paper explores the impact on teachers' self-efficacy to teach statistics from a graduate course aimed to develop teachers' knowledge of inferential statistics through engaging in data analysis using technology. This study uses qualitative and quantitative data from the Self-Efficacy to Teach Statistics Survey (Harrell-Williams et al., 2013) to provide data about teachers' confidence to teach statistical topics. The survey was given to 27 participants from two different institutions before and after the graduate course. We found that participants' self-efficacy to teach statistics increased after participation in the graduate course and references to specific course activities will be identified.

Keywords: Data Analysis and Statistics; Teacher Education-Inservice (Professional Development); Teacher Beliefs

Considerable research has addressed students' statistical thinking (Shaughnessy, 2007), and statistics continues to receive attention in the secondary US mathematics curriculum (NCTM, 2000; Common Core State Standards Initiative, 2010). However, there is a lack of research on secondary teachers' statistical reasoning and beliefs (Batanero, Burrill, & Reading, 2011). In fact, very little is known about teachers' self-efficacy to teach statistics (Harrell-Williams, Sorto, Pierce, Lesser, & Murphy, 2013). This study is situated in self-efficacy for teaching within a graduate course aimed at developing knowledge of the teaching and learning of statistics.

Researchers have investigated the statistical knowledge needed for teaching, using various frameworks (e.g., Groth, 2007). Each of these frameworks has identified teachers' own statistical reasoning as a foundational aspect of their ability to teach statistics. Thompson (1992) argues that researchers should not separate the study of teachers' beliefs from teachers' knowledge since they are intertwined. Thus this study aims to look at self-efficacy to teach as another component of teachers' readiness to teach statistical concepts to their students.

Background and Research Focus

Self-efficacy is often defined as "people's judgments of their capabilities to organize and execute courses of action required to designated types of performance" (Bandura, 1986, p.391). Self-efficacy to teach can be defined as a teacher's "belief to bring about student learning" (Ashton, 1985, p.142). Not only is self-efficacy to teach a central component of a teacher's beliefs (Greshman, 2008; Smith, 1996), it has been has been linked to positive influences on students' learning, the use of more innovative teaching strategies, and time spent teaching certain topics (e.g., Czerniak & Chiarelott, 1990). With these connections, it seems important to improve teachers' self-efficacy to teach. However, it has been suggested that it is hard to impact self-efficacy after teachers enter the classroom (e.g., Smith, 1996).

Bandura (1997) argued that there are four types of sources that may impact one's self-efficacy: mastery experiences, vicarious experiences, verbal persuasion, and physiological responses. For the purpose of this study, the focus is on how mastery experiences impact one's self-efficacy to teach. Mastery experiences are prior experiences in performing a task that are perceived to be a success

(Bandura, 1997). In terms of self-efficacy to teach there are two forms of mastery experiences: classroom teaching experiences and cognitive mastery (Palmer 2011). Arguably, classroom teaching experiences are the most crucial source of self-efficacy to teach because individuals can only assess their ability to teach by participating in the act of teaching (Tschannen-Moran, Hoy, & Hoy, 1998). Cognitive mastery refers to a teacher's perceived success in understanding the content and pedagogy to teach a specific topic (Palmer 2011). The cognitive mastery framework underpins our study to measure the development of self-efficacy to teach statistics from a graduate course aimed at developing subject matter knowledge and pedagogical content knowledge.

Our research is situated within the design and implementation of a graduate course that was largely influenced by Pfannkuch and Ben-Zvi's (2011) recommendations for designing experiences to develop teachers' statistical thinking, as well as the Guidelines for Assessment and Instruction in Statistics Education (GAISE) reports (Franklin et al., 2007; Garfield et al., 2007) and the Mathematical Education of Teachers II report (CBMS, 2012). Over two academic years, a team of four instructors from two institutions designed, and taught, a 15-week course which provided participants opportunities to develop a deeper understanding of a few statistical ideas. Two instructors taught at one university while the other two taught at the other university creating as similar of a course as possible at both institutions through continuous co-planning and reflection.

Throughout the semester-long course, participants implemented the cycle of statistical investigation (Friel, O'Connor, Mamer, 2006) as they engaged in with real data and tasks designed to develop their understandings of variation, distribution, samples and sampling distributions, and inferential statistics, especially randomization approaches using simulations. The course used dynamic software, *Fathom* (Finzer, 2005) and *TinkerPlots* (Konold & Miller, 2011), and online applets such as StatKey (lock5stat.com/statkey/). Assigned readings and discussions centered on (a) the nature of statistical reasoning and how it compares to mathematical reasoning, and (b) students' learning and reasoning related to the aforementioned topics. The software tools, new to most participants, were used to support their learning by allowing them to flexibly explore graphical representations, easily compute statistical measures, compare data sets, and make changes to data to explore conjectures. The software also provided simulation tools necessary to create representations of a population, a sample, and an empirical sampling distribution. This study addresses the following questions: 1) To what extent is teachers' self-efficacy to teach statistics changed from a graduate course focused on teaching and learning statistics? and 2) What learning experiences do teachers identify that influenced their self-efficacy to teach statistics?

Methodology

Participants

Participants came from all the teachers participating in either course across the two institutions. The course served a variety of graduate students (n=27). Participants consisted of one undergraduate pre-service teacher, six pre-service teachers in a masters program; 11 in-service teachers enrolled in a master's program; one full-time master's student in mathematics education; and eight doctoral students in mathematics or mathematics education. Twenty-one participants were female and six were male. Six participants indicated that English was their second language. Most participants had completed the equivalent of an undergraduate degree in mathematics, and all but two had at least one prior course in statistics. Hereafter we refer to course participants as teachers.

Data Collection and Analysis

To examine changes in teachers' self-efficacy to teaching statistics, the Self-Efficacy to Teach Statistics (SETS) survey was administered (Harrell-Williams, Sorto, Pierce, Lesser, & Murphy, 2014). This survey was chosen because it collects both qualitative and quantitative data about teachers' self-efficacy to teach statistics. Researchers argue both data sources are needed within the self-efficacy research (Wyatt, 2014). SETS was administered prior to the first day of class and during the last week of class. The SETS survey contains 44 six-point Likert scale items and six open response items that are aligned with the GAISE framework (Franklin et. al., 2007). An earlier version of this instrument was validated for use in measuring changes in elementary and middle grades preservice teachers' self-efficacy as a result of interventions, such as a course (Harrell-Williams et al., 2013). In addition to an overall score, the instrument provides sub-scale scores that correspond to Levels A-C in the GAISE framework. Although there are not explicit definitions given for each level in the GAISE report, each level is aligned to specific content. The content in level A is considered more concrete and level C is considered the most abstract. For example, in level A students are asked to compare groups without generalization while in level C students answer comparison questions and make generalizations (Franklin, 2007). There were 11 Likert items for level A, 15 items for level B and 18 items for level C. For all Likert items, the stem of the question was "Rate your confidence in teaching high school students the skills necessary to complete successfully the task given by selecting your choice on the following scale: 1 = not at all confident, 2 = only a little confident, 3 = somewhat confident, 4 = confident, 5 = very confident, 6 = completely confident" (Harrell-Williams et al., 2014). For the open-ended portion of SETS, in each GAISE level category, teachers were asked to identify an item which they felt least and most confident to teach to high school students and to explain their reasoning (total of six open-ended items).

The analysis of the SETS data was completed in two phases. The first phase focused on the responses to the 44 six-point Likert scale items. For both the pre- and post-survey, each teacher was given a total score calculated as the sum of his/her Likert scores. Sub-scale scores were also calculated for each teacher. The totals were divided by the number of items, which resulted in a final score that corresponded to the six-point Likert scale. Additionally, a gain score was calculated for each teacher as the difference of pre- and post- scores for each item. Means were computed for pre, post, and gain scores and a Wilcoxon Signed Rank Test for Matched Pairs was conducted to test for the significance from pre to post. Finally, the gain scores were averaged for each teacher and for each item. The item averages were examined for highest average gains in relationship to course content. Teachers with missing values within specific calculations were removed from the sample for that calculation.

The second phase of data analysis focused on analyzing the open-ended responses for ways in which the course influenced teachers' self efficacy to teach statistics. The code "course" identified responses that explicitly referred to specific course activities.

Results

First, we report the extent of the change in self-efficacy to teach statistics through the quantitative data from the pre and post SETS survey. Second, we report our findings from the qualitative responses to identify the course experiences that the teachers identified as influencing their self-efficacy to teach statistics.

Influence of Professional Development on Self-efficacy

We investigated the general influence of the course on self-efficacy to teach statistics by examining the mean scores for the pre and post survey and the mean gains by teacher and by item. Teachers began the course between somewhat confident (score of 3) and confident (score of 4) for each item; however, the teachers finished the course describing their self-efficacy to teach statistics as between confident and very confident (see Table 1). With the exception of one teacher, all teachers showed a positive average item gain in self-efficacy to teach statistics. The highest average item gain was 1.68 Likert points, which was recorded by two teachers. Figure 1 shows the distribution of average item gains by teacher. On average, teachers' self-efficacy for to teach statistics for each item increased one Likert point (0.95 increase). After accounting for missing values and using a Wilcoxon Signed Rank Test for Matched Pairs, the increase in self-efficacy between the pre and post surveys is considered statistically significant (see Table 2).

Table 1: Descriptive statistics of Likert scale items

		Pre	Post	Gain
Overall	N	26	24	23
	Mean	3.62	4.65	0.95
	Standard deviation	0.82	0.64	0.49
Level A topics	N	26	27	26
	Mean	3.95	5.10	1.14
	Standard deviation	0.80	0.51	0.55
Level B topics	N	27	26	26
	Mean	3.75	4.70	0.94
	Standard deviation	0.81	0.71	0.55
Level C topics	N	27	25	25
	Mean	3.39	4.35	0.97
	Standard deviation	0.96	0.74	0.63

Similar results were found for all three GAISE sub-scores. Level A had the highest pre score average of 3.95. This suggests that teachers started out confident in their ability to teach topics within that level. Interestingly, these topics are also the areas were teachers' confidence grew the most with a statistically significant (Wilcoxon signed rank test, $p>0.001$) average gain of 1.14. Level B had a pre survey mean score of 3.75 and a post survey mean of 4.70. Accounting for missing values, the average gain for level B was 0.94, which was also statistically significant. Finally level C started at the lowest confidence at 3.39, implying that most teachers on average feel only somewhat confident in their ability to teach statistics. The post mean score was 4.35, which is a growth in confidence to teach the level C topics in statistics. The average growth for level C was 0.97 points. Similarly, according to a Wilcoxon signed rank test this growth was statistically significant (Table 2). In

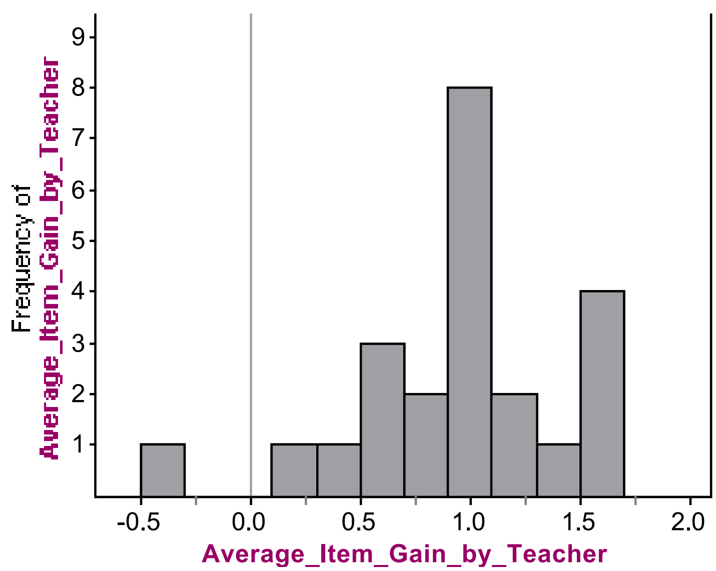

Figure 1: Distribution of Each Teachers' Average Likert Item Gain

Table 2: Wilcoxon Signed Rank Test for Matched Pairs

	Test Statistic	p-Value
Overall	4.14	0.000
Level A topics	4.44	0.000
Level B topics	4.46	0.000
Level C topics	4.07	0.000

addition to average gains at all levels, the standard deviation decrease at all levels indicating a decrease in variability in post confidence ratings.

Examining the average gain by item shed light on the specific content aligned to the teachers' growth in self-efficacy to teach statistics. The items that showed the greatest gain on average across teachers related directly back to the course goals: Item 44 (*Determine if the difference between two population means or proportions is statistically significant using simulations*) had an average gain of 1.85 and Items 9 (*Generalize a statistical result from a small group to a larger group*), 37 (*Evaluate whether a specified model is consistent with data generated from a simulation*), and 43 (*Compare two treatments from a randomized experiment by exploring numerical and graphical summaries of data*) all had an average gain in self-efficacy to teach of 1.42 points. All four of these items address the course foci of inferential statistics using randomization approaches, sampling distributions, and variation. The item with the lowest overall gain (0.48) was Item 33 (*Fit an appropriate model using technology for a scatterplot of two quantitative variables*), which was not a topic explicitly addressed during whole-class activities or discussions within the course.

Teachers' Reflection on Learning Experiences

In the open response items of the SETS instrument used at the end of the course, teachers identified course experiences when describing what, in each level, they felt most confident about. At both institutions, the course began with lengthy discussions on the cycle of statistical investigation (Friel et al., 2006). This cycle became a theme of the course as teachers gained repeated experience with posing statistical questions, collecting data, and data analysis and interpretation. Early in the course, teachers had opportunities to deepen their understanding of distribution through a series of tasks related to interpreting graphical representations. One such task asked teachers to match box plots to corresponding dotplots. This task revealed that a given boxplot could have underlying dotplot distributions that looked somewhat differently. About this activity, one teacher wrote

> "I feel most confident about working with box plots; the [activity] showed both the advantages and disadvantages of boxplots and [how] we can use them to describe data."

Based on research by delMas and Liu (2005), a second task teachers experienced was a game in *Fathom* designed to enhance teachers' conceptualization of the relationship between a distribution and its standard deviation. Teachers remembered this game at the end of the course. For example,

> "After doing the activity of "What Makes the Standard Deviation Larger or Smaller", I noticed a couple of patterns for justifying the characteristics of normal distributions with different centers, shapes, standard deviation, and so on."

As the course progressed, simulations became a means by which teachers developed understanding about variability and sampling distributions. The SETS item (44), which showed the greatest gain in self-efficacy focused on simulations. In the open response items, teachers remembered learning from the simulations with and without technology:

> "[Simulation] is something that we spent a lot of time on in the course. There are a lot of different ways to approach [it] with students such as hands-on simulations or technology simulations."

One hands-on simulation used physical devices, some of which did not have equiprobable outcomes. In the activity, each group had to describe a repeatable action that could produce an unpredictable result and the possible outcomes from this repeatable action. After the event(s) of interest was selected, for which results could be examined from the repeatable actions, each teacher in the group collected a sample of 10 trials. The activity continued with more samples being collected and a sampling distribution being created. While it is a familiar activity for statistics educators, it was not for the participating secondary teachers. One teacher wrote,

> "I liked the activity we did in class of having each person collect data for a sample of 10…I think I have a good conceptual understanding of the relationship between samples, distributions of samples, and populations."

The simulation focus continued as the course ended with randomization techniques. One teacher shared that she

> "already knew about randomization tests, but I feel more confident having multiple pieces of software that can perform the simulation for me. Before I was just using statcrunch and showing my students the output, but now I can actually have them do it!"

A specific course experience referenced in the SETS open responses was the Dolphin Therapy task (Rossman, 2008). This task required a re-randomization technique to test the difference of proportions. Teachers were given index cards to use in the design and simulation of the problem. Eventually, they used StatKey and TinkerPlots for a greater number of samples.

Another course experience that was highlighted by teachers in the open responses of the SETS survey was the course mid-term project. For the assignment, teachers self-assigned themselves to a working group. Each small group examined best practices for teaching learning a specific statistical topic. They applied research literature to create or adapt meaningful tasks and implemented one task with a group of students. Projects were shared through oral presentations and a course wiki. Topics for the midterm project included: Comparing Distributions, Sampling Techniques and Study Design, Sampling Distributions, Hypothesis Testing, Linear Regression/Covariation and Correlation, Using Probability to Make Decisions, Subjective Probability and Bayes Theorem.

The course experiences described above were ones specifically linked by teachers to content in which they felt most confident. In the survey, teachers were also asked to identify particular areas where they felt least confident. Mostly, teachers responded with comments such as *"these items were not specifically discussed in the course" or "I do not think I had a lot of practice … in the course."* Other times, however, teachers provided more insight into particular self-reported deficiencies (e.g. box plots, error, randomization, inference, sampling). Several teachers even suggested that they wanted more time with topics or would continue to refer to course materials to develop a deeper understanding. One teacher wrote,*"Sampling!!! I don't feel very confident teaching it yet. I began to develop a better internal understanding of it in class. I wish I could study it some more in a similar environment as was created in [my course]."* And, another teacher wrote, *"I am confident that randomization is highly important but I still second guess myself...Since I second guess myself, I am somewhat confident because I at least know that I have resources that I can reread."* Despite the fact that all teachers showed gains in self-efficacy overall, the open-ended responses provided details for instructors at each institution regarding potential pivotal experiences for teachers' own development of statistical understanding during the graduate course that seem to influence their statistics teaching efficacy.

Discussion and Conclusions

The results indicate that the course had a statistically significant positive impact on teachers' self-efficacy to teach statistics. These results were seen on the overall level and at all three GAISE levels. This suggests that a graduate course focused on the teaching and learning of statistics can impact a teachers' self-efficacy to teach statistics, and furthermore suggests that teachers can gain in self-efficacy to teach statistics from focusing on content knowledge and pedagogical content knowledge for teaching statistics. Additionally, our data also show that teachers have decreasing confidence to teach from level A to level C. This result holds for both the pre and post surveys and suggests that more abstract material corresponds to lower self-efficacy to teach. This result is similar to results found by Harrell-Williams et al., (2013) with pre-service teachers.

In addition to an overall gain in self-efficacy to teach statistics by the teachers, specific gains related to the course and its objectives were seen. After examining the data by SETS items, large gains were seen on topics related to the course objectives of inferential statistics, sampling distributions, and variation. Additionally, many teachers' mentioned course activities as reasons for their increase in self-efficacy to teach these topics. This speaks positively to the design of these activities and suggests that some course activities can have powerful impacts on teachers' confidence to teach statistics. These seem to be serving as a key mastery experiences.

However, not only did the areas that were emphasized in the course get impacted. There was an average increase on all items on the SETS survey including those that were not specifically stressed in the course. One possible source for this growth could be the course projects that allowed students to investigate topics of their choosing.

In general, these results point to specific activities that work to increase self-efficacy to teach statistics with teachers. Further research needs to be conducted to better understand what type of activities and how these activities are impacting teachers' self-efficacy to teach.

A METHOD FOR DESCRIBING THE INFORMAL INFERENTIAL REASONING OF MIDDLE SCHOOL STUDENTS

Joshua Goss
University of New Haven
JGoss@NewHaven.edu

A primary obstacle in the study of how students' informal understandings of statistical inference can be developed and leveraged into formal statistical understandings has been the lack of a method for describing and categorizing student thinking. In this research an adaptation was made to the Structure of Observed Learning Outcomes (SOLO) taxonomy to focus on Informal Inferential Reasoning (IIR). The adaptation evolved through two iterations of refinement and validation that included classroom observations and task-based interviews as part of a larger project that also developed an assessment for the purpose of eliciting students' IIR.

Keywords: Data Analysis and Statistics; Middle School Education

Focus of the Study

Statistical literacy has become an integral part of being an informed citizen, making informed personal choices, being a professional in the modern workplace, and working in the sciences (Franklin et al., 2005; Zieffler, Garfield, Delmas, & Reading, 2008). In response to this, there has been an increased emphasis on statistics education both in the US (National Council of Teachers of Mathematics, 1989, 2000; National Governors Association Center for Best Practices [NGACBP] & Council of Chief State School Officers [CCSSO], 2010), and internationally (Leavy, 2010; Makar & Rubin, 2009; Shaughnessy, 2007). Informal Inferential Reasoning (IIR), defined by Zieffler et al. (2008) as "the way in which students use their informal statistical knowledge to support inferences about unknown populations based on observed samples" (p. 44), has emerged as a foundation on which students can build their formal statistical understandings. Research has shown that IIR does not develop with maturation or increased content knowledge (Jacob, 2013; Zieffler et al., 2008), but it can be intentionally developed (Jacob, 2013; Langrall, Nisbet, Mooney, & Jansem, 2011; Makar, Bakker, & Ben-Zvi, 2011).

Underlying Framework

Research suggests that statistical literacy is a hierarchical construct (Watson & Callingham, 2003). The SOLO taxonomy is a neo-Piagetian model of looking at hierarchical learning from a cognitive perspective (Shaughnessy, 2007) developed by Biggs and Collis (1982). Because of its strength in describing hierarchical learning it has received a significant amount of attention in statistics education research.

SOLO cycles represent progress in a student's ability to reason with increased complexity about a topic, and are comprised of the following levels: Pre-structural (P), Uni-structural (U), Multi-Structural (M), Relational (R), and Abstract/extended abstract (A). The taxonomy is based on identifying how many methods for accessing a topic a student has. At P, the student has no cognitive structure through which they can access the objective. At U a student has a single relevant way of accessing the objective, and at M the student has more than one (though they are not coordinated). At R the student is able to coordinate different ways of accessing the objective, and at A they can make abstract statements about the objective (Watson & Moritz, 2000). In looking at the development of a concept, P is the beginning point and A is the ending point; however, as the concepts being looked at grow more complex it becomes necessary to use more than one cycle. When this occurs, the A level of one cycle can be considered the U level for a cycle that looks at more complex thought, resulting in the structure of $P\text{-}U_1\text{-}M_1\text{-}R_1\text{-}U_2\text{-}M_2\text{-}R_2\text{-}A$ for what is referred to as a two-cycle model (note that the letter remains the same but a subscript is used to denote which cycle is being referred to). These two-cycles are used widely (see Reading & Reid (2006), Watson & Moritz (2000)), and in response to a question at a conference presentation Reading suggested that a two-cycle SOLO-based framework could be used to describe the development of IIR (Zieffler et al., 2008),.

In order to apply the SOLO taxonomy there was also a need for clearly articulating the types of understandings that would be investigated. Zieffler et al.'s (2008) assessment framework was selected for this purpose. In this framework, IIR is identified as having three components: making judgments or predictions, using or integrating prior knowledge, and articulating evidence-based arguments (Zieffler et al., 2008). It also identifies three types of IIR tasks: Estimating and Drawing a Population Graph (EPG), Comparing Two Samples (CTS) of data, and Choosing Between Two Competing Models (CBM) (Zieffler et al., 2008), which were used in building the assessment and became important in classifying student reasoning.

Methodology

This research was conducted at a rural Midwestern middle school (grades 6-8) with approximately 900 enrolled students, 11% minority students, 16% qualified for the free or reduced-price lunch program. The study involved three cooperating teachers and 188 students. The research progressed through four phases: an initial development and modification phase, two modification phases, and a validation phase.

In the initial development phase a theoretical SOLO adaptation was constructed based off of the frameworks. Eight students were selected from the first teacher's classes using striated random sampling in order to ensure students at various levels of mathematics achievement were represented. The students completed an assessment designed to elicit their IIR, and subsequently participated in task-based semi-structured interviews to further explore their IIR abilities. Open coding was done on the responses from both the interviews and assessments, and the results were used to refine the cycles, cycle definitions, and assessments.

The first modification phase occurred at the beginning of the next school year with a separate group of students and the two remaining teachers. The assessment that was modified during the initial development was administered to 180 students as a pre-test to a unit on statistical inference, and student responses were used to ensure saturation of the codes from the initial development. The results were used to further refine the cycles, cycle definitions, and assessments. The results of the coding were also used to identify key examples that would be included with the framework.

The second modification phase occurred two weeks later, during the unit on inference. Sixteen students were selected using striated random sampling to include students of diverse IIR ability levels as identified by the pre-test. Students were placed into mixed-ability groups and data was collected using LiveScribe pens and by retaining written and digital student work during a six day unit on inference. Student conversations and artifacts were used to ensure saturation of the codes from the first modification. The results were again used to further refine the cycles, cycle definitions, and assessments, and to refine the list of key examples.

The validation phase occurred during the two weeks after the second modification phase, at the end of the unit on inference. The 180 students from the first modification phase took the final version of the assessment, and the 16 students from the second modification phase also participated in task-based semi-structured interviews. The results were used to identify whether any further modifications were needed to the SOLO adaptation or the assessment.

Results

During development a SOLO adaptation was posited that aligned with Reading's recommendations of a two-cycle model with one cycle dealing with naïve IIR and the second with appropriate IIR. Assessment and interview data was collected on eight sixth-grade students, and six of the eight students were classified as P, meaning their IIR ability was insufficient to place them into the Naïve cycle. However, amongst those six students there was a clear pattern; while they were all incapable of reasoning at the Naïve level, structures to their reasoning did emerge in the open coding. Those structures were compatible with the three components of IIR posited by Zieffler et al. (2008), and it became clear that there was value in extending the framework to lower levels of reasoning.

The data from the two modification phases supported the idea that the three question types tested three distinct concepts in IIR that students had developed at different rates. The impact on the SOLO adaptation was that it needed to be flexible enough to be applied to these three distinct concepts within IIR while still having level indicators that were defined clearly enough for inter-rater reliability. The bulk of the modifications in these phases involved balancing the specificity and generalizability of the cycle indicators. The resulting framework is presented in Table 1. Examples from EPG are presented in Table 2, while examples from CTS, and CBM question types were omitted for space but are available on request.

Table 1: Final SOLO Cycles and Indicators

Construct Cycle	Use of Variability	Use of Context	Certainty and Argumentation
Pre-Stuctural No Cycle		Modifies context to answer question	
Pre-IIR Cycle 1	No concept or use of variability	Answers based solely on context.	Deterministic language
Naïve-IIR Cycle 2	Limited conception or use of variability	Over-use of context over data or vice-versa.	Probabilistic language with minimal impact on conclusions
Appropriate IIR Cycle 3	Appropriate use of variability	Considers both context and data in strategies and solutions	Probabilistic language with uncertainty expressed in solution

Table 2: Solo Taxonomy Examples and Codes for EPG Question Type

SOLO Code	Estimating a Population Graph (EPG) Structure example	Structure Code
Pre-Structural	Expanding/personalizing context to provide answers.	Personal-context
	Student selects numbers from the context and/or problem and combines them arithmetically in an inappropriate or unfocused way	Undirected-arithmetic
U_1	Increasing all data values by a fixed amount.	Linear vertical-only
	Increasing all data values to level off the graph	Leveling-off-data
M_1	Using both strategies in U_1 independently	
R_1	Coordinating both U_1 strategies.	
U_2	Doubling existing data value frequencies	Doubling
	Proportionally increasing existing data values without including data at new values	Proportional vertical-only
M_2	Using both strategies in U_2 independently	
R_2	Coordinating the use of a U_2 strategy with consideration to the context	
U_3	Growing the sample proportionally both vertically and by including appropriate additional data values.	Proportional vertical-horizontal
	Student explanations include appropriate statements of uncertainty that reference (explicitly or implicitly) measures of spread or center.	Appropriate variability
M_3	Using both strategies in U_3 independently	
R_3	Coordinating the use of U_3 strategies.	

PRE-SERVICE TEACHERS' UNDERSTANDING OF ASSOCIATION AND CORRELATION IN AN INQUIRY-BASED INTRODUCTORY STATISTICS COURSE

Sihua Hu
Michigan State University
husihua@msu.edu

To teach statistics at the K-12 levels with success requires that preservice teachers (PSTs) to not only understand the statistics concepts, but also to make connections among them. Statistics educators call for the use of real data, technology, and active learning in an introductory statistics course for PSTs. But these components do not ensure desirable learning outcomes. This presentation provides an exemplar of such an content course, and presents a preliminary framework and qualitative analyses of pre-service teachers' activities related to the concepts of association/correlation in an inquiry-based and technology rich environment.

Keywords: Teacher Education-Preservice; Technology; Teacher Knowledge; Post-Secondary Education

The education community has recognized the importance and challenges of preparing future teachers to teach statistics (Committee on the Undergraduate Program in Mathematics, 2004; Conference Board of the Mathematical Sciences, 2001). Accordingly, the Guidelines for Assessment and Instruction in Statistics Education (GAISE) Project have produced the college report (GAISE, 2005) to provide six recommendations for educators to teach the introductory statistics courses and described 23 desirable student outcomes. This paper presents a snapshot of a content course for pre-service teachers (PSTs) that is designed to echo the call from the GAISE college report: incorporating a variety of data sets that are relatable to teachers' professional life and school life, using an educational software package that is relevant for teaching, and fostering active learning by engaging PSTs in statistical inquiries. By exploring PSTs' activities and their understandings of statistical concepts resulting from using real data and technology in an active learning environment, the realization of this content course and PSTs' learning outcomes in the light of the goals of statistics education as delineated in the GAISE college report is examined, which help fill in the gaps between the standards and their enactment.

In this paper, I present a case study of two groups of PSTs, and scrutinize the ways in which they use technology to engage in a small group activity related to the statistical concepts of association/correlation. *Statistical Association* is about the general relationship between any two or more variables, while *correlation* is specific to measuring the association between two *quantitative* variables to see the strength and direction of the relationship. The former concept is more inclusive than the latter one. In the existing literature, there are more studies on the (mis)conceptions of association in general, with seldom discussion of correlation explicitly.

In the literature, however, the problems used are mostly about finding the association between two or more categorical variables in a contingency table rather than quantitative variables, and the type of variables and its connection to the type of relationship one should look for are not explicit and highlighted. Moreover, these studies only asked the participants to find the statistical association between given variables in different problem settings, rather than asking them to pose a statistical question first and then to select the variables to answer the question. This study can also fill in the gaps of literature on the conceptions of association and correlation by connecting these two concepts, and to other statistical concepts, such as the type of variables.

Based on the literature and the vision of an introductory statistics course described above, I asked two research questions:

- What are the characteristics of PSTs' small group activities with the use of real data and the use of *TinkerPlots* (Konold & Miller, 2005) in an inquiry-based statistics content course?
- How well do PSTs understand and reason about the concepts of correlation/association as a result of learning, given such a context?

Method and Data Analysis

Statistics for Elementary Teacher is a 4-credit course for PSTs in the elementary teacher preparation program at a mid-west research university. The course in this study consisted of 28 sophomore and junior PSTs from social studies, literature, science, mathematics, and special education. The course was a mix of lectures and activities. Data include videos of students' on-screen activities and their talks recorded by a software package installed on the computer, and PSTs' written work. Video recordings were transcribed, and screen-shots were taken to serve as figures in the transcript for illustrative purposes. For this paper, two groups of four PSTs working on a 40-minute task were selected to illustrate the characteristics and patterns of PSTs' activities using technology and a real data set.

The Australia Student Data Task

Pre-task Instruction. The task happened in the second lesson of data analysis. The instructor had introduced graphing and using numerical indicator in regression as two ways to explore the *relationship* between *two* variables. The instructor elaborated on "correlation does not imply causation", and the idea that association can also mean a non-linear relationship between two variables. Also, he discussed other possibilities of the observed *association* such as chance or the existence of a lurking variable.

The Activity. The PSTs were given a data set with 29 attributes of 159 students in south Australia. They were asked to explore the data and formulate three questions that they could answer with these data, including one that compared two or more groups, and one that examines the *associations* between two quantitative variables. They were also encouraged to support their conclusions with the representations that they generated and with descriptions of statistics, and to discuss the possibilities of whether the *correlation* could imply a *causal relationship*.

Theoretical Framework

The characteristics of PSTs' classroom activities with the technology are operationalized by adapting the Model of Learning in Exploratory Data Analysis framework (Fitzallen, 2013). The framework consists of dimensions with *key behaviors* within each dimension. The dimensions are *Generic Knowledge*, *Being Creative with Data*, *Understanding Data*, and *Thinking about Data*, which come from previous research on statistical representation comprehension (Friel, Curcio, & Bright, 2001; Kosslyn, 1989; Moritz, 2004) and statistical thinking and reasoning frameworks (Shaughnessy, 2007; Wild & Pfannkuch, 1999). As a result, this framework is closely aligned to the GAISE report in terms of how the statistics community envisions the statistics education. In the coding process, new and repeatable *key behavior* that exemplifies each dimension was added to the list, and the descriptions of such codes were provided for iterative coding. I used the framework to code the transcripts, and themes related the student outcomes (of the lack thereof) in the GAISE report were surfaced. More analysis is underway for a wider scope, studying more activities across the spectrum of statistical topics. With more activities analyzed, a more comprehensive framework with new codes will be developed to capture the activities of PSTs in a technology-rich and inquiry-based statistical content course.

Results

The two groups of recorded PSTs engaged with the data at many different levels. Most of the time, they were (a) using their generic knowledge of the context and their technology knowledge of the software; and (b) engaging in basic transnumerations, including changing the scale of the axes, and color coding the icons in the plot by the third variable. The table below is a comprehensive account of these characteristics of their interactions:

Table 1. Percentage Of PST's Interactions At Each Dimension And Key Behaviors Within Each Dimension In The Australia Student Data Activity

Dimensions	Counts	Percentage	The two most frequent *Key Behaviors*	Percentage of The Two *Key Behaviors*
Generic Knowledge	N=26	45.61%	Speaking the language of the data and the graph	65.38%
			Understanding how to use the features of software and technology environment	19.23%
Being Creative with the Data	N=16	28.07%	Describing data from graphs	50.00%
			Constructing different form of graph	25.00%
Understanding the Data	N=8	14.04%	Making sense of data and graphs	62.50%
			Answering questions about the data	37.50%
Thinking about the Data	N=7	12.28%	Interpreting the data	57.14%
			Recognizing the limitation of the data	42.86%
	Total = 57			

In addition, patterns emerged from the quality of the salient *key behaviors*. In the next section, some salient characteristics of the activities that are astray from the goals of statistics education (as portrayed by the GAISE reports), and the misconceptions of association/correlation are described.

Anecdotes Mask Data as Opposed to Data Beats Anecdotes

The PSTs brought their own contextual knowledge extensively into their interactions, particularly when the task had open-ended questions (e.g., when a task did not specify which variables to analyze). Some anecdotes put forward by the PSTs were relevant to the discussion. These anecdotes helped the group choose attributes to consider, contributed to explanations of the variables as displayed on the graph, or helped them make sense of the data. But often the PSTs began sharing personal anecdotes irrelevant to the data, and got distracted by the extreme value in the data set without raising any question about the potential mistake in the data collection process. For example, one group spent quite some time to discuss a data point (30 hours of exercises per week) and their own exercise habits. Also, the PSTs did not persist in examining representations when the representations did not conform to their preconceptions of the relationships between the variables based on their contextual knowledge. For example, one group generated 27 different representations without scrutiny, and none of them "can be presented", according to them, in the whole class discussion that followed.

Misuse of Variables in Finding Statistical Relationships

The PSTs showed robust misunderstanding of association/correlation and the type of variables that they should be looking for. Both groups used correlation and association interchangeably in their discussions. As a result, they did not look among quantitative variables consciously to find potential correlation between variable pairs. It was evidenced in their discussion that they had many misconceptions on the variable types, and how types relate to the relationship between variables. Accordingly, even when they were instructed to look for quantitative variables, they would select a qualitative variable, or they tried to convert a qualitative variable to a quantitative one just by modifying the label on the axes to be numeric. Some features of *TinkerPlots* also emerged to contribute to PSTs' confusion about the variable type. For example, regardless of the variable types, the data points were put into bins in the graph by *TinkerPlots* after the PSTs selected the variables, which sometimes let the PSTs see visually how "qualitative" data could be "transformed" into quantitative ones by spreading out the points.

Discussion

The PSTs did not display most of the misconceptions discussed in the literature (e.g., Batanero, Estepa, Godino, & Green, 1996; Batanero, Estepa, & Godino, 1997). But it is evidenced in these two groups of PSTs' discussion that they could not consciously choose the right type of variables to explore the possible relationship, and they seemed to confuse *correlation* and the more inclusive concept *association*, and sometimes even equate them. Continuous variables can be transformed into categorical ones (e.g., age), if needed, but vice versa does not always hold (e.g., race). The lack of experience in collecting and cleaning data may render PSTs less knowledgeable in this statistical concept of variables, and eventually hinder their profound understandings of other related statistical concepts. The presence of technology and statistical inquiry using real data as advocated by the research community does not automatically ensure desirable learning outcomes in PSTs. By studying PSTs' understanding of various topics in statistics in such an environment, we can refine the process of the implementation of an introductory content course by making explicit the necessary connections among certain statistical concepts, and by refining our statistical discourse to make distinctions among different concepts during class discussions.

MATHEMATICS TEACHERS' APPROACHES TO STATISTICAL INVESTIGATIONS WITH MULTIVARIATE DATA SETS USING TECHNOLOGY

Tyler Pulis
North Carolina State University
hpulis@ncsu.edu

Hollylynne S. Lee
North Carolina State University
hollylynne@ncsu.edu

The purpose of this qualitative case study was to provide rich descriptions of mathematics teachers' approaches to statistical investigations using technology. Twenty participants completed parallel statistical investigations individually at the beginning and end of a course on teaching and learning statistics. Additionally, participants completed two group investigations during the course. The tasks provided different opportunities for participants to engage in statistical investigations using technology. A hybrid qualitative analysis including both deductive coding and inductive coding was used to characterize teachers' approaches.

Introduction

New school mathematics standards in the United States have an increased focus on statistics and data analysis (Common Core State Standards Initiative, 2010), while statistics education researchers have called for an emphasis at the secondary level on statistical investigations (Franklin et al., 2007). Dynamic statistical software developed specifically for teaching and learning statistics exists, but has not yet been widely adopted in schools. There is general consensus regarding the lack of teacher preparation and professional development to teach statistical investigations (MET-II, 2012; ASA & NCTM, 2013) as well as the need to ensure that teachers have adequate statistics content knowledge and opportunities to engage in all stages of a statistical investigation (Franklin et al., 2010). Recommendations included in the MET-II report include a statistics and probability course for teachers emphasizing active learning with hands-on devices (middle school) and technology (high school) focused on a four-step process of statistical investigation.

Since few teachers have had such a course or experienced learning statistics in the ways recommended by the GAISE and MET-II reports, research is needed to understand how to best prepare teachers to teach new statistical standards utilizing the recommended pedagogical practices. Literature in mathematics and statistics education has addressed student and teacher knowledge related to various statistical concepts, but there is a need for a study that examines teachers' approaches to an entire statistical investigation cycle while using technology. The purpose of this study is to describe and characterize teachers' approaches to statistical investigations with multivariate date sets using technology throughout a graduate level course on teaching and learning statistics.

Theoretical Background

There are many descriptions of statistical investigations in the statistics education literature. All agree the process is non-linear and involves going back and forth between various phases. Wild and Pfannkuch's (1999) statistical thinking framework included an investigative cycle adapted from MacKay & Oldford's (1995) PPDAC cycle (Problem, Plan, Data, Analysis, Conclusions). Additionally, Wild and Pfannkuch's (1999) description of five types of statistical thinking, (a) recognition of the need for data, (b) transnumeration, (c) consideration of variation, (d) reasoning with statistical models, and (e) integrating the statistical and contextual, guided the evaluation of teachers' work during a statistical investigation.

Recognition of the need for data to make decisions refers to acknowledging the inadequacy of personal experiences and anecdotes for drawing conclusions and making decisions (Wild & Pfannkuch, 1999). Snee (1999) described recognizing and collecting appropriate data as knowing which data are relevant. Chance (2002) added the key question, "Have we collected the right data?"

Transnumeration is a dynamic process of collecting, forming, and changing data representations to engender better understanding of a process or system (Wild & Pfannkuch, 1999). Transnumeration is involved in selecting appropriate measures, displays, and statistics for presenting and describing data. Chick (2004) described transnumeration as choosing the most appropriate representational technique. Shaughnessy (2007) suggested that different representations of data could reveal new information about the data that were previously hidden.

Consideration of variation means anticipating and recognizing the role of uncertainty and randomness in all processes (Wild & Pfannkuch, 1999). This consideration includes recognizing potential causes and sources of variation as well as knowledge of how to act on variation (Noll, 2007). Shaughnessy (2007) and Pfannkuch and Ben-Zvi (2011) also highlighted the centrality of variation to statistical thinking. Snee (1990) defined statistical thinking as "thought processes, which recognize that variation is all around us and present in everything we do, all work is a series of interconnected processes, and identifying, characterizing, quantifying, controlling, and reducing variation provide opportunities for improvement" (p. 118).

Reasoning with statistical models includes reasoning with tables and graphs as well as more complicated models (Wild & Pfannkuch, 1999). This includes reasoning with distributions or viewing data as an aggregate (Konold & Higgins, 2003). Moore (1999) described the importance of looking for overall patterns and deviations from patterns in data, choosing appropriate numerical descriptions of aspects of the data, and seeking compact mathematical models for sufficiently regular overall patterns in data.

Finally, integrating statistical and contextual reinforces the notion that statistical analysis cannot be divorced from context. Where, why, and how data are collected all play a role in decisions regarding data analysis (Wild & Pfannkuch, 1999). Chance (2002) described this type of thinking as constantly relating data to the context of the problem and interpreting conclusions in non-statistical terms.

Methods

This study examined twenty participants' responses to a pre- and post-task assigned in a graduate level class focused on teaching and learning statistics. The graduate course is considered an intervention because it was specifically designed to improve teachers' knowledge of statistical investigations from posing questions to making inferences. The course engaged teachers as learners in completing statistical investigations, reading relevant research on teaching and learning statistics, and designing statistical tasks for students. The instructor expected that teachers would learn to use dynamic statistical software during the course and assignments provided opportunities to both read about and engage in statistical investigations. As such, it was expected that teachers would demonstrate more evidence of statistical thinking at the end of the semester. This was not an experimental study and there was no control group, therefore no causal claims related to the course and changes in teachers' approaches can be made. However, information about the course provides useful context for understanding possible influences on teachers' approaches.

The participants consisted of one undergraduate in the last year of a secondary mathematics education program, fourteen current or pre-service mathematics teachers enrolled in masters' programs, and five PhD students in Mathematics Education. Sixteen participants were female and four were male. Five of the participants had no teaching experience, two had middle-school teaching experience only, and thirteen had secondary and/or post-secondary teaching experience. Those with teaching experience had between 3 and 15 years of experience with a mean of 6.9 years. Six of the participants had taught a statistics course at the secondary or post-secondary level.

Tasks for Assessment

Two parallel tasks were used for the purpose of describing participants' approaches to statistical investigation with a given multivariate data set using technology. The initial task, completed in the first week of the semester, was modified from Connected Mathematics: Data about Us (Lappan, 2004, p. 40). Participants were given data about sixth grade students' jump roping that included three variables, two of which were categorical (class and gender) and one quantitative (number of consecutive jump ropes). Participants were asked to generate questions, explore one of the questions using technology, describe their exploration and findings, and note any new questions that arose. They were provided with data files for Excel, TinkerPlots, and Fathom. Most participants had used these technologies in earlier courses.

For the final task, given in the last week of the semester, participants were provided with a new data set and asked to complete the same process. The data set was parallel in structure to the initial task including a quantitative variable (students' scores on the PSAT math section), as well as two categorical variables (grade level, and class).

In addition, two group investigations were completed during the course. In the first investigation, groups posed their own questions based on Census at School survey data (http://www.amstat.org/censusatschool/) and downloaded samples of data from the Census at School Random Sampler. The second group investigation involved planning how to collect and analyze data to determine whether different sets of dice were fair. Groups had to evaluate each other's claims and decide which set of dice they would recommend to a game manufacturer.

Coding

All initial and final tasks were blinded and initially coded using deductive, open coding, similar to a grounded theory approach (Strauss & Corbin, 1990). The researcher noted types of questions asked, the order and types of representations and calculations, descriptions of analysis, conclusions, and how technology was used during the investigation. After noting general similarities and differences in approaches, the researcher used inductive coding and identified evidence of Wild and Pfannkuch's (1999) five types of statistical thinking. For example, including multiple representations was considered evidence of Transnumeration when the participant described the new information gleaned from each representation. Multiple representations were also considered evidence of Reasoning with Statistical Models when participants used representations to make decisions about choices of statistical tests and measures. Results of the deductive and inductive coding were synthesized to create rich descriptions of teachers' approaches.

Findings

Participants' approaches to investigations varied more at the beginning of the course than at the end of the course. Most participants were able to ask appropriate statistical questions and draw appropriate conclusions on both the initial and final tasks as well as in the group investigations. On the initial task, participants were more likely to engage in either informal analysis or formal analysis, while on the final task most participants engaged in both informal and formal analysis, using the informal analysis to guide the formal analysis. On the initial task and first group investigation, participants used a wide variety of representations and approaches, while on the second group investigation and final task participants tended to use more similar approaches and representations.

Conclusion & Summary

This study examined teachers' approaches to statistical investigations using technology throughout a graduate level course on teaching and learning statistics. There was evidence of an increase in statistical thinking exhibited between the initial and final tasks. Additionally, various approaches to statistical investigations used by participants throughout the course were documented through an in-depth hybrid qualitative analysis. Detailed descriptions of these approaches and documentation of the statistical thinking evidenced in these approaches should prove valuable for planning experiences designed to engage teachers in statistical investigations.

EXPLORING REASONING OF MIDDLE SCHOOL STUDENTS ABOUT DATA DISPERSION IN RISK CONTEXTS

The aim of this research study is to explore students' reasoning concerning variation when they compare groups and have to interpret dispersion in terms of risk. We analyze in this paper the responses to two problems from a questionnaire administered to 82 ninth-grade students. The first one composed of losses and winnings coming from a hypothetical game; the second is about medical treatments. The results show the difficulty students had in interpreting variation in a risk context. Although they identify the data group with more variation, this is not enough for interpreting the variation in terms of risk and making a rational decision. The categories of risk-seeking and risk-aversion are used to explain the behavior of students. As a conclusion, it is suggested that more risk context situations should be studied.

Keywords: Data Analysis and Statistics; Middle School Education

Introduction

Variation is the underlying reason for the existence of statistics (Watson, 2006, p. 217). Moore (1990) emphasized the omnipresence of variation and the importance of modeling and measuring it in statistics; Wild & Pfannkuch (1999) included the perception of variation as part of the fundamental types of statistical reasoning. Burrill and Biehler (2011) proposed a list of seven fundamental statistical ideas in which variation is the second idea after data. Several researchers have explored contexts and problems to encourage students from different scholar levels to perceive, describe or/and measure variation in data. For example, variability in sampling (Watson & Moritz, 2000), chance (Watson & Kelly, 2004), repeated measurement (Petrosino, Lehrer & Schauble, 2003), weather (Reading, 2004). In this paper we propose two problems in risk contexts where dispersion is relevant and we explore the reasoning of middle school students in front of these problems.

Conceptual Framework

Four concepts constitute our conceptual framework: tasks or problems, risk context, reasoning and the SOLO model. An important part of research is to seek problems that promote the capacity to think and reason, about and with the fundamental ideas of the study area. Problems should be formulated in an appropriate context and encourage students to engage with the concept to be learned. Tasks on making decision under uncertainty are common in statistics and have been widely used to promote and analyze important aspects of the statistical reasoning of people. In addition, problems on comparing groups are frequently used to engage students in reasoning about data since in many statistical studies are used this kind of problems. In the present work two problems on decision making and comparing groups of data are proposed, in these problems variation is significant and their solution implies some risk preferences.

The interpretation of dispersion depends on the situation from which the data come. One kind of elemental problems where variation could emerge can be formulated in risk context. These situations appear when there are potential and unwanted results that, as a consequence, lead to losses or damages. A paradigmatic task in risk context consists in making a decision about two games where gains and losses are at stake. Consider the following problem:

The gains of realizations of *n* times the game A and *m* the game B are:
Game A: $x_1, x_2 \ldots ; x_n$

Game B: $y_1, y_2 \cdots; y_m$

Which of the two games would you choose to play in?

The solution is reached by following a flow diagram: 1) Compare $\bar{x}$ and $\bar{y}$, 2) if $\bar{x} \neq \bar{y}$ then chose the Game whose mean is the greatest; 3) if $\bar{x} = \bar{y}$ then there are two options: 3a) Choose any game, 3b) Analyze the dispersion of data in each game and choose according to risk preferences. These preferences can be defined as generalizations of the attitudes to reject or seek the risk identified by psychologists:

> …a preference for a sure outcome over a gamble that has higher or equal expectation is called risk aversion, and the rejection of a sure thing in favor of a gamble of lower or equal expectation is called risk seeking (Kahneman & Tversky, 2000, p. 2).

It is worth noting that in a game the dispersion of gains can be considered a measure of risk. A preference is motivated by risk aversion when an option whose data have less dispersion over another whose data have greater dispersion is preferred. The decision is motivated by risk seeking when the option whose data have greater dispersion is chosen.

This study is located in the area of statistical reasoning; the purpose of the research on it is to understand how people reason with statistical ideas (Garfield & Ben-Zvi, 2008). When students try to justify their responses, elements that they think are important to the situation are revealed; in particular, the data they choose, operations made with these and knowledge and beliefs on which they rest for doing that, are important in reasoning.

The Biggs and Collis (1982) Structure of Observed Learning Outcomes (SOLO) model is based on the assumption that development can be represented in hierarchical structures. Five levels are postulated in SOLO model: Prestructural level, the responses only show that students engage to task but do not use any relevant aspect to its solution. The Unistructural level, responses have one relevant aspect to the task solution. The Multistructural level present more than one relevant aspect but without integrate them. Relational level responses integrate in a coherent way more than one relevant aspect to the task. Finally, at the Extended Abstract level responses would show a higher abstract response. Applying these levels to analyze the answers to the tasks allows us to create a hierarchy that describes levels of students' reasoning of increasing complexity.

Method

The participants were 82 students (aged 14 to 16) belonging to two different ninth grade groups in a private school in Mexico City (last year of middle school).Two problems (which are presented below) were designed to explore the reasoning of the students:

Problem 1. In a fair, the attendees are invited to participate in one of two games, but not in both. In order to know which game to play, John observes, takes note and sorts the results of 10 people playing each game. The cash losses (-) or prizes (+) obtained by the 20 people are shown in the following lists:

Game 1: 15, -21, -4, 50, -2, 11, 13, -25, 16, -4
Game 2: 120, -120, 60, -24, -21, 133, -81, 96, -132, 18

If you had the possibility of playing only one of the two games, which one would you choose? Why?

Problem 2. Consider you must advice a person who suffers from a severe, incurable and deathly illness, which may be treated with a drug that may extend the patient's life for several years. It is possible to choose between three different treatments. People show different effects to the medication: while in some cases the drugs have the desired results, in some others the effects may be more favorable or more adverse. The following lists show the number of years ten patients in each treatment have lived after being treated with one of the different options; each number in the list corresponds to the time in years a patient has survived with the respective treatment. The graphs corresponding to the treatments are shown after.

Treatment 1:	5.2,	5.6,	8.5,	8.5,	7.0,	7.0,	7.0,	7.9,	8.7,	9.1
Treatment 2:	6.8,	6.9,	6.9,	7.0,	7.0,	7.0,	7.1,	7.1,	7.2,	7.4
Treatment 3:	6.8,	6.8,	6.9,	7.0,	7.0,	7.1,	7.1,	7.1,	7.2,	7.4

[There were graphs with values shown above]

What kind of treatment would you prefer (1, 2 ó 3)? Why?

Results

In this section we present examples of responses to questions: If you had the possibility of playing only one of the two games, which one would you choose? Why?, and What kind of treatment would you prefer (1, 2 ó 3)? Why? In order to show answers that were classified at each SOLO level.

Prestructural. In this level one option is chosen but without justification. For example, a student chose game 2, “because you win more”, but there is no evidence of how the data are used. This kind of responses provides no progress in understanding the situation.

Unistructural. In this level the maximum, minimum or mode of each data list are observed and compared to give the response; for example, a student chooses Game 1 “because you can also lose as in game two but fewer and you risk less”. The student provides an indication that shows he compares the minimum of both games. Indeed, it is possible that the way in which the student approaches the problem is influenced by risk aversion, since he skews his attention toward the losses, ignoring the information that provides positive gains.

Multistructural. In this level the sums of the data lists are compared or both the maximum and minimum are considered and, in this case, risk is perceived. For example, a student chose the treatment 3 “Because maybe I will not live nine years but I have secured from 6.8 to 7.4”. Although not mentioned, it appears that the student perceives the risk involved in the first treatment (the possibility to live only 5.2 years) because he gives up the opportunity to live 9, "ensuring" live at least 6.8 years.

Relational. In this level the mode of the data and its range are considered; the final decision is influenced by preferences about risk. Only two cases were included in this level. For example, a student chose treatment 3 "because it is more likely to live 7.1 years or less, but the results are not so far apart and are more likely to live from 6.8 to 7.2 years".

In general, predominate Prestructural responses (76 %); students whose answers are classified at this level understand what is asked them and they make a choice but fail to use the data to support their preferences. However, there are students who see in a single value of each data set (maximum, minimum or mode) a key to make a decision. These responses have been classified in the Unistructural level (15 %); they prefigure the valid scheme of solution. The value chosen is one that students consider a representative of the set. In responses of Multistructural level (7 %), a step forward towards the solution scheme is given, since more than one value of each data is considered. Two main strategies were identified: 1) compare the sum of values of each set data, 2) take into account the maxima and minima. Each of these strategies is an early or primitive form of the two main statistical tools of the case: the mean and dispersion. The second strategy led some students to perceive the risk. Finally, In Relational level responses (2 %), both strategies are used and the decision is made according of attitude towards risk. In these responses a scheme of solution is complete.

Conclusions

Our main result is a SOLO hierarchy which describes the students' reasoning patterns. Such hierarchy is the next: *Prestructural level*, one option is chosen but without justification. *Unistructural level*, the maximum, minimum or mode of each data list is observed and compared. *Multistructural level*s, the sums of the data lists are compared or both the maximum and minimum are considered. *Relational level*, the sums or modes of the data lists are compared and the range is considered; the final decision is influenced by preferences about risk.

In the problems that we have reviewed may be not convincing that the choice of a game or treatment is not completely determined by the behavior of the data, but also depends on the solver attitude towards risk. This relativity can disturb those who believe that science must give absolute and conclusive answers to the problems that arise on it. Relativity of the responses may obscure the main point which is that the analysis of the ranges, and more generally the analysis of variation, that provides information about the risks involved in the situation and therefore helps to make rational decisions. The use in teaching of problems as those treated in this study can help the students to construct schemes for assessing the results of the statistical analysis and help them to retreat from certainty in a profitably way.

GLIMPSING SECONDARY MATHEMATICS TEACHERS' AFFECT TOWARD STATISTICS: WHICH TEACHING AND LEARNING EXPERIENCES ARE MOST SIGNIFICANT?

Christina M. Zumbrun
Trine University
zumbrunc@trine.edu

As a result of the recent increase of statistical topics in the school curriculum, there is a need to study the attitudes and beliefs of secondary mathematics teachers with respect to statistics since research has shown that teachers' affect is connected to student learning (Estrada & Batanero, 2008; Shaughnessy, 2007). Because the attitudes, beliefs, and emotions (affect system) of practicing secondary mathematics teachers toward statistics are not known, an initial inventory of these constructs was conducted via a survey instrument. This introductory study explored the connection between affect and statistical teaching and learning experience by examining teachers' responses to several items on the survey. Based on the responses to the survey items, experience teaching a stand-alone statistics course did influence teachers' confidence to teach and learn statistics, while undergraduate courses in statistics had less impact.

Keywords: Teacher Beliefs; Data Analysis and Statistics; Affect and Beliefs

Introduction

Over the last few decades there has been a growing concern that large numbers of secondary mathematics teachers "have backgrounds in mathematics with little or no training in statistics," with no teaching certification available or required for statistics (Gould & Peck, 2004, p. 1). This emphasis on mathematical topics in pre-service teacher programs has contributed to teachers' deficiency in statistical literacy, which may impact student learning of statistical topics (Pierce & Chick, 2008). Because of inadequate formal training in statistics, many teachers may feel anxiety at the prospect of teaching the subject and may elect to exclude statistical topics from their courses altogether. In other cases, teachers' anxiety towards statistics can contribute to a dislike of the subject or a feeling that statistics is not valuable (Estrada, Batanero, & Lancaster, 2011), feelings that may later be transferred to students from their teacher (Estrada & Batanero, 2008).

Secondary mathematics teachers (SMTs) who teach statistics as a stand-alone course gain important experience despite any possible deficiencies in their formal university training in the subject. It is possible that this population of SMTs may have more positive attitudes towards statistics than those teachers who lack any experience teaching statistics. However, the exact nature of any possible differences between the attitudes, beliefs, and emotions (*affect system*) of those teachers who have taught statistics and those who have not is unknown at this time.

Unfortunately, practicing teachers who have no special preparation or education in statistics may exhibit negative attitudes towards statistics (Estrada, et al., 2011). Not surprisingly, in research conducted with prospective teachers it was found that with more courses taken in statistics and more knowledge of statistics, attitudes tended to be more positive (Estrada, et al., 2011). In addition, research with in-service elementary teachers indicated that their earlier education of statistics (and positive learning experiences with statistics) was a major impact on their attitudes (Estrada, et al., 2011). Hence knowledge of statistics alone does not predict one's attitudes towards statistics, but personal experiences that one has with statistics are influential.

In this initial study, teachers' formal educational experiences with statistics were defined by the number of undergraduate statistics courses they completed. The teachers also shared information related to their teaching experiences by responding to survey items related to number of years teaching high school mathematics and whether they had taught statistics as a stand-alone course (or not). In fact, teachers' experience with teaching statistics as a stand-alone course provided a useful framework for considering their responses to the other survey items. Differences in responses between the two groups of teachers (defined by experience teaching statistics versus those without such experience) provided the structure for exploring their formal experiences with statistics, both as a teacher and as a student.

A teacher's affect toward teaching statistics is connected to the teacher's experience: it connects to the teacher's beliefs about statistics, mathematics, statistics and mathematics in relation to one another, and about teaching practice in general. Pierce and Chick (2008) stated that "teachers' beliefs about statistics itself will contribute to both their attitude towards teaching statistics and their [teaching] practice" and "such beliefs will depend on their own experiences of learning and using statistics" (p. 4). Therefore, examining teachers' personalized beliefs about statistics itself was critical, and two survey items were designed to gauge teachers' assessment of their own ability to master statistical content (general versus introductory coursework).

Purpose of the Study

Since the teaching and learning of statistics is influenced by the teacher's affect system toward statistics, this introductory study focused on the teachers' own participation within the teaching and learning cycle. Some of these personal experiences have likely shaped the teachers' affect toward statistics as well as the teachers' views of themselves as students and as teachers. Because of this, the role of the teacher's attitudes, beliefs, and emotions becomes increasingly important as one considers the connection to teaching practice and student learning.

Thus the purpose of this study was to begin to examine the affect system of the population of SMTs toward statistics by focusing on the teachers' experience with teaching and learning statistical topics. The study focused on the following research question: What are the key differences in teaching and learning experiences related to statistical concepts between practicing SMTs who have taught a statistics course versus those who have taught statistical concepts only as part of a regular mathematics class, and are there related differences in affect?

Methods

The SATS-36 (Survey of Attitudes Toward Statistics) was designed to capture the attitudes and beliefs of university students taking an introductory statistics course (Schau, Stevens, Dauphine, & del Vecchio, 1995). Because the attitudes, beliefs, and emotions of SMTs was expected to be similar to this population (Pierce & Chick, 2008), the existing instrument provided the best basis on which to begin studying this new population. Thus, the SATS-36 provided a basis for the survey instrument that was used for the present study. Some additional items were constructed in order to provide demographic information regarding the experience of the teachers with teaching and learning statistical topics.

The teacher response data was collected by using an online survey system which emailed the survey to a random sample of SMTs from a Midwestern state. The survey was initially emailed to 502 teachers. Of the 502 who were emailed the survey, 92 filled out the survey giving a response rate of 18.3%. Based on this response rate, the survey was emailed to an additional random sample of 276. Of the 276 who were emailed the survey, 49 filled out the survey giving a response rate of 17.8% for the second mailing. Thus, the overall response rate was 18.1%. The results for six survey items related to teaching experience and education is found in Table 1; responses were broken down by experience teaching statistics.

Table 1: Statistical Teaching and Learning Experiences

Have you ever taught a stand-alone high school statistics course?		How good at mathematics are you?*	How many years have you taught high school mathematics?	How many undergraduate statistics courses did you complete?	How good at statistics are you?*	How confident are you that you can master introductory statistical content?*
NO n=112	Mean	6.3	3.4	2.4	4.7	5.7
	Std. Deviation	0.6	1.7	0.9	1.1	1.2
YES n=27	Mean	6.5	4.6	2.4	5.7	6.4
	Std. Deviation	0.5	1.7	0.9	1.3	1.2
	P-value for difference between means for two groups	0.108	0.001	0.944	0.000	0.007

*Starred items originated on SATS-36 (Schau, et al., 1995)

Discussion of Results

For each of the five survey items, means and standard deviations were calculated for those teachers who had taught statistics as a stand-alone course and those who had not. Two-sample T-tests were run to determine which items showed significant differences in responses between the two groups of teachers. The resulting p-values from the two-sample T-tests are shown in Table 1. At the 0.05 level, significant differences were found for three items.

There was a significant difference between the two groups of teachers for the total number of years teaching high school mathematics. The mean number of years was 4.6 years (s=1.7) for the group of teachers who had taught statistics as a stand-alone course, and the mean for those without experience teaching a statistics course was 3.4 years (s=1.7) (p-value for difference=0.001). This result suggested meaningful differences in overall mathematical teaching experience and provided a context for evaluating the other survey items.

The differences between the two groups of teachers were also statistically significant for the survey items in the last two columns in Table 1. Both of these items related directly to teachers' confidence in learning and applying statistics, and it was not surprising that the teachers who had taught statistics as a stand – alone course had higher mean responses to these items than teachers with no experience teaching statistics as a stand-alone course. The SMTs who had taught statistics as a stand-alone course generally agreed that they could master introductory statistical content. The difference in level of agreement with this statement was significantly higher for the group who had taught statistics compared with those who had not taught statistics (p-value=0.007). This group of SMTs with experience teaching statistics also reported a higher level of proficiency for their own statistical skills. The difference in level of ability reported by the two groups of teachers on the item "How good at statistics are you?" was significant (p-value=0.000). Based on the responses to these two items, confidence to learn and apply statistical content is strengthened with teaching experience in the population of SMTs.

The SMTs with experience teaching statistics reported higher levels of personal confidence regarding mathematical abilities, but the difference between the two groups of teachers was not significant on this item (p-value=0.108). The teachers who had never taught a stand-alone statistics course had a slightly higher mean value, although the difference between the means on this item were not statistically significant (p-value=0.944) so a difference cannot be assumed for the two populations of teachers on this item. In fact, one could not exclude the possibility that the number of undergraduate statistics courses completed was the same for the two groups.

Based on these introductory results, SMTs who teach statistics as a stand-alone course have been teaching high school mathematics longer than teachers who have not taught statistics as a stand-alone course, their confidence in their ability to employ statistics is generally more positive, and they are more secure in their ability to master introductory statistical content. Taken together these findings are not surprising, but future work involving classroom observations and interviews will delve more deeply into the mechanisms driving the differences.

EXPLORING UPPER ELEMENTARY STUDENTS' USE OF THE REPRESENTATIVENESS HEURISTIC

Karen Zwanch
Virginia Tech University
kzwanch@vt.edu

Jesse L. M. Wilkins
Virginia Tech University
wilkins@vt.edu

A common theme in the study of math education is that students do not necessarily reason normatively through uncertain probabilistic situations. Instead, they rely upon heuristics as a means of reducing the mental strain necessary for normative probabilistic thinking (Kahneman & Tversky, 1972). This study explores use of heuristical reasoning by fifth grade students on probabilistic tasks related to game spinners. Reasoning classified by the representativeness heuristic was found to be utilized by eleven out of the fourteen students interviewed across four series of questions. Their reasoning, however, was inconsistent and vacillated between normative and heuristic.

Keywords: Probability; Elementary School Education; Cognition

Literature Review

The use of heuristics within statistical reasoning refers to thinking that deviates from the stochastically accepted norm, and is employed in uncertain stochastic situations as a means of mitigating mental strain (Kahneman & Tversky, 1972). Heuristics exist, then, in staunch contrast to normative reasoning, which is considered to be the standard and expected reasoning accepted by stochastic experts. Heuristics are commonly applied in probabilistic situations, and are not exclusively used by students. For example, they have also been found to be employed by seasoned professionals trained in research (Kahneman & Tversky, 1972).

The use of heuristics, although non-normative, can be intermittently successful, as heuristical reasoning will at times provide sufficient information to make reasonable decisions (Shaughnessy, 1992). The sporadic success achieved through non-normative reasoning makes the elimination of heuristical reasoning difficult (Kahneman & Tversky, 1972). These difficulties in eliminating and identifying non-normative student reasoning has become the focus of much research in the teaching and learning of probability (Jones & Thornton, 2005).

The representativeness heuristic is one type of non-normative reasoning which plagues student reasoning. Kahneman and Tversky (1972) identify the application of the representativeness heuristic in the following manner:

> A person who follows this [representativeness] heuristic evaluates the probability of an uncertain event, or a sample, by the degree to which it is: (i) similar in essential properties to its parent population; and (ii) reflects the salient features of the process by which it is generated. (p. 431)

This definition describes two distinct ways in which the representativeness heuristic may be relied upon by those who do not have a deep understanding of probabilistic concepts.

Konold, Pollatsek, Well, Lohmeier, and Lipson (1993) asked students to select which outcome from five coin tosses was most likely, or whether all choices were equally likely. Reasoning that THHTH is more likely than HTHTH because it appears more random represents a limited understanding of randomness, therefore indicating reliance upon the representativeness heuristic. Reasoning that THHTH is more likely than THTTT because it is closer to an equal proportion of heads and tails would demonstrate reasoning characteristic of the representativeness heuristic due to insufficient understanding of sample size. Reasoning characteristic of the representativeness heuristic has additionally been identified in a range of ages beginning in second grade (Davidson, 1995) and continuing through both pre-service (Chernoff, 2012) and in-service (Wilkins, 2007) teachers. This research across various ages indicates that the representativeness heuristic is developed prior to the onset of formal instruction in probability and continues to plague normative reasoning into adulthood.

Additional research has identified non-normative reasoning related to a game spinner. Green (1983) found that students ages 11-16 overwhelmingly struggled to reason about game spinners with noncontiguous sections. This inability to reason normatively may be due to students' use of a subcategory of representativeness known as recency (Jones & Thornton, 2005). Recency may manifest itself visually when students become hyperaware of whether the sections of a noncontiguous spinner are contiguous or noncontiguous (Green, 1983).

The present study specifically seeks to determine: 1) whether upper elementary students engage in use of the representativeness heuristic to reason about game spinners, and if so, 2) whether the representativeness heuristic is consistently applied across questions.

Methods and Procedures

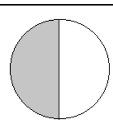
Sample

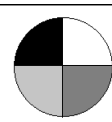
The participants in this study include 14 fifth grade students in a rural elementary school in the south eastern United States. This age range was selected due to the recommendation of the National Council of Teachers of Mathematics (2000) that formal probabilistic instruction not begin prior to third grade. Students selected were chosen from three ability categories, as determined by the teacher; Level 1 being most advanced, Level 2 being intermediate, and Level 3 being least advanced. One of the participant's responses were uninterpretable in terms of normative and non-normative reasoning, so analyses are based on only 13 of the 14 participants.

Procedures

Participants were engaged in a semi-structured clinical interview during which they manipulated three distinct game spinners and were asked a series of questions about the likelihood of different events. The semi-structured interview was video and audio recorded so as to allow the researcher to retrospectively analyze the students' reasoning with each spinner.

The first two game spinners contained equally proportioned, colored sections, with each color represented once (Figure 1). The third game spinner contains six sections and four colors. Each section covers a different portion of the spinner, and yellow is represented by three sections. The three yellow sections are noncontiguous and the yellow sections represent the smallest overall portion of the spinner.



Spinner 1	Spinner 2	Spinner 3

Figure 1: Spinners used in the clinical interview

Results

In the first of four series of questions, students spun Spinner 1 (Figure 1) and were asked if the resulting color was more likely to be spun again on the next spin, less likely, or equally likely. Seven out of 13 students answered in a manner which suggested use of the representativeness heuristic (see Table 1). One student reasoning normatively indicated understanding that the second spin was independent of the first by remarking that the second spin "might land on either because it's half and half." Many students demonstrating reasoning characteristic of the representativeness heuristic either reasoned that a second spin was more or less likely to result in the same color; this type of reasoning is termed recency and is a subset of the representativeness heuristic (Jones & Thornton, 2005). One student explained that after spinning red the second spin was more likely to be “red again because it’s easier to spin.”

In the second series of questions, students spun two of Spinner 1 at the same time. Prior to spinning, they were asked if it was more likely for both spinners to result in the same color or different colors, or if both outcomes were equally likely (note: it is equally likely to be the same or different). Eight out of 13 students gave responses consistent with the representativeness heuristic by indicating that it was more likely for the spinners to land on different colors (see Table 1). Common responses from students engaging the representativeness heuristic included an explanation that because each color had a 50% chance of being spun, two spinners were more likely to land on different colors.

The third series of questions mirrors the first by asking students to spin Spinner 1 and observe the result, and then spin a second but identical spinner. Only after knowing the result of the first spinner are they asked to determine if the same color is more likely, less likely, or equally likely to be spun on the second spinner. Seven out of 13 students answered in such a way as to indicate their use of the representativeness heuristic (Table 1). Six out of 7 students identified with representative thinking also employed the representativeness heuristic in the second series of questions. Five out of the 7 students identified also employed the representativeness heuristic in the first series of questions.

Table 1: Comparison of Students’ Reasoning in Similar Series of Questions

		Q2		
		R	N	Total
Q1	R	6	0	6
	N	2	5	7
	Total	8	5	13

		Q3		
		R	N	Total
Q1	R	5	1	6
	N	2	5	7
	Total	7	6	13

		Q3		
		R	N	Total
Q2	R	6	2	8
	N	1	4	5
	Total	7	6	13

Series of questions are denoted Q1, Q2, Q3. R denotes representative reasoning and N denotes normative reasoning. All comparisons sum to 13, as one student’s reasoning was not interpretable on the second and third series of questions.*

In the fourth series of questions students predicted the results of spinning each spinner ten times, then were asked whether this represented a sufficient sample to expect results representative of the total population. Four students out of 10 consistently engaged in reasoning consistent with the representativeness heuristic by indicating the results should equate with the theoretical probabilities. One student in particular was unable to predict the outcome of ten spins on Spinner 2. Theoretically, each section of Spinner 2 would be spun 2.5 times out of ten. Practically, this is an impossibility. This student’s trouble with this mismatch was verbalized when she answered, “It… well… I’m not… it can’t.” When this student was instead prompted to make a prediction for spinning Spinner 2 eight times, she readily answered that each color would be spun twice. Students reasoning normatively arbitrarily selected each section to be spun two or three times and did not seem confused when the results did not match their prediction.

Conclusion

The results of this study answered the first research question by indicating that fifth grade students do engage the representativeness heuristic when reasoning about game spinners. Of the 13 students, 10 used the representativeness heuristic predominantly to reason through at least one series of questions. The three remaining students reasoned normatively throughout the interview. In response to the second research question, three groups of students emerged. Students in Group 1 reasoned normatively throughout the interview. Students in Group 2 reasoned both normatively and non-normatively. Students in Group 3 consistently using the representativeness heuristic.

In addition to providing evidence of the use of the representativeness heuristic by fifth grade students, this study further provides evidence that in statistically equivalent situations, students do not necessarily reason in the same way. Series of Questions 1, 2, and 3 were statistically equivalent. However, students did not necessarily reason consistently throughout. Five students engaged the representativeness heuristic in these situations, and conversely, four students reasoned normatively in these situations. The remaining five students reasoned both normatively and non-normatively. This is indicative of the inability of students to view the two situations as identical and further may relate to students' notions of event independence (Konold et al., 1993). This finding lends itself to further investigation of what other statistically identical situations and models exist which students may not be prepared to distinguish between.

The procedural context of situation 2 was not identical to situations 1 and 3, although the probabilities of each outcome are identical. The difference lies in the timing of the spinners, and the inability of the students to know the outcome of the first spinner prior to predicting the outcome of the second. Eight students used the representativeness heuristic as a predominant part of their reasoning on this question, which represents a higher percentage than any other question. Of those eight students, five engaged the representativeness heuristic on Questions 1, 2, and 3.

The current research contributes to the breadth of understanding related to the types of questions to which fifth grade students may apply the representativeness heuristic. This brings relevance to the type of questions which must be considered in upper elementary curricula and in future research.

HOW STUDENTS NAVIGATE STEM-INTEGRATED DATA ANALYSIS TASKS

Aran W. Glancy
University of Minnesota
aran@umn.edu

Keywords: Data Analysis and Statistics; Elementary School Education; Measurement

In recent years, the increased attention of policy makers, educators, and researchers on education in science, technology, engineering, and mathematics (STEM) has resulted in various reforms aimed at improving student performance within these disciplines. One approach to this that is gaining in popularity is the integration of the disciplines through rich problem-solving situations. According to a report from the National Research Council's Committee on Integrated STEM Education (2014), research on the impact of STEM integration indicates that this approach has promise both with regard to learning outcomes and attitudes toward the STEM disciplines, but as of yet, the evidence for this is limited, and the benefits are less pronounced with regard to mathematics learning outcomes. More research is needed to identify the mechanisms by which integration can enhance learning, specifically in mathematics. This multiple embedded case study begins to address this by examining the ways students apply statistical concepts and engage with data in integrated settings.

The data analysis techniques used in science and engineering contexts are built on mathematical ideas making data analysis tasks ideal for studying the interactions between these disciplines. In this study, I document the work of eight groups of fifth grade students as they navigate data analysis tasks and attempt to reason from data in science and engineering contexts. The tasks ask students to collect, organize, interpret, and ultimately make decisions or draw conclusions from their data in the context of scientific inquiries or engineering design challenges. Previous literature has argued that tasks such as these that focus on authentic problems with real data and encourage students to generate their own questions (Franklin et al., 2007; Moore, 1998; Watson, 2006) are successful strategies for supporting statistical reasoning, and the results of this study conditionally support those findings. One key observation in this study, however, was that in many cases, students' informal understanding of the phenomenon being tested helped them make sense of the data rather than their analysis of the data allowing them to draw conclusions about the phenomenon. Additionally, students' general number sense and difficulty making sense of measurement error and uncertainty were significant barriers to their success. These findings have implications for the design of data analysis tasks in science and engineering contexts if they are to support statistical reasoning.

EIGHTH GRADE STUDENTS USE CONTENT SUBSTITUTION WHEN SOLVING PROBABILITY PROBLEMS

Jean Mistele
Radford University
jmistele@radford.edu

Keywords: Probability; Middle School Education; Problem Solving

Framework. Heuristic and Biases theory (e.g. Tversky & Kahneman, 1974) has been used to study people's cognitive processes by mathematics educators and psychologists (e.g. Fischbein, 1999; Shaughnessy, 1981). The theory was updated to include dual process theory –System 1 (intuition) and System 2 (reasoning)- that may explain biased results when people, unaware, use the *attribute substitution* process linked to System 1 thinking (e.g. Kahneman & Fredrick, 2002).

Purpose. The aim of this paper is to share a particular phenomenon observed from a larger study (Mistele, 2014) that explored eighth grade students' probability problem solving strategies using this updated framework. Focusing on this particular phenomenon required a more targeted research question using the same data. The revised research question is: "In what way was a participant's problem solving strategy influenced by System 1 thinking or slow intuition?"

Participants. There were six eighth grade students from a rural, predominantly white, middle class school located in a mid-Atlantic state. Purposeful sampling (Patton, 1990) was used to identify these students that had strong probability knowledge and prone to using heuristics.

Research design. This was a basic exploratory research study. Data was collected from two, multiple choice, questionnaires and two, tasked based, interview sessions that used the think-aloud protocol (Van Someren, et al., 1994). The questionnaires were analyzed based on the literature. The constant comparison method (Glaser, 1965) was used to analyze the interviews.

Findings/Results. At times, some students used the attribute substitution process as expected (Kahneman & Fredrick, 2002). Another process called, *content substitution* was identified (Mistele, 2014) in which a person replaces probability knowledge with fraction knowledge when using System 1thinking or a slower intuitive process called slow intuition. Fischbein (1999) also noted proportional thinking when exploring his notion of intuition that seems to differ from this.

Conclusion. Some students were observed replacing probability knowledge with fraction knowledge, specifically, they used equivalent fractions procedures. Targeting instructional strategies to off-set the inappropriate use of fraction knowledge requires more research.

ELEMENTARY PRE-SERVICE TEACHERS' STRATEGIES TO COMPARE VARIABILITY IN DOT PLOTS

Feng-Chiu Tsai-Goss
Western Michigan University
feng-chiu.tsai@wmich.edu

Joshua Michael Goss
University of New Haven
jgoss@newhaven.edu

Keywords: Data Analysis and Statistics; Teacher Education-Preservice; Teacher Knowledge

Variability has been recognized as an important concept in K-12 statistics curriculum (Franklin et al., 2007). It is recommended that pre-service teachers be prepared with an adequate knowledge of variability to describe and interpret data, and to use the results to draw conclusions about questions of interest (Conference Board of the Mathematical Sciences [CBMS], 2012). Elementary school teachers are expected to at least possess the concepts of statistics at the level that are expected of middle school students (Franklin, 2013). That is, elementary pre-service teachers (EPTs) should be prepared beyond knowledge about statstical graphs. Prior studies had focused on evaluating EPTs' performance to find the variability in various types of statistical graphs (e.g., Cooper & Shore, 2008; Lem et al., 2013). However we still do not know enough about EPTs' reasoning about variability when they encounter the tasks to compare variability in dot plots. Thus, this study aimed to answer the following research question:

What strategies do elementary pre-service teachers use to compare variability in dot plots?

This work is part of a larger study investigating EPTs' understanding of variability. A task-based interview was used in the study to collect nine EPTs' thinking about variability. Each interview lasted approximately one hour and eight tasks were designed to deeply explore participants' understanding of variability. This study presented nine EPTs' responses in five tasks that asked to compare variability in dot plots. Shapes were deliberately incorporated into the design of the tasks to challenge EPTs' thinking of variability in dot plots. The results showed six strategies identified from the participants' responses and discussed their misunderstanding of variability revealed in their interpretations of the strategies. Implications for learning from elementary pre-service teachers' thinking in comparing variability in dot plots will be presented.

IN-SERVICE STATISTICS TEACHERS' PROFESSIONAL IDENTITIES

Douglas Whitaker
University of Florida
whitaker@ufl.edu

Keywords: Data Analysis and Statistics; Affect and Beliefs; Teacher Beliefs

In the present US context, statistics represents a substantial component of the Common Core State Standards for Mathematics (NGACBP & CCSSO, 2010) in grades 6-12 and generally represents the trend of increasing statistical requirements for both students and their teachers. The expectation is that statistics content will be taught primarily by mathematics teachers, most of whom have limited statistical training. The growth that these teachers are being asked to undertake is complex and may require changes in their beliefs, attitudes, values, and practices germane to the teaching of mathematics and statistics. These and other affective constructs can be profitably viewed as subconstructs of a broader 'identity' construct (Philipp, 2007).

Because statistics is a mathematical science and not a branch of math (Cobb & Moore, 1997; Moore & Cobb, 2000), the professional identity that mathematics teachers are expected to develop (NCTM, 1991) may not be directly applicable to teaching statistics. Instead, a professional identity as a statistics teacher may be required to ensure that students learn statistics at the level expected of them. What precipitates such a statistics identity is not currently known.

The purpose of this study is to understand how exemplary statistics teachers developed their professional identities by answering the following research question: *What learning trajectories help to explain the identity of exemplary statistics teachers?* Exemplary statistics teachers will be identified by experts in the field of statistics education.

The identity framework used in this study synthesizes work from communities of practice (Lave & Wenger, 1991; Wenger, 1998) and Gee's (2000) identity framework. This framework is further informed by Social Cognitive Career Theory (Lent, Brown, & Hackett, 1994) and Philipp's (2007) summary of the various aspects of identity. Because of the multi-faceted nature of identity, multiple data sources will be used, including two semi-structured interviews and surveys that foreground specific aspects of identity (such as attitudes and beliefs). Data collection and analysis will begin in June 2015 with findings to be presented in November 2015.

MATHEMATICAL AND FINANCIAL LITERACY WITH FAMILIES

Lorraine M. Baron
University of Hawaiʻi at Mānoa
baronl@hawaii.edu

There is a strong link between citizens' quantitative literacy abilities and their financial prosperity. This study applied a social justice perspective to describe families' personal flourishing within the context of numerical, mathematical, and financial literacy (NMFL) education. Four families participated in a weekly community program with mathematical and financial literacy goals. The data showed that participants gained confidence and skills and felt empowered to teach/transfer that knowledge to their children. The author proposes a conceptual framework linking personal flourishing with NMFLs, and suggests the framework be used to investigate and describe quantitative and financial literacy in future empowering pedagogies research.

Keywords: Equity and Diversity; Informal Education; Policy Matters; Affect and Beliefs

Numerical, mathematical and financial literacies (NMFLs) are pressing economic, social, and cultural challenges. There is a strong link between citizens' basic numerical or mathematical abilities and their financial prosperity and civic engagement (Human Resources and Skills Development Canada, 2012). It is becoming evident that NMFLs are increasingly necessary for fully contributing citizens of tomorrow (Steen, 2001). This study applied a qualitative research approach to describe personal flourishing (Grant, 2012) which includes participants making meaning and sense of important aspects in their lives, having a sense of agency, and participating in activities of financial literacy. Personal flourishing was investigated within the context of numerical, mathematical, and financial literacy (NMFL) education.

Four families participated in a weekly evening program (eight consecutive weeks). The Count On Yourself (COY) project was designed to inform participants about NMFLs. Count On Yourself provided a parallel program for adult and child NMFL literacy: while parents were involved in a financial literacy course, their children participated in a *Math Camp* led by teacher candidates from a local university. The goal of the project was for both adult and child participants to become more mathematically empowered. Analysis of the individual and focus group interview data showed that adult participants described a sense of personal flourishing, gained confidence and skills, and felt financially empowered enough to teach/transfer that knowledge to their children. This initiative integrated research and practice and addressed the practical needs of a community.

Based on a research study that sought to analyze how participants would express their ideas of financial literacy and express their personal flourishing, I propose a conceptual framework designed to study programs that promote Numerical, Mathematical and Financial Literacies (NMFLs) and to describe the participants' voices. A robust social justice research vision (Grant, 2012) was applied to offer numerical, mathematical and financial literacies in a community. The research asked: 1) How did the adult participants describe their learning about financial literacy? and 2) How did this impact them and their families, and what, if any action did they take?

On Numerical, Mathematical and Financial Literacies (NMFLs)

Innumeracy, or "an inability to deal comfortably with the fundamental notions of number and chance, plagues far too many otherwise knowledgeable citizens" (Paulos, 2001, pp. 3-4). Numeracy was determined by Smith, McArdle, and Willis (2010) to be "by far the most predictive of wealth among all cognitive variables" (p. 18). Behrman, Mitchell, Soo, and Bravo (2010) worked to isolate the causal effect of financial literacy on wealth accumulation, and found that the largest effect was financial literacy. In these studies, numeracy and financial literacy were both found to be predictors of wealth.

This study is set in a Canadian community, and though North American data was sought and utilized, the issues surrounding Numerical, Mathematical and Financial Literacies are not unique to the North American context. As defined by the Human Resources and Skills Development Branch (2012), quantitative literacy or numeracy is "the knowledge and skills required to effectively manage the mathematical demands of diverse situations". The 2003 study found that over half of respondents (55 %) scored only Level 1 or 2 [of 5 levels] on the numeracy proficiency scale. These low results are significant because numeracy and problem solving are linked to financial prosperity and civic engagement (Behrman et al., 2010; Human Resources and Skills Development Canada, 2012; Smith et al., 2010). Similarly, a Canadian report (Statistics Canada, 2008) found that 49 percent of all adults say they do not engage in household budgeting.

There is also substantial evidence that financial literacy programs "can make an important contribution to the well-being of vulnerable groups" (McFayden, 2012, p. 1). Gutstein (2006) wrote that "[r]eading the mathematical word is equivalent to developing mathematical power" (p. 29) and included that "opportunity to learn, access, and equity all demand that marginalized students get the chance to develop" the tools for mathematical empowerment (p. 30). This study engaged grassroots community resources to support NMFLs, and applied a qualitative research approach for the purpose of improving awareness, access, and quality of programs available to the participating school community.

School Community

The elementary school involved in the Count On Yourself project is located in a smaller urban community adjacent to a larger city. The community elementary school involved had been identified as a low-literacy school. The school Principal was an administrator in the larger community for more than 20 years. The school historically had poor academic performance, and data indicated that students had poor achievement in intermediate grades and were less likely to graduate than their peers (British Columbia Ministry of Education, 2006). The school Principal was highly trusted and a consistent and dedicated member of the community, and I had been a district consultant. Given these predetermined trusting relationships, the Parent Council for the school was quick to approve the program and the research.

The project was announced at a community forum, and four families chose to participate in the Count On Yourself quantitative and financial literacy program. Though all members of the school community were invited to participate, it was fortunate that a fairly small group signed up for the first iteration of this program. A trusting environment could be built with a smaller group. The four families who participated were (aliases assigned) Valerie and Brent, parents of two children in 4th and 5th grade. Ema and Phil, parents of one 2nd grade child and three not yet in school, Anna (whose husband did not participate) with children in 1st and 6th grade, and Carolyn, whose husband and children did not participate.

Theoretical Framework

Reading and Writing the World

Freire wrote about the fallacy of teaching the technical skills of reading as disconnected from social and political contexts. Mathematics is also typically taught as apolitical, and contexts are often imposed rather than the mathematics naturally emerging from situational problems. Freire rejected this technocratic method with respect to teaching literacy, and aimed to teach "adults how to read in relation to the awakening of their consciousness… [he] wanted a literacy program which would be an introduction to the democratization of culture, a program with men *[sic]* as its Subjects rather than as patient recipients" (Freire, 1973, p. 43).

Similarly, this study sought to deepen participants' "understanding of society [leading] to engagement in social movements, at whatever level people are capable of participating given the daily struggles for survival" (Gutstein, 2006, p. 25). Gutstein (2006) viewed "writing the world with mathematics as a developmental process, of beginning to see oneself capable of making change, and…developing a sense of social agency (gradual growth)" (p. 27). The research sought to identify how participants described their gradual growth of understanding and engagement with mathematical and financial literacies.

On Personal Flourishing

Grant (2012) explained how to cultivate a more robust social justice vision of education, and argued for a democratic education for a flourishing and whole life. Brighouse (2006) and Grant (2012) described how, in order to make meaning and sense of important aspects of their lives, individuals should experience personal flourishing and personal autonomy. They must also develop the confidence and skills to contribute to society and to the (broadly defined) economy, democratic competency, and the facility and desire for cooperation (Grant, 2012). Personal flourishing also includes living and doing well, having a positive identity, having family and friends as support mechanisms, financial stability, education, and a commitment to children's flourishing minds.

On Quantitative Literacy

Steen (2001) described elements and expressions of quantitative literacy (QL) that included confidence with mathematics, being able to use mathematics in context, expressing quantitative literacy through citizenship (e.g., understanding data, projections, inferences etc.), the application of mathematics in one's educational trajectory, the application of quantitative literacy in one's personal finance and management, and the ability to make quantitative decisions with respect to one's personal health (e.g., options, dosages, risks, nutrition and exercise data etc.). Quantitative Literacy "empowers people by giving them tools to think for themselves, to ask intelligent questions of experts, and to confront authority confidently. These are skills required to thrive in the modern world" (p. 2).

Table 1: Framework for NMFL Educational Research

Assessing NMFL Educational Research	Description
Theme 1) Financial Knowledge	Data were coded this way when participants indicated a shift in financial knowledge or skills, or described their financial knowledge.
Theme 2) Re-Imagining Self and Possibilities	Data were coded this way when participants examined their assumptions and either realized that things should change, that things could change, or that they were not alone in the struggle for change. This theme represented a shift in beliefs about what was possible and about their agency.
Theme 3) Taking Action	Data were coded in this category when participants felt so strongly about the possibilities for change that they took action. These shifting practices were realizations of their beliefs about their agency.
Theme 4) Impact on Family	Data were coded in this theme when participants described the impact of the COY project on their relationships with other members of their family, including their ability to communicate with their children and impact their children's financial futures.
Theme 5) Features of the COY Program	This theme includes data that described how and why the structures of the COY program were beneficial.

Conceptual Framework

Though Grant (2012) did not write about mathematics education in particular, he advocated for core practices that would help cultivate flourishing lives while describing a robust social justice vision of education. I applied Grant's work to educational research, and in particular, to a Freirean approach and empowering pedagogy, attending to quantitative literacies that I refer to as NMFLs. I invoked some of Steen's *Elements* and *Expressions* of Quantitative Literacy to connect both Grant's and Steen's works together to create a framework through which I could study NMFL educational research. Table 1 shows some of the parallel ideas in both authors' works. This framework was used to analyze the data collected in this study.

Methodology

On Freirean Research and Pedagogy

The theoretical and methodological grounding for this study is decidedly Freirean. Freire's (2000/1970) work originated in an historical place and reality that required emancipatory action in order to free the oppressed from their illiteracy, and his works became symbolic for many marginalized people around the world. Educators and educational researchers have used *Pedagogy of the Oppressed,* and its liberatory practices, in situations that were not necessarily as political, but that arguably required a similar research approach. Freire described the ideas of human agency and empowerment as being essential to worthwhile learning and research practice. Critical social theorist were to take an ethical and political position using theory of education as a "practice of freedom" (Glass, 2001, p. 22) to shape a just and democratic society. Grant (2013) reminded us that social action is "individual or group behavior that involves interaction with other individuals or groups, especially organized action towards social reform" (p. 926). The goal of this project was to act to make financial decision-making and numerical empowerment accessible for the participants in this community of families.

The COY Project – Resources

A series of children's books on Financial Literacy were provided (e.g., Phillips, 2010) as well as adult and teen financial literacy books by Gail Vaz-Oxlade. The adults' Financial Literacy course was based on *Momentum* (see Table 2 below), a curriculum that was developed in Calgary, Canada (2010), and was provided free of charge by a local non-profit community partner. I designed and led this research project; however, it resulted from the collaborative efforts of several groups including the local university's Faculty of Education and four non-profit community partners.

Table 2: Financial Literacy Curriculum Materials – Momentum (2010)

Topic	Content
Assets	set short- and long-term goals for 5 types of assets (human, personal, social, physical, and financial)
Credit	take charge of it, develop an awareness and understanding of advantages and disadvantages of credit, wise use, and consumer credit tools
Budgeting	learn the difference between needs and wants, identify and track spending habits, build a budget and set short- and long-term goals
Consumerism	awareness of effects of consumerism and advertising, and develop ability to control consumerism, and live more simply
Banking	become aware of banking account options and benefits, learn how to use banking services, and access banking tools and resources

The COY project consisted of eight meetings on Wednesday evenings in the school's library. A meal and refreshments was available for participating adults and children. Funds for purchasing and preparing meals were raised by a group of college students from a local institution. The Math Camp curriculum was designed and implemented by the volunteer teacher candidates who participated as Math Camp Leaders. Various mathematics and financial literacy activities were personalized for the school-aged children who attended. Pre-school-aged children attended a child-care service provided free of charge by the school community. Adults participated in a Financial Literacy course; the facilitator was associated with a non-profit agency whose mission was to provide instruction in financial literacy at no charge.

Data Collection and Procedures

The proceedings of the adult financial literacy course were digitally recorded, as were individual pre- and post-interviews. Adults were asked three questions at the beginning of the program in an informal interview setting that was selected by each participant (either at their homes, in the school, or at a coffee shop). They were asked six questions at the end of the program. These were digitally audio-recorded. Each participating adult was interviewed for approximately 35 minutes at the beginning and at the end of the program. The semi-structured interview questions asked early in the program (pre-survey) dealt with the perceived quantitative needs for the families involved and the immediate community, the kind of mathematical learning and support the participants would appreciate, and the predicted benefits of the program. Near the end of the program, similar questions were asked (post-survey), including what kind of support was preferred, what were the benefits and disadvantages, and which specific teaching strategies, advice, structures, or "technologies" were believed to be of most benefit.

Data Analysis

After transcription and multiple readings of the text, the data were coded and classified into the framework's themes, as shown in Table 1. After initial data coding, the results were analyzed with respect to the research questions and the literature using *systematic combining* (Dubois & Gadde, 2014), and the data categories were clarified. Theory building involved the development of a research framework by critically evaluating emerging constructs against ongoing observations refining and re-combining theoretical ideas with empirical data.

Results and Analysis

This research study sought to determine whether participants could express personal flourishing within the context of numerical, mathematical, and financial literacies. As evidenced from the participants' responses, their beliefs, skills, knowledge, and actions could be classified into five themes that are supported by Grant's (2012) description of cultivating flourishing lives, and Steen's (2001) quantitative literacy, and are supported by literature (e.g., Freire, 2000; Gutstein, 2006). The five themes discussed here, and reflected in the participants' voices are 1) Financial Knowledge, 2) Re-Imagining Self and Possibilities, 3) Taking Action, 4) Impact on Family, and 5) Features of the COY Program.

Theme 1 Sample) Financial Knowledge

For this theme, participants made sense of important financial aspects of their lives, and described their financial knowledge:

> Consumerism, everything that you see out there is an ad. You are bombarded on television, media, print, advertising: "You deserve it, it's about you! You're entitled to this. You've worked hard. Enjoy it! Spend it! Here's a way that we can make it more affordable to you. People are sucked into this, and they are really not aware of it until it's too late, and that's for me, what I

> think this community, city, province, country, nation, I'm not going to say the world, it's North America that's got the problem. (Brent's Post-Interview)

Brent described his place in the larger picture of consumerism (one of the topics in the Momentum course). He understood and interpreted consumerism in his world.

Theme 2 Sample) Re-Imagining Self and Possibilities

For this theme, participants described beliefs of agency and confidence. During Valerie's post-interview, she described how she now felt that she had the ability to accomplish something of value:

> I finally felt that I had hope for the future and less of a defeatist attitude, because of what we had learned, we can make as small or as big of a change as you want, and any change would be better than where we were at. (Valerie's Post-Interview)

Theme 3 Sample) Taking Action

For this theme, participants engaged in, participated in, and contributed through personal agency in society. This theme describes adults who take action on their beliefs. During Carolyn's post-interview, she described how the COY program gave her the skills and understanding to run her household budget as well as the family's business budget. She explained:

> I got the financial support that I needed to start and maintain a budget. My household budget – I run my business budget as well. It will have an impact on my husband because I do run the household budget. It will have accountability impact on him. Instead of going with the flow, there will be more proactive planning involved. (Carolyn's Post-Interview)

Theme 4 Sample) Impact on Family

This theme describes adults who have the dispositions and communication skills to make decisions or take social action to contribute to society and participate in the democratic process. During Brent's post-interview, he described his parenting role as also the role of being a teacher for his children:

> I've always believed that I'm not just raising my kids but I'm teaching my kids to be a good parent, so there's a responsibility and there are tools in the program that now I can use to explain finances to them. (Brent's Post-Interview)

Theme 5 Sample) Features of the COY Program

This theme describes features of the Count On Yourself program that the participants felt were beneficial. This included specific topics and the content of the Momentum curriculum, and mostly the structure of the program including the importance of providing a safe, trusting, and inclusive environment for all members of the family:

> The researcher and facilitators were willing to be there, to be involved and share in personal experiences. It was obvious to everyone that you were excited about what you were doing and, because of your enthusiasm it's easier for us to be excited about it when we see your enthusiasm because we can see that it matters to us, and your ability to educate us, and to see the children all excited about learning? That's priceless! (Ema's Post-Interview)

Discussion

The participants were able to make meaning and sense of numerical, mathematical, and financial literacies in context. They developed knowledge from each other and made sense of those ideas throughout the process of the financial literacy course and curriculum. Guba and Lincoln (2005) reminded us that, as critical theorists, we continue to seek the active construction and co-construction of knowledge by human agents. As a group and individually, the participants made sense of financial knowledge and stresses in their lives and in each other's. Guba and Lincoln (2005) also stated that: "Critical theorists, especially those who work in community organizing programs, are painfully aware of the necessity for members of the community, or research participants, to take control of their futures (p. 202)". One of the participants used this very language to describe how she felt that the COY program helped her take control of her live and *give herself a future*.

In other data gathered, participants demonstrated their financial literacy by indicating that they successfully managed their money by paying their bills on time, making sure they didn't spend more than they earned each month, and paid their debts when they owed money. They became more knowledgeable about credit scores, being more in control of finances, and budgeting. Participants also displayed more agency and self-confidence with finances. Being heard was essential for this. The practice of "letting research participants speak for themselves" (Guba & Lincoln, 2005, p. 209) allowed them the voice to tell me they felt empowered themselves, in their ability to speak to their children, and that their children also felt empowered as individuals.

Guba and Lincoln (2005) discussed the validity of a study as *catalytic authenticity* when the researcher creates capacity in participants for positive social change and forms of emancipatory community action. Grant (2012) also spoke of the researcher's ability to encourage social action. In this study, there is evidence that the participants appreciated the community aspect of the project, and took action by visiting banks and credit unions, investment groups, and mortgage brokers. They began budgeting processes online and using software, contacted credit companies to ask for a reduction in their interest rates, opened separate bank accounts to better keep track of their expenses, consolidated their debt, and applied for loans. The exit survey supports this data indicating that all of the participants not only felt comfortable getting help, but also did get help with their finances. Taking action is powerful evidence of emancipation, and by taking action in the ways that they did, the participants showed evidence of practicing democracy.

Perhaps the most significant result of this project was the belief from participants that they had influence upon their children. Though not all families participated as complete units, those who had children in the COY program felt more able, and did discuss financial information with their children when appropriate. All participants agreed that they found value in the program and would recommend it to someone else. The implications for this result is that programs such as Count On Yourself, that involve the whole family, might possibly help break cycles of poverty in communities in which they are implemented. As I continue to consider Grant's (2012) vision, I am struck by his statement that:

> …you learn about how the practice of democracy can be made to work for you or against you and that it is important that you understand the differences as well as you know what you can do to influence an outcome that befits those who are marginalized. (p. 925)

Grant's intent was to clarify what it means to practice democracy. I find that this statement is reflected both in my practice as a researcher and in the evidence that was produced from this study through the voices of the participants. I entered this work to make a difference and to provide a learning space for families who could participate more democratically in society because they chose to learn to be more financially literate. I have learned that I can make a difference, and they have learned that they can make a difference in their own life situations. This most certainly reflects Grant's "practice of democracy" (p. 925).

DEVELOPING A FRAMEWORK FOR ASSESSING THE IMPACT OF WHITENESS IN MATHEMATICS EDUCATION

Dan Battey
Rutgers University
dan.battey@gse.rutgers.edu

Luis Leyva
Rutgers University
luis.leyva@gse.rutgers.edu

The ideology of whiteness has received little attention in mathematics education. In this paper, we develop a framework for documenting how whiteness shapes mathematics education as a racialized space. Drawing on the sociological concept of "white institutional space" (Feagin, Vera, & Imani, 1996; Moore, 2008), the framework examines mathematics education across institutional, interpersonal, and individual levels of analysis. The authors argue that this framework captures how ideological discourses of whiteness and colorblindness (Lewis, 2004) and racialized hierarchies of mathematics ability (Martin, 2009) are perpetuated through institutional structures and interpersonal relations in mathematics education.

Keywords: Equity and Diversity; Instructional Activities and Practices; Learning Theory

Introduction

Lipsitz (1995) states that "a fictive identity of whiteness" appeared in law as an abstraction and became actualized in everyday life. Much like 'black' is a cultural construction based on skin color, not biology, whiteness developed out of the reality of slavery and segregation, giving groups unequal access to citizenship, immigration, and property. By giving whites a privileged position in relation to the "other", European Americans united into a fictitious community. Whiteness is a constantly shifting boundary separating those who are entitled to certain privileges from those whose exploitation is justified by not being white. However, the boundaries of whiteness have shifted substantially over time (see Brodkin, 1998).

Recently, the ideology of whiteness and its material benefits has been sustained more covertly. Whiteness is supported by a colorblind ideology, a form of maintaining the social order, covertly, institutionally, and with the appearance of not being racial. Bonilla-Silva (2003) connects colorblindness with the resistance to framing, defining, or pathologizing whiteness and the ways that race plays out in the United States since the civil rights movement. While racism often calls forth overt practices such as slavery, the Jim Crow era, and lynchings, but the more recent avoidance of explicit racial discourses signifies colorblind racism, the dominant racial ideology since the civil rights movement (Bonilla-Silva & Forman, 2000).

Under colorblindness, it does not matter whether whites are racially conscious. Whites benefit from an external reading of themselves as white (Lewis, 2004), whether or not they identify as white. In other words, whites benefit not from their own realization of being white, but by others treating them as white. This distinction is important in understanding whiteness as an ideology rather than an identity. Therefore, a felt identity is not a prerequisite to reap unearned privileges. Whiteness functions within structures, deciding how resources, labor, and space will be distributed by means of housing segregation and educational and financial stratification. These structures are in place to benefit future generations, whether those generations adopt an intentional white identity. The point is not that all whites benefit the same, as this would be essentializing a very diverse group of people, but that one's racial position is constructed in relation to a racial history that has distributed space, resources and labor, and reproduced racist discourses (Lewis, 2004).

Connecting Whiteness to Mathematics Education

Whiteness plays out in very real ways through the divvying up of resources such as earnings, homes, wealth, and health (Lipsitz, 1995). Sewell (1992) and Lewis (2004) discuss racism both ideologically and concretely through considering its dual nature: symbolic (ideological) and material (structural resources) (Sewell, 1992; Lewis, 2004). Whiteness and colorblindness produce symbolic and material consequences within mathematics education (Battey, 2013a).

There are common *symbolic* narratives about who is better mathematically – whites and Asians. These perceptions are then made *materially* real in terms of how African American and Latin@s are treated in mathematics classrooms, the forms of instruction available, and course offerings, which in turn lead to different testing outcomes or "achievement gaps." Through impoverished instruction quality, tracking, and reduced funding, society makes the racial ideologies concrete. Therefore, "achievement gaps" in mathematics education reify the idea that whites and Asians are better at math, and African Americans are Latin@s are innately inferior.

Martin (2009) acknowledges the need for further research on race in mathematics education as a social construction shaped by existing sociopolitical contexts. More specifically, Martin (2009, 2013) calls for research on whiteness operating in mathematics education to address forms of racism in relation to achievement, participation, and student learning. Sociological work (Feagin, Vera, & Imani, 1996; Moore, 2008) informs Martin's (2008, 2009, 2013) conceptualization of mathematics education as a *white institutional space* based on four tenets:

> (a) numerical domination by Whites and the exclusion of people of color from positions of power in institutional contexts, (b) the development of a White frame that organizes the logic of the institution or discipline, (c) the historical construction of curricular models based upon the thinking of White elites, and (d) the assertion of knowledge production as neutral and impartial, unconnected to power relations (Martin, 2013, p. 323)

Using these tenets, Martin (2008) highlights how the National Math Advisory Panel is an example of mathematics education policy as white institutional space resulting in "e(race)sure" – the exclusion or ignoring of race – that perpetuate notions of whiteness and white supremacy in mathematics. We similarly draw upon these four tenets in the next section to propose a framework that assesses the extent to which mathematics education is a white institutional space.

Theoretical Framework

Our framework in assessing the impact of whiteness on mathematics education presented in Table 1 considers three dimensions: institutional, interpersonal, and identity. Martin's four tenets cut across these three dimensions. The first tenet of white institutional space, racialized patterns of representation, aligns with parts of both division of labor and physical space. This directly relates to distribution of power, but also the representations of images symbols, and behaviors presented in schools. Therefore, it is not only about the distribution of people, but of the distribution of valuing and devaluing various ways of being as well. The second tenet also aligns with ideology and division of labor, but more in terms of the organizational structure. The organizational structure of the school determines behavioral sanctions and classroom norms that then shape interpersonal interactions and identity construction. The organizational structure also legitimizes certain ideologies over others, such as tracking supporting a fixed notion of mathematical intelligence. The third tenet of historically white curricular models is aligned with the section on history, but as students respond to this history, they take on varying identities in relation to the mathematics and schooling. Finally, the fourth tenet of white institutional space corresponds with how ideological discourses in mathematics differentially shape whites and students of color's mathematics experiences. This, in turn, structures notions of competence and legitimacy in students' negotiations of their mathematics identities including what it means be "good" at mathematics. These four tenets are threaded throughout the framework.

Table 1: Framework to Assess Whiteness in Mathematics Education

Institutional	Ideological Discourses	• Racial hierarchy of math ability • Innateness of mathematics ability • Mathematics as neutral • Abstract individualism • Meritocracy
	History	• Histories of schools • Patterns of inclusion and exclusion • Curricular perspectives • Multiple perspectives
	Organizational Logic	• Distribution of power and work • Organizational structure • Positioning of Stakeholders
	Physical Space	• Physical representations • School messages • Visibility of students • Control of physical expression
Labor	Cognition	• Differential cognitive demand • Distribution of classroom and mathematical authority • Academic expectations
	Emotion	• Management of emotional experiences • Regulation of emotion • Range of emotional experiences allowed
	Behavior	• Discipline • Management of Behavior • Language Norms • Teacher praise/acknowledgment
Identity	Academic (De)Legitimization	• Identification with mathematics • Legitimacy of intellectual ability
	Co-Construction of Meaning	• Hierarchy of mathematics ability • Peer perceptions of each other • Hypervisibility/invisibility
	Agency and Resistance	• Relationship with deficit discourses • Forms of (dis)engagement • Association with peer group

Institutional

Institutional spaces constrain or afford different access to people, resources, and work. In distributing this access, they legitimize certain ideologies through the physical space, positioning of different groups, and presentation of history. The institutional level is responsible for framing the levels of labor and identity since it is responsible for the organization of labor and determines the ideologies and people in which individuals will develop relationships.

Ideological Discourses. As noted in the introduction, broad discourses such as colorblindness and abstract individualism often accompany whiteness. Within mathematics education, whiteness takes the form of racial hierarchies of mathematics ability (Martin, 2009) as well as the innateness of mathematics ability (Ernest, 1991). The racial hierarchy of mathematics ability benefits the identities that white and Asian American students can construct with the domain, but accompanying discourse around the innateness of ability makes the racial hierarchy stable. Evidence for these discourses come in teachers' and schools' stable notions of high and low mathematics students that are then institutionalized in forms of tracking and subsequent differential access to cognitive demand. In terms of privilege, the discourses are evidenced by the automatic attribution of Asian Americans and whites as being good at mathematics and/or surprise when these student struggles.

History. Schools have histories that are inseparable from issues of exclusion, segregation, and differential resources in the United States. These historical issues contribute to current educational inequality. For instance, a school may have been segregated, then bussed in African American students, only to see white flight result in home prices dropping and the tax base that determines school funding collapse. Therefore, a history of inclusion or exclusion has an impact on teacher retention, school demographics, and school funding. Curricula also present who has been involved in constructing history. The inclusion or exclusion of groups within curricula communicates to students whose perspectives matter and who is important. Finally, the perspective within curricula communicates notions of exclusion, assimilation, resistance, or valuing regarding different cultures and values. Martin (2008), for example, describes how the National Math Advisory Panel's curricula recommendations focused on algebra and other mathematical content to advance white elites' agenda of international competitiveness.

Organizational Logic. Schools are organizations that situate people in different ways and distribute power accordingly. How that power is distributed and who it is distributed to matters. The power distribution between administrators, teachers, parents, and students says a lot about who is included and valued within schools. For instance, parents who are viewed as over-involved with the influence to determine curriculum, positions them as having power in contrast to those framed as oppositional in defending their children, uninvolved, or not caring. In these differing logics, parents are granted varied power. The same can be true for teachers and students. Organizational logic is what determines who has power, who does what work, and who evaluates whom. In this distribution of power, there is the potential to have different races in more privileged and more subservient roles leading to inequitable racial representation in positions of power. This distribution determines different forms of labor including the labor that is required of students and the extent to which this prepares them for future success.

Physical Space. Images, charts, symbols, and objects are concrete representations that communicate central aspects of institutions. Pictures that designate notable people in history, student recognition, and school history pass on messages about who is accepted, welcomed, and who can excel academically. Images, histories, and perspectives of African American and Latin@ students can be invisible at times (Moore, 2008). This can contrast with the hypervisibility (Higginbotham, 2001) when students are asked to speak for their race or teachers hyper focus on the misbehavior of students of color. Aligned with this, charts about acceptable behavior can be ways of controlling students. For instance, behavioral norms that promote militaristic rules of order or student "uniforms" are clear messages that the school sees students as needing to be controlled. Repeated school slogans in schools such as "I'm smart! I know that I'm smart" found in Kozol's (2005, p. 36) work communicate just the opposite. If students were assumed to be smart, there would be no need to repeat these types of mantras. Similarly, the lack of these messages in predominantly white contexts is an implicit transmission that students are expected to be intelligent, under control, or that these students do not need to see representations of current and historical figures that do not look like them. This is also a way to perpetuate whiteness, by communicating that there are such a limited number of significant African Americans or Latin@s that white students do not need to know about them.

Labor

How labor is divided in classrooms can reflect the presence of whiteness. Normative expectations of emotional and behavioral work can restrict students to being certain types of students - controlling them to fit unquestioned cultural expectations. When forms of labor are restricted in such a way that students of color's contributions and behaviors are not seen as valid, it can be a sign that whiteness is operating in a context. We use three dimensions of labor to detail how whiteness can operate within classrooms: cognition, behavior, and emotion.

Cognition. Cognition is interpersonal in the sense that the kinds of mathematical work students are asked to do sends messages about what students are capable of. A number of researchers have documented the lower levels of work that African American and Latin@ students are asked to do in classrooms. Classroom settings that only ask students to replicate procedures, follow worksheets page by page, and lack the opportunity to engage in cognitive depth permeate the literature for African American and Latin@ students (Ladson-Billings, 1997; Lubienski, 2002). Additionally, how authority is distributed, both for classroom procedures and the mathematics, also speaks to whether a teacher holds expectations that students can self-monitor their behavior and gain command of the mathematics. If these ways of parsing classroom cognition are coupled with ideologies of a racialized hierarchy of mathematical ability, then they are signs that whiteness is at play. But it is also more complex than this. For instance, even in a mostly African American classroom, some students may have more access to content and authority than others. If the students who are seen as more capable fit norms for white behavior, then whiteness is still at play. Patterns as to which students have access to which cognitive tasks can be quite telling.

Emotional. Coping with discrimination and racism in everyday experience requires significant emotional labor in terms of sadness, frustration, and anger (Moore, 2008). However, schools and classrooms often do not provide the time, space, or support for students to process these experiences and emotions. When students do process or exhibit these emotions, they can be seen as angry, aggressive, or violent rather than struggling with a complex and unfair world. Moore (2008) discusses how law schools continue to ignore and undervalue this emotional labor:

> Coping with everyday racism in the law school frequently produces frustration, anger, or sadness, but the institutional logic of the law school does not recognize expressions of these emotions as legitimate. Students are thus forced to manage their emotion in order to avoid further marginalization… This demands that students of color perform invisible and emotional labor that their white counterparts are not required to perform. Both in the law school and in the profession of law, this labor is expected of law students of color, yet it goes unrecognized and unrewarded (p. 31).

Additionally, students must manage the ways in which they express emotions to avoid deficit discourses about being perceived as argumentative, angry, aggressive, and a multiple of other negative associations. When students of color are expected to relate experiences they consider unfair in a calm, dispassionate, and disconnected way, then whiteness is restricting acceptable ways of grappling with the emotions of discrimination and racism (Moore, 2008). Finally, this emotional labor places an undue cognitive burden on students as well. Dovidio and Gaertner (2008) found that when solving mathematics problems, African American students within groups that made them process emotions related to discrimination more, performed work slower when compared to those who did not. Steele and Aronson's (1995) work on stereotype threat can also be seen as the result of the added emotional labor due to priming race during cognitive tasks.

Behavior. One way in which labor is handled is by deeming certain student behaviors appropriate and others not. This has immense consequences in classrooms as harsh and frequent discipline has been found to frequently lead to missed instructional time and expulsion from school for African American and Latin@ males in particular (Gregory, Noguera, & Skiba, 2010). Within mathematics, this can take the form of deeming certain ways of language use as inappropriate for mathematical argumentation or by requiring students to sit still in seats in regimented ways (Battey, 2013b). Further, whiteness can function by valuing behaviors of white students over others in subtle ways of how language and behavior are perceived to align with understandings of appropriate classroom actions. When students align with white ideals about behavior, their actions will likely be praised or sanctioned. When students do not align, maybe through being too argumentative, too quiet, too excited, or abrasive, we would expect to see behavior to be called out, positive behaviors to go unnoticed and a hyper-focus on misbehavior leading to increasing discipline and eventually suspensions and expulsions. When teachers employ such behavioral control despite substantive mathematical contributions in classrooms (see Battey, 2013b), it is evidence that a broader ideology is at play.

Identity

Martin (2009) defines *mathematical identities* as "dispositions and deeply held beliefs that individuals develop about their ability to participate and perform effectively in mathematical contexts and to use mathematics to change the condition of their lives" (p. 326). The construction of mathematical identities, however, is not a strictly personal, internal process as it is constantly negotiated with institutional influences and interpersonal encounters. More specifically, the organizing white frame relegates African Americans and Latin@s as mathematically incapable and innumerate and thus grants unquestioned legitimacy to whites in mathematics education spaces. This aligns with Martin's (2009) notion of mathematics as a racialized such that the social construction of whiteness is maintained in mathematics classrooms through the inequitable learning opportunities and academic de-legitimization experienced of marginalized students.

Academic (De)Legititmization. Mathematics classrooms that function as white institutional spaces require students to negotiate academic legitimacy across a racialized hierarchy of ability based on white norms and values. Understanding mathematical identities, therefore, can only be attained by detailing processes of negotiation within racialized discourses as opposed to traditional analyses of achievement gaps between different races (Martin, 2009). With whites and Asian Americans – considered "honorary whites" (see Bonilla-Silva, 2003) – at the top of the hierarchy of mathematics ability, whiteness in mathematics classrooms operates in ways that they are assumed or assume themselves that they are mathematically intelligent. Conversely, students of color's legitimacy is always under question so that they need to prove themselves mathematically capable by subscribing to white views of success that structure the academic spaces. Deficit perspectives on students of color's mathematics ability stem from these ideological discourses and in turn position these students as illegitimate members of mathematics classrooms resulting in poor relationships with teachers, lower-quality instructional experiences, and expressed disidentification with the mathematics subject (Spencer, 2009). Therefore, whiteness can be seen in students' stable identification or dissociations with the mathematics domain, consistent with racial hierarchies.

Co-Construction of Meaning. Students construct mathematical identities in relation to the people and the institutions in which they participate. Therefore, the explicit and implicit ways in which people and institutions pass on messages are critical for how students develop mathematical identities. For instance, ability grouping or tracking along racial lines send messages to students about the racial hierarchy of ability (Lewis, 2004). Teacher comments about low and high students or needing to learn the "basics" pass on messages more overtly (Battey & Fanke, 2015). Within school contexts, students construct what being good at mathematics means. Maybe being good means the student who finishes first, but cannot explain their thinking. Additionally, Moore (2008) discusses peer perceptions of academic support programs in law schools such that some students think that students of color in the programs were admitted to the school based on race rather than earning it. This anti-historical view ignores the reasons for programs that remedy institutional racism. This view also perpetuates whiteness by not recognizing the material racism that produced and continues to produce differential access to educational quality. However, as institutions leave these perspectives, programs, and racism unaddressed, they participate in limiting spaces for students to construct identities that counter the racial hierarchies contained by whiteness.

Agency and Resistance. Despite racial oppression, it is important to also consider African Americans and Latin@s agency in negotiating their racial identities and mathematics success. Although Martin (2009) uses African Americans' experiences to illustrate racial struggles in mathematics, his discussion can be extended to other marginalized student populations as they "negotiate and resist the racialization processes that attempt to position and confine [them] within an existing racial hierarchy" (Martin, 2009, p. 325). This illustrates the importance of inclusion of the voices and experiences of those marginalized. Martin (2009, p. 315) states:

Moreover, because little attention has been given to resistance, contestation, and negotiation of these meanings, disparities in mathematics achievement and persistence are often inadequately framed as reflecting race effects rather than as the consequences of the *racialized* nature of students' mathematical experiences [emphasis in original].

Therefore, examining unchallenged racialized discourses in mathematics classrooms is making plain whiteness as taken for granted. Unchallenged racial discourses keep individual experiences of race internal for both whites and students of color. However, for students of color, this is more detrimental because unchallenged, they may either disassociate from their race, community, and history to succeed mathematically, or internalize the discourse. For mathematically successful African American students then, they may disassociate from peers or downplay their success. For mathematically unsuccessful Latin@ students, they may disassociate from mathematics or schooling through resistance by active challenging of educators views of students, purposeful disengagement, or dropping out.

Conclusion

Whiteness is a widespread ideology in society. While it is getting more attention in the broader education literature, mathematics educators have been slow to research it's impact on African American and Latin@ students (Battey, 2013a). However, its impact on white students is just as important in making unearned privileges visible to the field. We hope this framework supports the field in identifying the effects of whiteness at different levels of the educational system. The goal for us it to support the development of a mathematics space that builds collective consciousness of racism in order to prevent students of color from internalizing deficit ideologies (Feagin, 2006; Moore, 2008). This in turn would open more space for student identities that challenge existing racial hierarchies.

In this study, we surveyed 570 Calculus I and Calculus II students at two large public universities in the Northeastern region of the United States. We explored the relationship between these students' career goals in mathematics and other STEM fields, with their mathematics identity and self-identified personality attributes. Our findings suggest that mathematics identity can be used as a way of explaining persistence in mathematics and other STEM fields. We also found certain personality attributes to be correlated with persistence in these fields and these personality attributes varied based on gender. We conclude with a detailed analysis of our findings and some implications.

Keywords: Affect and Beliefs; Gender; Post-Secondary Education

Introduction

There is a shortage of individuals entering STEM (Science, Technology, Engineering, and Mathematics) careers in the United States (Langdon, McKittrick, Beede, Khan & Doms, 2011; National Academy of Sciences, 2010). For the past 50 years, there has been a notable decline in the number of college students choosing STEM majors, and college students are more likely to switch from a STEM major to a non-STEM major than the other way around (Seymour & Hewitt, 1997). Furthermore, data suggest that there has not been notable increases in the percentage of students receiving STEM degrees in recent years, with only a 1% increase of bachelor's degrees awarded in STEM fields between 2002 and 2012 (NSF, 2015). Given that the growth of STEM jobs was three times that of non-STEM jobs during the past decade or so, this shortage of citizens interested and educated in the STEM fields is of national concern (Langdon, McKittrick, Beede, Khan, & Doms, 2011).

In addition, there is evidence of a continued underrepresentation of women choosing a career in STEM fields. For instance, based on data reported by the National Science Foundation, in 2013 although women made up 46.1% of the entire U.S. workforce, they were only 14.8% of those employed as engineers, 11.8% of those employed as physicists and astronomers, and only 25.4% of those employed as mathematical or computer scientists (NSF, 2015). Furthermore, the percentage of women earning degrees in STEM fields has been declining. For example, the percentage of women earning bachelor's degrees in the mathematical sciences fell from 48% in 2001 to 43% in 2009. Other fields, such as engineering and computer science, have seen similar declines in women earning such degrees during the same timeframe (NSF, 2015). Though these results inform us of the underrepresentation of women in these fields, they do not provide insight as to why these trends are occurring. It is important to explore reasons why this underrepresentation is still persisting and why gender gaps in participation are increasing in some cases.

Prior research has shown a connection between individuals' mathematics identity and students' persistence and commitment to mathematics and other STEM fields (Boaler & Greeno, 2000; Cass, Hazari, Cribbs, Sadler, & Sonnert, 2011). Furthermore, in previous work, Piatek-Jimenez (2015) noted specific self-identified personality attributes common amongst women mathematics majors.

For this study we are combining these two constructs to determine what relationships exist between students' mathematics identities and self-identified personality attributes with their intended choice of career.

The following research questions were used to guide this study: 1) What is the relationship between students' career goals in a STEM field with their mathematics identity and self-identified personality attributes?; 2) What is the relationship between students' career goals in a mathematics field (mathematician and mathematics teachers) with their mathematics identity and self-identified personality attributes?; and 3) How do these models vary between females and males?

Theoretical Framework

Identity is a construct that is becoming increasingly utilized in mathematics education research when exploring students' persistence and attrition in mathematics (Boaler & Greeno, 2000; Martin, 2000; Piatek-Jimenez, 2008; Piatek-Jimenez, 2015). Though different authors have conceptualized the construct in slightly different ways, we view "mathematics identity" as how individuals see themselves in relation to mathematics based on their perceptions and navigation of everyday experiences with mathematics (Enyedy, Goldberg & Welsh, 2006). We view this as being a part of an individual's "core identity", which is a more enduring sense of who an individual is and who he or she wants to become (Cobb & Hodge, 2011).

Our framework for mathematics identity draws from prior work in the field of mathematics and science (Cribbs, Hazari, Sadler, Sonnert, 2012; Carlone & Johnson, 2007; Hazari, Sonnert, Sadler & Shanahan, 2010). In our framework, mathematics identity is comprised of the sub-constructs interest, recognition, and competence/performance. Interest refers to an individual's desire or curiosity to think and learn about mathematics. Recognition refers to how an individual perceives others view him or her in relation to mathematics. Competence/performance refers to an individual's beliefs about his or her ability to understand and perform in mathematics. It is the inclusion of these three factors that provide a better picture of an individual's mathematics identity.

While mathematics identity is a strong predictor for students' career goals in certain STEM fields, such as engineering (Cass et al., 2011) and mathematics (Cribbs et al., 2012), other factors influence an individual's choice whether or not to pursue a STEM career. Furthermore, Gee's (2001) work related to identity indicates that an individual may have many different identities. For example, a woman mathematics major may identify as both a woman and a mathematics major. Potentially conflicting expectations about what it means to be a woman and what it means be a mathematics major may inform her decision whether or not to enter a career in mathematics.

In particular, our study is concerned with the role that gender plays in the expectations and choices an individual makes. For example, gender stereotyping could play a role in how individuals view themselves and subsequently the choices they make. Research notes that parents (Furnham, Reeves & Budhani, 2002; Frome & Eccles, 1998) and teachers (Helwig, Anderson & Tindal, 2001; Li, 1999) hold different beliefs about males' and females' abilities in mathematics. In addition, many scholars have noted connections between individuals' personality attributes and career choice (Ackerman & Beier, 2003; Buddeberg-Fischer, Klaghofer, Abel & Buddeberg, 2006; Schaub & Tokar, 2004). Furthermore, Luyckx, Soenens, and Goossens (2006) found correlations between an individual's identity and personality traits. By exploring mathematics identity and students' self-identified personality attributes, we might develop a better understanding of how expectations and other identities interact to influence students' career goals.

Methods

This study collected data from two different universities in the northeast region of the United States by administering surveys in the fall of 2014 with students enrolled in Calculus I and Calculus

II courses, yielding 570 completed surveys. The survey was developed to collect student demographic information, career goals, perceptions related to mathematics identity, and self-identified personality attributes. Content validity was insured through: 1) pulling from literature related to personality attributes, gender, and mathematics identity (Cribbs et al., 2012; Piatek-Jimenez, 2015; Ely, 1995; Jones & Myhill, 2002; Luhtanen & Crocker, 1992), 2) conducting a pilot test with survey items related to personality attributes and gender stereotyping in the spring of 2014, and 3) conducting a pilot test with the completed survey in the summer of 2014. The initial pilot test also included a series of focus group sessions with participants to further refine the survey items. Both pilot tests were done with college students enrolled in mathematics and mathematics education courses at the universities where the study was conducted.

Logistic regression was used to address each research question because the outcome variable (career goals) was dichotomous. One regression model was created to examine students' career goals in a STEM field and another was created to explore students' career goals specifically in a mathematics field (mathematician or mathematics teacher). Table 1 details the possible choices available on the survey and corresponding number of responses. We can see from the table that of the 53 participants with career goals in a mathematics field, just under 60% of them were interested in becoming K-12 mathematics teachers.

Table 1: Number of Students Selecting each Career Goal

Career Goal	Number	Percent of Sample
Non-STEM (e.g. lawyer, business person)	197	35
STEM		
Mathematician	22	4
Math teacher	31	6
Life/earth/environmental scientist	52	9
Physical scientist	26	5
Engineer	176	31
Computer scientist, IT	53	9
Science teacher	8	1
STEM Total	368	65

Because we were looking at mathematics identity in particular (and not STEM identity), we were also interested in how the results might differ when comparing students who have chosen a mathematics field to those choosing a non-STEM field. Therefore, in conducting the regression analysis for research question 2, all other STEM participants were excluded in order create a model that compared how participants selecting mathematician or mathematics teacher related to those who selected a non-STEM field. A proxy for mathematics identity was used based on results from a previous analysis (Cribbs et al., 2012). In addition, the following control variables were considered for the model: gender, age, class standing in college, and mathematics course enrollment.

Results

Table 2 details the results for research question 1: What is the relationship between students' career goals in a STEM field with their mathematics identity and self-identified personality attributes? Only significant control variables, with a significance level of $p < 0.05$, were included in the final models shown in this section.

Table 2 shows that the only control variable remaining in the model was "current math class." The results indicate that mathematics identity significantly predicts students' career goals in a STEM field with an odds ratio of 1.5. In other words, a one unit increase in the mathematics identity proxy increases the odds of a student selecting a STEM career field by one and a half times. The results also indicate that several self-identified personality attributes are correlated with students' career goals STEM. The positively correlated items are "I am able to be 'one of the guys'" with an odds ratio of 1.2, "I am inquisitive" with an odds ratio of 1.3, and "I am passionate about my major" with an odds ratio of 1.4. The negatively correlated items include "I am feminine" with an odds ratio of 0.9, "I am forceful with my opinions" with an odds ratio of 0.8, "I earn good grades" with an odds ratio of 0.6, "I am academically motivated" with an odds ratio of 0.8, and "I show concern for people's well-being" with an odds ratio of 0.7.

Table 3 shows that mathematics identity significantly predicts students' career goals as a mathematician or mathematics teacher with an odds ratio of 3.8. The results also indicate that several self-identified personality attributes are correlated with students' career choice as a mathematician or mathematics teacher. The positively correlated items are "I cry easily when I am angry/upset" with an odds ratio of 1.2, "I am concerned about future family obligations" with an odds ratio of 1.4, and "I have a strong work ethic" with an odds ratio of 1.8. The negatively correlated items include "I am self-sufficient" with an odds ratio of 0.7, "I am concerned about future career obligations" with an odds ratio of 0.7, "I have high career aspirations" with an odds ratio of 0.4, and "I do not mind sacrificing my personal time for my studies" with an odds ratio of 0.6.

Table 4 and 5 detail results for research question 3: How do these models vary between females and males?

Table 5 indicates that mathematics identity significantly predicts male students' career goals in a STEM field with an odds ratio of 2.1. The results also indicate that several self-identified personality attributes are correlated with male students' career goals in STEM. The positively correlated items are "I am inquisitive" with an odds ratio of 1.4 and "I am passionate about my major" with an odds ratio of 1.5. The negatively correlated items include "I am forceful with my opinions" with an odds ratio of 0.8, "I earn good grades" with an odds ratio of 0.7, and "I do not mind sacrificing my personal time for my studies" with an odds ratio of 0.8.

Discussion

Our findings provide evidence that mathematics identity can be used as a way of explaining student persistence in STEM fields. Specifically, a shift in the mathematics identity proxy of one standard deviation corresponds to a 1.5 higher odds of having career goals in a STEM field and a 3.8 higher odds of having career goals as a mathematician or mathematics teacher. The odds ratio is much higher for career goals as a mathematician or mathematics teacher than for a general STEM field, as might be expected.

Our results also suggest that certain self-identified personality attributes are positively correlated to students' career goals in STEM. In particular, we found that "I am able to be 'one of the guys'" is positively correlated with having career goals in a STEM field. This finding might be a result of society's stereotypical belief that scientists and mathematicians are generally male (Picker & Berry, 2000). Therefore, individuals who believe that they can fit in as "one of the guys" may be more likely to choose a career in STEM. We also found that the attribute "I am passionate about my major" was positively correlated with choosing a STEM field. This, too, many be related to the belief that scientists and mathematicians are obsessed with their field (Piatek-Jimenez, 2008; Picker & Berry, 2000). Furthermore, we found that "I am inquisitive" was positively correlated with choosing a STEM field. We believe that this finding could relate to the fact that the field of science is often affiliated with inquiry, and other STEM fields, such as engineering and mathematics, are often related to problem solving.

There were also five negatively correlated self-identified personality attributes with choosing a STEM field. One of these attributes was "I am feminine". This may not be a surprising result given that, as previously mentioned, STEM fields are often believed to be masculine fields. This finding is consistent with that of Piatek-Jimenez (2015) who found that women mathematics majors often do not identify with being highly feminine. Another attribute that negatively correlated with wanting a STEM career was "I show concern for other people's well-being". This finding is consistent with Morgan, Isaac, and Sansone's (2001) work that shows college students believe that the physical and mathematical sciences are less likely to have "people-oriented" careers. Therefore, individuals who are highly concerned for other people's well-being may be less likely to choose a STEM career. Two items we found more difficult to interpret were "I earn good grades" and "I am academically motivated" as being negatively correlated with choosing a STEM field. Initially these both seemed counter-intuitive to us, given that STEM fields tend to be viewed as more rigorous fields. However, we believe this is the exact reason that "I earn good grades" did show up as a negative correlation. Because STEM fields are often seen as more rigorous, students in these fields may be used to earning lower grades than in other non-STEM fields. As of yet, we are still unable to determine why "I am academically motivated" was negatively correlated with STEM. In future work, we intend to do qualitative interviews with students to learn more about this finding.

In addressing our second research question, our results shown in Table 2 suggest that certain self-identified personality attributes are correlated specifically with career goals in a mathematics field, and that these are slightly different than for STEM careers, in general. In particular, we found that "I am concerned about future family obligations" was positively correlated with wanting a career in mathematics while "I am concerned about future career obligations" and "I have high career aspirations" were negatively correlated with wanting a career in mathematics. We believe that these findings may be a result of the fact that approximately three-fifths of the participants wanting a career in mathematics were intending to become a K-12 mathematics teacher. Given that the societal perception of teaching is that it provides a schedule more conducive to fulfilling family obligations (Anthony & Ord, 2008) than possibly other STEM fields may be a reason for this finding.

In order to address our third research question, we ran the model with regards to choice of STEM career separately for females and males. There were three personality attributes that remained consistent in all three models. We found that "I am passionate about my major" was positively correlated and "I am forceful with my opinions" and "I earn good grades" were negatively correlated in all three models. This finding shows that these personality attributes in predicting STEM career goals were not dependent upon gender. However, there were personality attributes that did depend on gender. Interestingly enough, the personality attribute of "I am able to be 'one of the guys'" was found to be statistically significant for female students wanting STEM careers but not for male students. We find this result to be important because it demonstrates the need for women to feel like they fit in as "one of the guys" when choosing a career in a STEM field. This result suggests that there may still be an embedded societal belief that the STEM fields remain male-dominated and male-driven and that in order to enter these fields, one must be able to be "one of the guys".

While having a strong mathematics identity is an important factor in choosing mathematics or other STEM career goals, it certainly is not the only factor influencing such decisions. Many factors play a role in career choice, and our work suggests that personality attributes may be one of those factors. Furthermore, we found that the personality attributes that correlate to choosing STEM careers differ slightly between males and females. If our goal is to encourage more students, and specifically more women, to enter STEM careers, a better understanding of the role that these personality attributes play in such decisions will allow us to better recruit talented students into these fields.

Prospective teachers must be prepared for their role in providing equitable access for learning high quality mathematics. Therefore, it is imperative that mathematics teacher educators provide opportunities to develop an equity-centered orientation in teacher preparation courses. In this study, we begin to address this issue by identifying what prospective teachers attend to in a classroom vignette of an African American male student who is above grade level in mathematics and exhibits disruptive behavior during instruction. The results of the study indicate that while participants are beginning to attend to cultural influences, most responses are focused on classroom management strategies.

Keywords: Equity and Diversity; Teacher Education-Preservice

Introduction and Background

The National Council of Teachers of Mathematics (NCTM) asserts that in order to teach in an equitable manner, teachers and schools must maintain "high expectations and strong support for all students" (NCTM, 2000, p. 11), meaning mathematics teachers must provide opportunities for students to learn challenging mathematics regardless of their students' "personal characteristics, backgrounds, or physical challenges" (p. 12). For the past two decades, mathematics educators conceptualized what it means to teach mathematics for equity (Gutiérrez, 2002; Gutstein, 2003; Hart, 2003; Matthews, 2005); yet only in recent years have mathematics teacher educators documented efforts to prepare prospective teachers (PTs) to teach mathematics while considering matters of equity (Bartell, 2010; Freitas, 2008; Wager, 2014). Unfortunately, many PTs and practicing teachers do not know how to make these necessary connections, especially with students who are different from their own culture and background (Futrell, Gomez, & Bedden, 2003; Turner, Drake, Roth McDuffie, Aguirre, Gau Bartell, & Foote, 2012). Therefore, within the current educational system, students from non-dominant backgrounds are often denied equitable opportunities to learn (Wager, 2014).

To further complicate the issue, many mathematics teachers dismiss issues of equity as relevant factors in the mathematics classroom because they view mathematics as a universal, culture-free subject (Rousseau & Tate, 2003). However, there is a growing body of mathematics education researchers who understand that mathematics and mathematical knowledge are neither universal nor culturally neutral, but are situated in a sociocultural framework (Ukpokodu, 2011). Moreover, Gay (2000) argues that if we "decontextualiz[e] teaching and learning from the ethnicities and cultures of students [it] minimizes the chances that their achievement potential will ever be fully realized" (p. 23). Reducing the opportunity gap in mathematics education is possible by transitioning to an equity-centered paradigm. With this goal in mind researchers, practitioners, and teacher educators in the mathematics education community must learn how to "value the cultural and lived experiences of all children…[and emphasize] the belief that all children possess strong intellectual capacity and bring a wealth of informal, out-of-school knowledge to the teaching and learning process" (Lemons-Smith, 2008, p. 913). It is imperative that mathematics teacher educators begin this process by encouraging prospective and practicing teachers to critically examine their current beliefs while explicitly addressing the elements of teaching mathematics through an equitable lens. Attending to these practices in teacher preparation programs can help all teachers observe the actions that occur in the classroom, and determine effective strategies that will enhance all students' access to high quality mathematics instruction.

The extant literature in mathematics education provides an initial glance into equitable mathematics pedagogy, yet there is a need to better prepare PTs for their role in creating opportunities that provide equitable access for learning high quality mathematics. It is imperative PTs are given the opportunity to develop an equity-centered orientation toward mathematics teaching and learning to effectively instruct *all* students. In order to accomplish this goal, we must first recognize what PTs attend to as they direct their attention to various classroom events and how they relate the events to broader principles of teaching and learning, including cultural contexts that contribute to students' learning. In this study, we begin to address Wager's (2012) call and Hand's (2012) recommendation to assess how equity issues are perceived in classroom episodes by reporting what PTs notice about students' mathematical thinking and its relation to culture, home, and community.

Theoretical Framing for the Study

Equity may be viewed as a process or as a product (Crenshaw, 1988; Gutiérrez, 2002; Martin, 2003; Rousseau & Tate, 2003). Seeing equity as a process means treating all students equally, without regard to race, ethnicity, or economic background. On the other hand, seeing equity as a product means differentiating instruction based upon students' needs in order to promote equal learning outcomes. We adopt the view of equity as a product, and define teaching mathematics for equitable outcomes as approaches that are respectful of students' ethnic, racial, and economic background and promote equal learning outcomes.

Classroom episodes are complex; therefore, it is inevitable that individuals choose, consciously or subconsciously, what they attend to and then use these events to make instructional decisions. Before defining an approach that develops PTs' orientations toward teaching mathematics through an equity lens, we must first attend to how PTs perceive classroom situations and identify what they notice—or attend to—during the teaching and learning process. This process is referred to as the discipline of noticing. The ability to notice noteworthy classroom interactions or events among the plethora that occur in a complex classroom environment is a key component of teaching expertise (van Es & Sherin, 2006).

van Es and Sherin (2010) emphasize the key in the process of noticing is identifying what is significant, and then reasoning about the situation to effectively contribute to mathematics learning. Furthermore, Wager (2006) argues that mathematics teachers must not only attend to students' achievement, but also explore access, identity, and culture in order to provide students with equitable opportunities. Turner et. al. (2012) expand upon this sentiment in the context of noticing as they emphasize noticing critical elements within a classroom environment includes not only analyses of mathematical thinking, but also considers the impact of cultural knowledge as a foundation of students' mathematical knowledge base. The process of noticing generally involves three components: (a) identifying noteworthy instances within a classroom situation, (b) relating classroom interactions or events to principles of teaching and learning, and (c) using the cultural context to interpret the events and make instructional decisions. In this study, we incorporate a noticing lens to explore what PTs attend to as they reflect on a teaching vignette and how the events they notice correspond to equitable practice.

Method

In this paper, we describe an activity used in our elementary mathematics methods course that was designed to encourage PTs to face existing (and often hidden) biases in order to alter unproductive beliefs and consequently broaden their *ways of seeing*. We view this as an essential activity to help PTs: (a) develop an awareness of equity, (b) define what equity means in classroom instruction, and (c) implement equity practices within the mathematics classroom. Participants in the study were PTs from three different universities in the U.S. who were within a year of their student teaching experience. The demographics of the PTs reflected demographic patterns of elementary education majors at our universities and included 91.4% white females, 4.3% white males, 1.4% Asian female, and 2.9% African American females. A less diverse population of PTs is facing an ever increasingly diverse population of students in our public school systems.

To access the PTs' thoughts and ideas on issues related to equity in the mathematics classroom, we used classroom vignettes, each representing a different scenario that potentially challenges learners' equitable access to high quality mathematics. The five authentic topics included one of the following teachers: (a) one who exhibits gender bias for class participation, (b) one with preconceived biases that cause him to withdraw from students who are from different backgrounds than himself, (c) an instructor who does not take time to develop relationships with her racially diverse students, (d) one who recommends a new English Learner with limited English proficiency for special education services without adequately assessing the child's content knowledge, and (e) a teacher who is frustrated with a student who is above grade level in mathematics and exhibits disruptive classroom behavior.

To help ensure all PTs fully participated in the discussion of the equity cases, each PT independently read and responded to corresponding reflection questions for each case (Data Source 1 [DS 1]). Using a modified version of "jigsaw," a cooperative learning structure, the PTs were divided into five groups, where each group was randomly assigned a specific case and asked to discuss their responses (DS 2), which were audio-recorded and transcribed. The PTs recorded their thoughts to the guiding questions that accompanied their case on chart paper (DS 3), and an expert was selected from each small group to share their results with other members in the class. Everyone from each group, except the expert, rotated from case to case and listened to the "expert" report the group's analysis of the situation before the PTs shared their individual thoughts pertaining to the events in the vignette. At the conclusion of the discussion, the PTs recorded their thoughts and ideas on post-it notes that were placed on the chart paper (DS 4). Once the PTs finished rotating to each of the five groups, they returned to their original group where the expert shared what he/she learned from the discussions with the other groups. Finally, the PTs shared their thoughts and ideas on each case within a large group discussion.

For the purpose of this paper, we focus our results on one case, *Eric*, in particular because of the dichotomy the PTs perceived between Eric's mathematical knowledge and his exhibited behavior during a mathematics lesson. See figure 1 for the stated case and corresponding reflection questions.

Case: Eric

Eric, an African American third grader, is a good-looking nine-year old boy who was retained in first grade. He is below grade level in reading and language, but above grade level in mathematics. He has been removed from his home because of abuse and is being raised by a caring grandmother. During mathematics lessons, Eric harasses the other children. He closes their books while they are working, knocks their books and pencils off their desks, writes on their papers, and crumples up their work. He does his best to disrupt the lessons by making gestures and deliberately making noises. Ms. Maben, his teacher, is frustrated.

Reflection Questions:

1. If you were the teacher in this situation, how would you respond?
2. What are the implications for elementary teachers?
3. Additional comments or thoughts?

Figure 1: The case of Eric and corresponding reflection questions.

Data Collection and Data Analysis

The first part of the classroom assignment with Eric's case served as an opportunity to gain insight into what individual PTs highlighted as significant. When students read the vignette and addressed the reflection prompts we could ascertain the three elements in the noticing process. First we identified what the PTs found noteworthy in the classroom situation with Eric. Secondly, we determined how the PTs related classroom interactions or events to principles of teaching and learning from their responses to the first, and particularly second, question. Finally, we thoroughly examined their responses for evidence of using the cultural context in the given situation to interpret the events and make instructional decisions.

As PTs continued to work through the jigsaw activity discussing the scenario in small groups and with a follow-up large group discussion, the mathematics teacher educator in each of the three methods courses guided the conversations to further engage PTs in the second and third characteristics of noticing: (a) using contextual information to reason about witnessed events, and (b) making sense of the events through a contextual lens and using the knowledge to inform instructional decisions.

The data generated from the individual reflections, group poster notes, and transcriptions from small group discussions served as evidence of PTs' conceptions related to issues of equity. The data analysis process began by first making notes to identify PTs' comments in the transcripts of the small group discussions and all written work. These notes served as indications of what the PTs noticed from the vignette. Then the margin notes were summarized into short phrases that emphasized the nature of the comment and were coded independently by three researchers for common themes. Any differences were resolved through refining the common themes. Finally, using Barnes and Solomon's 2013 observational categories as an initial analysis template, the common themes were clustered into the following four categories: (a) classroom management (i.e., classroom events—including disruptive events, pace changes, routines or procedures), (b) classroom environment (i.e., physical setting, equipment, demographics, grade level), (c) task selection (i.e., activities students do during the teaching episode), and (d) communication (i.e., interactions or dialogue between or among students, the classroom teacher, school personnel, or the family).

Results

Eric's case provided an opportunity for mathematics teacher educators to engage PTs in a discussion on issues related to equity, which brought an awareness to and challenged their stereotypes, hidden biases, and unproductive beliefs about students from diverse backgrounds. The results across the three classes (see Table 1) provided an interesting perspective on what the PTs noticed in the case.

While the mathematics teacher educator guided follow-up discussions to the activity that emphasized principles of equity, throughout the three classes the PTs primarily attended to classroom management with 39.9% of the referring responses pertaining to strategies such as reward systems, punishments, or behavior plans. About one-third of the classroom management responses encouraged a classroom teacher in this situation to provide students like Eric with more leadership responsibilities. Specifically, one PT expressed,

> I would make Eric the classroom leader and give him jobs to do around the classroom. Like having him turn the lights on and off and having him sharpen the pencils. This will make him feel more like he is a part of the classroom and hopefully it will make him more of a helper than someone who disrupts other student's work.

Approximately 34% of the PTs' classroom management responses focused on classroom behavior systems, with some students indicating that Eric was in need of a behavior intervention plan or an Individual Education Plan (IEP). In fact, one PT stated, "If he was put on an IEP for his

Table 1: Summary of what prospective teachers noticed from the case of Eric

BROAD CATEGORY	CLUSTERED THEMES	CODE CATEGORIES
CLASSROOM MANAGEMENT 39.9%	Positive Reinforcement 11.8%	Reward system (e.g., praise when good) Positive rewards for class Special role (e.g., leader, peer tutor)
	Negative Consequences 14.6%	Punish Eric for his behavior Remove Eric from group Hold Eric back
	Behavioral Assessment 13.5%	Document behavior Individualized Education Plan (IEP) Firm, Clear Rules Set Goals
COMMUNICATION 29.7%	Collaboration with Family 21.3%	Contact Grandmother for ideas Speak with Student 1-1
	Collaboration with School 8.4%	Contact Principal Refer to Guidance Counselor Refer to Special Education Teacher
TASK SELECTION 22.5%	Increase Rigor 12.9%	Provide Enrichment Activities Challenge Eric More
	Increase Amount of Work 9.6%	Provide "Busy Work"
CLASSROOM ENVIRONMENT 7.9%	Culturally Relevant Pedagogy 7.3%	Home learning/Background Connect with Student
	Positive Influence/Support System 0.6%	Male Role Model

behavior, then maybe he could get instruction in a special education setting. This way he would not be disruptive towards his peers." Another PT expressed her belief that the behavior was such an obstacle that Eric should not continue with his peers to the next grade. She articulated, "I believe that Eric would be a great student that could really benefit from being held back this year so that he could grow and learn to practice age appropriate behaviors." These responses seem to imply that the student is at fault for the behavioral issues. The PTs who responded to the first reflection prompt whose solutions to the situation included behavior plans, IEPs, or retention were focused on Eric's behavior without critically reflecting on how the teacher's actions may be contributing to his outbursts.

While the PTs did indicate positive solutions to address Eric's behavior, several identified classroom management strategies focused on negative consequences for Eric's actions such as removing him from the group. One PT even noted, "Eric would be on an island far away from the rest of the class." From these responses, it was evident the majority of PTs first noticed the behaviors, and initially directed concern to "deal with" Eric's actions rather than attend to additional information that could provide insight to the source of these behaviors. These responses reflect a common perception or stereotype of black males as a menace to society, which can negatively impact the child and provides an obstacle for him (or her) in receiving opportunities for high quality instruction.

Communication was the second most common category that the PTs responses aligned to with 29.7% of the referring responses coded under this category. For example, in order to help subside Eric's disruptive behavior, several PTs suggested speaking to Eric one-on-one or having Eric speak to a counselor, principal, or some other positive male role model. While collaboration with families, the school, and constructive influences in the community are integral to students' successes, the PTs again first noticed Eric's behavior and directed their contacts and references as resources for fixing the behaviors they found to be inappropriate for school. These actions seemed to indicate that the PTs did not feel comfortable or confident in effectively working with children who exhibit such behaviors, and also that they do not initially consider the whole child and how the classroom environment or teachers' instructional methods may be a key factor in transforming behavior.

One of the most interesting results under the task selection category was that in each of the three courses many of the PTs focused on giving Eric more work. Some PTs across the three groups, focused on providing more challenging work, with one even emphasizing the job of the classroom teacher is to "make sure that a student is being challenged and engaged on a level that is appropriate for them." Several of the responses (12.9% of 22.5% of the task selection responses) PTs generated seemed to support the need to select appropriately challenging tasks for Eric and indicated that a strategy to quell his behavior could be to stimulate his thinking. One PT wrote, "I would gather different math problems that challenge Eric and meet his learning needs. If need be I would have an associate take Eric out during math to work on more challenging problems to keep him engaged." However, others suggested Eric should be given additional work to keep him busy so he would not "distract" the other students. These students' responses (9.6% of 22.5% of the task selection responses) seemed to overlook the possibility that Eric was bored with the current assignments, and rather than exploring opportunities to stimulate his thinking through high quality tasks that appropriately challenge Eric, the PTs merely indicated the need to increase the quantity of work rather than the rigor. Decisions such as these again serve as additional obstacles in providing access to high quality mathematics instruction.

While many PTs did attend solely to Eric's disruptive behavior, approximately 7.9% of the responses reflected an attempt to identify the source of the issue by focusing on ways they could establish a positive, caring classroom environment where students felt accepted as individuals. One PT claimed, "Students just want love and attention. This is why I think it is so important to create a caring community in the classroom. I truly believe that when students trust and feel loved and accepted they will preform much better in school." The PTs noticed the former abuse in the fictional child's past and his current living situation being with his grandmother. Recognizing these events can negatively impact a child and can be exhibited through defiant or inappropriate behavior. Consequently, several PTs saw the need to create a place in which Eric could feel safe and secure. One PT articulated, "I think that the student is acting up because of his home life and I have seen this many times. Yes, you should have clear, set rules in class, but as an educator you should take the time to see where the student is coming from and maybe provide resources such as counseling." One of the participants who commented on classroom environment recognized the need for a supportive environment and made connections to her field placement,

> This similar situation happened in my practicum classroom. The boy was African American and was constantly causing problems. His home life was very busy and his single mother had him and 7 other kids with another on the way so he did not get much attention at home. I do not think that he was abused, but he definitely was disruptive in the classroom. He did not respect me and when I taught, he would do all of those things mentioned above with messing with other people's papers and making noises during lessons…Eventually while I started to build a relationship with [him] he was really sad to see me go. It really is about making a relationship with the child and then showing them that you want to help them learn.

Although classroom environment was the least referred response in the reflection assignment, it was reassuring that some PTs did notice the need to develop a positive classroom culture by connecting with their students and providing support systems. The attention to classroom environment in the large group discussion provoked PTs' thinking on issues related to equity. In subsequent discussions, PTs began to uncover some of their stereotypes and unproductive beliefs related to Eric's scenario. They recognized that initially many beliefs focused on Eric and his family situation as the root of the problem, rather than noticing that behavioral issues may stem from inappropriate instructional strategies. While more efforts are needed, these discussions seem to contribute to moving PTs into the other dimensions of noticing.

Conclusion

To provide opportunities for *all* students that will challenge the status quo, we must first identify what is salient to PTs by understanding what they attend to in complex classroom situations. With this knowledge, mathematics teacher educators can more effectively address PT's philosophies and beliefs. We understand teachers cannot attend to everything that occurs in a classroom; thus they must make choices—whether consciously or subconsciously—about what they notice. Barnes and Solomon (2013) found that novices are often attracted to whatever is most salient or personally intriguing, such as evidenced in this study with classroom management strategies to address a student's behavior.

While classroom management is at the forefront of our PT's thoughts, we must help them move beyond this surface layer of noticing. NCTM (2014) argues that effective mathematics instruction builds from students' culture—their values, beliefs, language, and experiences. Therefore, the teaching and learning of mathematics is not void of cultural influence, but positioned within a social context. Noticing involves three components. From the results discussed above it is evident that PTs are attending to noteworthy instances in a classroom situation. However, mathematics teacher educators need to provide more explicit support and attention to the second and third aspects of noticing: (a) using contextual information to reason about witnessed events, and (b) making sense of the events through a contextual lens and using the knowledge to inform instructional decisions. Aligning teachers' beliefs about equity and equitable practices in mathematics education with productive beliefs (NCTM, 2014) and research-proven attitudes and practices (Jackson, 2010) is vital. Engaging PTs in classroom activities—such as the one described with Eric's scenario—helps foster reflective discussions, which can positively contribute to developing an equity-centered orientation toward mathematics teaching and learning.

MAINTAINING CONVENTIONS AND CONSTRAINING ABSTRACTION

Kevin C. Moore

kvcmoore@uga.edu

Jason Silverman
Drexel University
silverman@drexel.edu

Conventions play an important communicative role in mathematics. Likely due to the complex relationship between conventions and school mathematics, few education researchers have questioned or investigated the consequences of instruction and curricula that primarily, if not unquestionably, maintain conventions. Drawing on Piagetian notions of abstraction and our work with students and teachers, we argue that students' repeated experiences with instruction and curricula that maintain conventions likely constrain students' learning opportunities. We hypothesize that by 'breaking' conventions, educators could better support students in differentiating those aspects of their activity essential to a concept from those that are unessential. We characterize student work on two tasks to illustrate potential relationships between the nature of students' abstractions and what we perceive to be conventions.

Keywords: Abstraction; Radical constructivism; Student cognition; Multiple representations

…la mathématique est l'art de donner le même nom à des choses différentes. (Poincaré, 1908, p. 29)

Mathematicians and mathematics educators widely hold the study of mathematics as dependent upon abstraction. Said simply, abstraction is the process of coming to understand some sense of invariance among seemingly different activities, situations, or objects so that this understanding is not tied to particular features of any one activity, situation, or object; translating the Poincaré quote above, "mathematics is the art of giving the same name to different things." Despite the central role of abstraction in the study of mathematics, students' abstraction processes and how educators can support students in constructing productive (in the short- and long-term) meanings through abstraction remain pressing areas of research (Oehrtman, 2008; Simon et al., 2010). We agree with Thompson (2013), who argued that making fundamental improvements to U.S. mathematics education requires that educators at all levels take the meanings that students abstract more seriously.

We draw on theoretical accounts of abstraction and our work with students (and teachers) to clarify students' abstracted meanings. Namely, we argue that students' actions and opportunities to abstract productive meanings for mathematical concepts are likely unintentionally constrained by educators who maintain conventions common to school mathematics (e.g., using the Cartesian horizontal axis to represent a function's input). After discussing our motivation and background, we provide a theoretical framing of abstraction and examples of student activity that clarify how educators maintaining particular conventions might constrain students' experiences and hence abstracted meanings. We also illustrate students operating productively in non-canonical situations so that we can clarify how experiences with such situations might influence the meanings that students abstract. We close with connections to related areas of research and ideas about lines of inquiry that can contribute insights into students' abstraction processes.

Background and Motivation

The present work emerged from a collection of studies (e.g., Moore, 2014a, 2014c; Moore, Paoletti, & Musgrave, 2013; Thompson & Silverman, 2007). Our goal in each study was to understand students' and teachers' *quantitative and covariational reasoning* (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Saldanha & Thompson, 1998; Thompson, 1993)–how individuals conceive of a situation as composed of measureable attributes and relationships between these attributes–

including how teachers support said reasoning. Our research settings have included teaching experiments (Steffe & Thompson, 2000) and task-based clinical interviews (Goldin, 2000), with these settings sometimes occurring in the larger context of professional development projects. Our data analyses efforts have followed a combination of conceptual analysis techniques (Thompson, 2008) and open/axial methods (Strauss & Corbin, 1998). Such efforts entail fine-grained, iterative analyses for the purpose of constructing viable models of individuals' thinking. We direct the reader to our prior studies for more detailed explanations of the work that informed this theoretically oriented paper.

Motivating our present focus, it was in trying to support students' and teachers' quantitative reasoning that we noticed their difficulty assimilating non-canonical situations in quantitative ways (Moore, Silverman, Paoletti, & LaForest, 2014; Moore, Silverman, et al., 2013). We found this outcome noteworthy for two reasons. First, the students' difficulties assimilating situations that we had designed to be non-canonical often led to their (consciously or subconsciously) imposing conventions on situations. For instance, in cases that we had designed tasks to explicitly define–in spoken or written text–a Cartesian axis oriented vertically as representing a function's input values (see the following section for task examples), students persisted in conceiving the axis oriented horizontally as a function's input (Moore, Silverman, et al., 2013). Second, the students and teachers often exhibited actions within canonical situations that they were unable to relate to and re-present in non-canonical situations. As an example, students would describe a graph of a function in terms of how two quantities varied in tandem, but then be unable to describe a non-canonical graph of that same (to us) function in an equivalent way (Moore et al., 2014). Due to the frequency of these outcomes, we inferred from the students' actions that what we perceived to be conventions were instead inherent aspects of students' meanings (i.e., not conventions) (Moore et al., 2014). This inference has led us to question the relationships between students' and teachers' abstracted meanings and what we, as educators and researchers, perceive to be conventions. In addition to discussing our theoretical framing, we use student work on two tasks to clarify important differences with respect to these relationships.

Abstraction and Student Illustrations

A detailed comparison of theories of abstraction is beyond the scope of this work given space constraints, and thus we discuss those constructs most relevant to our focus: Piaget's constructs of (pseudo-)empirical and reflective abstractions. The former type of abstraction, whether empirical or pseudo-empirical, concerns itself with the results of activity, whereas reflective abstraction concerns itself with internalized coordinations (Chapman, 1988; Piaget, 1980; von Glasersfeld, 1991). Empirical abstractions involve characteristics of experiential objects (e.g., color) including the results of sensorimotor activity on those objects. Empirical abstractions support repeated actions and motor patterns based in sensorimotor experience. Pseudo-empirical abstractions are similar to empirical abstractions in that they foreground abstraction from objects and results of activity, but they differ from empirical abstractions due to the individual introducing properties of these results into objects at the level of mental actions (Dubinsky, 1991). For instance, after working several problems graphing linear functions, a student might abstract rate of change or slope as an indicator of direction (e.g., all lines with a positive rate of change means slope upward left-to-right). Such an abstraction is not constrained solely to sensorimotor operations and observables (e.g., empirical abstractions), but the generalization does stem from patterns tied to the product of an activity (e.g., graphing linear functions) and conditions for this activity (e.g., having a rate of change and graph).

Reflective abstractions involve re-presentation, symbolization, and the coordination of (mental) actions so that the locus of abstraction is on activity itself, as opposed to activity results (Chapman, 1988; Piaget, 2001; von Glasersfeld, 1991). Relative to graphing linear functions, a student might conceive rate of change as entailing the imagery of coordinating the relative change in two quantities. The student might also coordinate this process with graphs in several orientations or coordinate systems; the linear function and rate of change become a coordinated system so that each is a "pointer" to coordinating relative changes, but the process itself need not be carried out. In the case of pseudo-empirical abstraction, the rate of change value or slope signals executing an activity and obtaining a particular graph-as-picture; the linear function or rate of change symbolizes a structure of mental actions and associated representations all at once. In what follows, we provide student responses to two non-canonical tasks and then synthesize their activities with respect to these notions of abstraction.

Student Illustrations 1

We presented the graph in Figure 1 to undergraduate (secondary) mathematics education students (*Student Quotes for Figure 1*) with the claim that a hypothetical student deemed it a graph of the inverse sine function. We also provided a statement by the hypothetical student: "Well, because we are graphing the inverse of the sine function, we just think about *x* as the output and *y* as the input." Among other considerations, we designed the task to incorporate a non-canonical representation of the inverse sine function and to capture fundamental aspects of the inverse relationship, namely the understanding that if $y = \sin(x)$, then $x = \sin^{-1}(y)$ with appropriate restrictions on *x*.

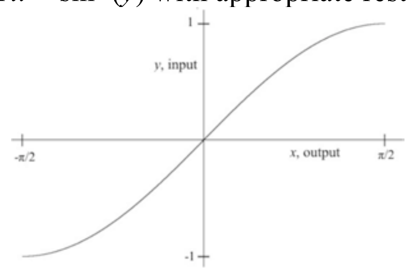

Figure 1: A Non-canonical Graph of the Inverse Sine Function

Student Quotes for Figure 1

Molly: I feel like he's missing the whole concept of a graph…I know you can call whatever axis you know if you are doing time and weight or volume or whatever. You can flip-flop those and be OK. But not necessarily with the sine graph. Like a sine graph's like a, it's a graph like everyone knows about, you know.

Rowena: I'm thinking this just kind of looks like the sine graph, like the plain sine graph [*laughs*]. Which is going to be different…I don't know if, or like an inverse function, like the graph of an inverse function, like, can't be the same as the original graph.

Ariana: You could just like disregard the *y* and *x* for a minute, and just look at, like, angle measures. So it's like here [*referring to graph of* $\sin^{-1}(x) = y$*, see Figure 2, left*], with equal changes of angle measures [*denoting equal changes along the vertical axis*] my vertical distance is increasing at a decreasing rate [*tracing graph*]. And then show them here [*referring to graph of* $\sin^{-1}(y) = x$*, see Figure 2, right*] it's doing the exact same thing. With equal changes of angle measures [*denoting equal changes along the horizontal axis*] my vertical distance is increasing at a decreasing rate [*tracing graph*]. So even though the curves, like, this one looks like it's concave up [*referring to graph of* $\sin^{-1}(x) = y$ from $0 < x < 1$] and this one concave down [*referring to graph of* $\sin^{-1}(y) = x$ from $0 < x < \pi/2$], it's still showing the same thing [*denotes equivalent changes on graphs, see Figure 2*].

We contend that each student *understood* the given graph, and we interpret their actions to suggest differences in their meanings. Molly and Rowena understood the sine function to be uniquely associated or in a one-to-one relationship with the given graph. An implication of this understanding is that "the sine function" or "inverse sine function" were, in the moment of their assimilating the graph, as much about associating a function name to a unique shape as about associating a function name and graph to a particular relationship. In contrast, Ariana understood "the sine function," "inverse sine function," and graphs in terms of a relationship between covarying quantities. Moreover, she was not constrained to reasoning about this relationship in a particular coordinate orientation. Hence, when we presented Ariana an alternative graph, she understood differences in shape did not imply a difference in the represented relationship; to Ariana, both graphs represented an invariant relationship associated with "the sine function," written as $y = \sin(x)$, and "the arcsine function," written as $x = \sin^{-1}(y)$.

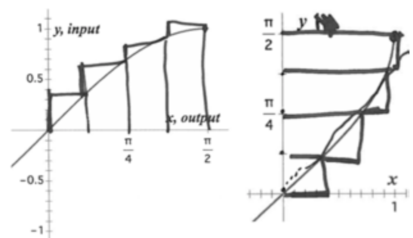

Figure 2: Two Graphs, One Relationship

Student Illustrations 2

We presented a graph (Figure 3) to undergraduate (secondary) mathematics education students (*Student Quotes for Figure 3*) with the claim that a hypothetical student produced the graph to represent $y = 3x$. We designed the task to explore rate of change (or slope as rate of change) in non-canonical axes orientations. The following student responses are in reply to our asking them to comment on the student's solution including their interpretation of its correctness.

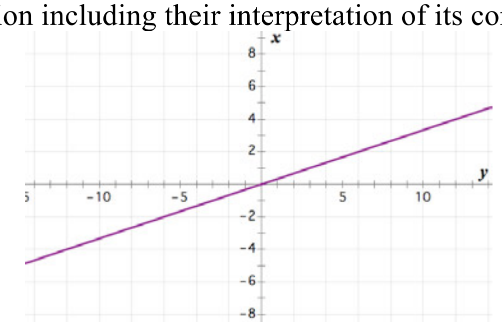

Figure 3: A Non-canonical Graph of $y = 3x$

Student Quotes for Figure 3

Rowena: Because if you turn it this way [referring to Figure 3 rotated 90-degrees counterclockwise] then this [traces left to right along the x-axis which is now oriented horizontally] and this [traces top to bottom along the y-axis] and it would be still not right though…this [laying the marker on the line which is sloping downward left-to-right] is negative slope. So I would…show them like the difference between positive and negative slopes also. Because that's something that, like, when I was in middle school we, like, learned kind of like a trick to remember positive, negative, no slope, and zero [making hand motions to indicate a direction of line for each]. Like where the slopes were…it's important to know which direction they're going…

Rubeus: They messed up the placement of x and y…They are looking at it like this [rotating graph 90-degress counterclockwise]…If you are looking at it this way, it's a negative slope [tracing graph] and it should be a positive slope [tracing imagined graph upward left-to-right]…slope is wrong.

Amelia: I think it demonstrates understanding of the relationship…I don't care what axis you put it on…[interview rotates graph and says a student claims it has negative slope] [The way we teach slope] is just a very visual thing and no understanding of like what slope means or where it came from…your negatives are over here and your positives are over here [referring to horizontal axis value orientations]…So if we look for like a change of x of one [identifies change with a segment], zero to one, we see that y changes by positive three [identifies change with a segment]…positive slope because you are looking at change…If you're so obsessed with convention and the way things are supposed to be, you're going to take more work to get it to the way that you are comfortable with…than to just interpret the graph.

Rowena and Rubeus drew on meanings for slope rooted in visual queues including the direction of a line (e.g., "where the slopes are"). When they rotated the graph, which we interpret to be for the purpose of maintaining conventional x-y axes orientations, the students understood the "slope" to be different and hence they understood the line to represent a different relationship once rotated. In contrast, Amelia assimilated the graph in terms of reasoning about how two quantities vary in tandem while remaining attentive to how these quantities were represented with respect to the axes. No matter the rotation, Amelia understood the graph and slope in terms of a relationship such that the rate of change of y with respect to x is 3 (e.g., $y = 3x$). Amelia also distinguished between someone constrained to a conventional understanding of slope (e.g., "visual" understandings) and someone who is focused on interpreting the graph as a relationship.

Looking Across the Illustrations

Despite differences in the tasks and student responses, we interpret an underlying commonality to Molly, Rowena, and Rubeus' actions and meanings. Likewise, we interpret there to be an underlying commonality to Ariana and Amelia's actions and meanings. In the former case, the students primarily focused on observables or perceptual features of the given graphs in relation to particular topics (e.g., function name or slope). In the latter case, the students operated beyond the level of observables and perceptual features. They understood the graphs in terms of interiorized covariation schemes, and they drew on these schemes to make sense of the non-canonical representations and conceive invariance among perceptually different graphs.

Returning to theories of abstraction, we interpret Molly, Rowena, and Rubeus' actions to be compatible with meanings stemming from pseudo-empirical abstractions due to their focus on observables and the products or results of activity (e.g., produced shapes and associations with these shapes). One explanation for this result is that the students had experiences constrained to associating a function name with *one particular* graph or associating slope values with lines in *one particular* coordinate system orientation. Through repeatedly and habitually assimilating experiences to these meanings, the students abstracted function names and slope as essentially facts of perceptual shape. We interpret Ariana and Amelia's actions to be compatible with meanings stemming from reflective abstractions. That is, their understandings of "the sine function" and slope entailed internalized coordinated actions that they re-presented to make sense of the non-canonical graphs. One explanation for this understanding, which we expand upon in the next section as a future line of inquiry, is that the students had sustained opportunities to make sense of functions, function properties, and function graphs (including those that are non-canonical) in terms of covarying quantities. Hence, the students came to understand slope (or rate of change) and function names in ways not restricted to visual shape, but instead as properties of internalized covariation schemes.

Connections and Moving Forward

Mamolo and Zazkis (Mamolo & Zazkis, 2012; Zazkis, 2008) hypothesized that individuals face difficulties constructing sophisticated understandings of mathematical ideas when they only experience instruction that maintains particular conventions. Zazkis (2008) explained, "Of course, conventions are to be respected…but there is a need to become aware of them" (p. 138). Zazkis (2008) proposed that by becoming aware of conventions and structure specific to a representational system, individuals have an opportunity to develop "richer or more abstract schema" (p. 154). We agree with Mamolo and Zazkis, and we contend that students have said opportunities due to the nature of abstractions that can occur when students have experiences with both canonical and non-canonical representations. These experiences give students the opportunity to abstract meanings that differentiate what is essential to a mathematical idea from what is a convention or structure of the representational system. Students who only have experiences with conventional representations (e.g., *one* graph in a particular axes orientation) do not have the same collection of experiences or activity to reflect upon and coordinate in order to differentiate aspects of their activity that are critical to an idea from those that are not.

One area of research that the relationship between conventions and abstraction is most relevant to is that of multiple representations. Educators often frame a focus on multiple representations in terms of graphical, tabular, analytic, etc. representational contexts. We argue that it is productive to extend the 'multiple representations' perspective to incorporate the use of canonical and non-canonical representations within these representational contexts. Without offering students an opportunity to work with both canonical and non-canonical representations, we likely unintentionally enable students' construction of meanings that take what we perceive to be conventions of a representational context to be essential or unquestionable facts of mathematical ideas. On the other hand, offering students experiences with both canonical and non-canonical representations in a multitude of representational contexts enable them to reflect on and coordinate their activity both *within* and *among* representational contexts. In doing so, students have a collection of experiences to reflect upon in order to come to understand an idea in terms of what is invariant among their activity within and among representational contexts; we envision that these experiences might address Thompson's (1994) call for a focus on "representations of something that, from the students' perspective, is *representable*" (p. 40).

We also conceive relationships between abstraction and conventions to be relevant to researchers who explore students' quantitative and covariational reasoning. Specifically, we have found it necessary to be more careful and nuanced in our claims about students' covariational reasoning, especially in distinguishing between a student who is able to carry out a particular activity in one coordinate orientation versus a student who has internalized and coordinated their actions in a way that is not constrained to one coordinate orientation. For instance, despite students exhibiting actions in one coordinate orientation compatible with that of Ariana (e.g., drawing and comparing segments within a canonical representation of a function in ways that suggest covariation mental actions outlined by Carlson et al. (2002)), we have found that students encounter much difficulty extending their activity to other coordinate orientations and systems. We interpret such difficulties to highlight the importance of researchers identifying the extent that students' meanings are tied to their activity and its results (e.g., pseudo-empirical abstractions versus reflected abstractions). With respect to characterizing students' quantitative reasoning, researchers might explain students' learning through constructing an *increasingly abstract quantitative structure*. By increasingly abstract quantitative structure, we mean a student constructing and reconstructing a quantitative structure that becomes so internalized and operational that the student is increasingly able to assimilate novel representational contexts and situations to that structure, as opposed to being dependent on activity tied to particular representational contexts and conventions.

We close by noting that we do not intend the reader to interpret that pseudo-empirical abstractions are not desirable, nor are we arguing for the dismissal of conventions. Pseudo-empirical abstractions are a critical part of the learning process and are the source material for reflective abstractions (Dubinsky, 1991). For instance, in the context of graphing, students abstracting shape-based associations is a natural outcome (Weber, 2012). An issue arises when a student repeatedly assimilates their experiences to these shape-based associations so that the shape associations become nearly the entirety of her or his operating meanings. This outcome stands in contrast to a student coming to know graphical representations so well that they can operate at the level of shape associations while anticipating these associations in terms of internalized processes that can be carried out and adjusted if necessary. Despite the critical role of pseudo-empirical abstractions to the learning process, as educators we must look to support students in pushing beyond pseudo-empirical abstractions, lest the results of those abstractions become the entirety of their meanings. Simon et al. (2010) argued that gaining insights into nuances of students' abstraction processes with respect to their activity is a promising area of research. In accomplishing this goal in the context of using canonical and non-canonical representations, we might come to better understand how to support students in experiencing mathematics as "l'art de donner le même nom à des choses différentes" (Poincaré, 1908, p. 29).

BILINGUALS' NON-LINGUISTIC COMMUNICATION: GESTURES AND TOUCHSCREEN DRAGGING IN CALCULUS

Oi-Lam Ng
Simon Fraser University, Canada
oilamn@sfu.ca

This paper discusses the importance of considering bilingual learners' non-linguistic forms of communication for understanding their mathematical thinking. In particular, I provide an analysis of communication involving a pair of high school calculus bilingual learners, who interacted with a touchscreen-based DGE (dynamic geometry environment). The paper focuses on the word-use, gestures, and touchscreen dragging actions in student-pair communication. Findings suggest that the students relied on gestures and dragging as multimodal features of the mathematical discourse to communicate dynamic aspects of calculus. This paper raises questions about new forms of communication mobilized in dynamic, touchscreen environments, particularly for bilingual learners.

Keywords: Classroom Discourse; Equity and Diversity; Technology

Introduction

In British Columbia, Canada, "In 2011–12, one in four (23.8 %) of public school students spoke a primary language at home other than English. Almost double the number of [English language learners] (135,651) live in families where the primary language spoken at home is other than English […]" (BCTF, 2012, p.11-12). Speaking from my own experience teaching mathematics in Canada, the home languages spoken in a typical mathematics classroom are very diverse, ranging from five to ten in any given classroom. This context is one result of globalisation and rapidly changing student demographics not only locally but worldwide.

Currently, research focusing on bilingual learners' mathematical communication has provided tremendous insight into the *complexities* of teaching and learning mathematics in multilingual contexts: the language dilemmas of teaching mathematics (Adler, 1999), the role of code switching in learning mathematics (Clarkson, 2007) as well as associating mathematics learning with socio-economic and epistemological access (Setati, 2005). These studies, however, had not critically examined bilingual learners' communication patterns and, in particular, addressed their competence in mathematical communication. As argued by Moschkovich (2010), future studies on bilingual learners must consider broader linguistic frameworks for understanding bilingual learning.

Research on multimodality can shed light on bilingual learners' communication as a multimodal activity that includes the use of language, gestures and interactions with diagrams (Arzarello, 2006; de Freitas & Sinclair, 2012; Radford, 2009). Aligned with the idea of multimodality in mathematical thinking, a small number of research studies have drawn on bilingual learners' non-linguistic forms of communication such as gestures and diagrams (Moschkovich, 2009). Moreover, although numerous studies have discussed the effect of the DGE-mediated learning of calculus concepts (Yerushalmy & Swidan, 2012), research on the effects of touchscreen-based DGE is limited. It is hypothesized that a touchscreen-based DGE may offer additional affordances by providing tactile and kinesthetic modes of interaction—hence, further facilitate bilingual learners' communication in calculus.

In a previous study working with bilingual learners, I showed that certain dragging actions on a touchscreen-based DGE constitute a form of communication (Ng, 2014). Using a Sfard's (2008, 2009) communicational approach, my analysis showed that some dragging actions were not merely dragging, but also instances of gestural communication—to communicate *dynamic* features and properties in the sketch as obtained by dragging. The touchscreen-dragging modality allows the dragging with one finger on the touchscreen and the gesturing with the index finger to blend together as one action. The importance here is that the *dragging-gesturing* action subsumes both dragging and gesturing characteristics, in that it allows the point to be moved on the screen (dragging), and it fulfills a communicational function (Sfard's definition of gesturing).

Building on this work, the current study examines the communication patterns that arise as bilingual learners interact with a touchscreen-based DGE. In particular, I investigate bilingual learners' language, gestures, and dragging in DGE as they communicate a given calculus concept in their non-native language. My study concerns the non-linguistic resources utilized by bilingual learners in communication as they work with a DGE. Further, it is the goal of the study that this analysis will identify bilingual learners' competence in mathematical communications.

Theoretical Framework

Sfard's communicational framework (2008) is based upon the social dimensions of learning, which suggests that learning is located neither in the head nor outside of the individual, but in the relationship between a person and a social world. It provides a suitable theoretical lens for highlighting the communicative aspects of thinking and learning. For Sfard, *thinking* is part and parcel of the process of *communicating*. This non-dualistic approach, which disobjectifies thinking as a purely cognitive phenomenon, is helpful for examining the relationships between talking, gesturing and mathematical thinking. Sfard (2009) defines *language* in unrestrictive terms, as any symbolic system used in communications, and *gestures* as bodily movements fulfilling communicational function: "Language is a tool for communication, whereas gesture… is an actual communicational action" (p.194). In this sense, a gesture can be performed to communicate with others (interpersonal) or with oneself (intrapersonal). Sfard's approach highlights the way in which thinking and communicating (for Sfard, this includes talking and gesturing) stop being "expressions" of thinking and become the process of thinking in itself.

Sfard (2008) proposes four features of the mathematical discourse, *word use, visual mediators, routines, and narratives*, which could be used to analyze mathematical thinking and changes in thinking. For the purpose of this paper, the first three features will be used for analyzing the use of language, gestures, and dragging in one's mathematical discourse. *Word use* is a main feature in mathematical discourse; it is "an-all important matter because […] it is what the user is able to say about (and thus to see in) the world" (p. 133). However, as a student engages in a mathematical problem, her mathematical discourse is not limited to the vocabulary she uses. For example, her hand-drawn diagrams and gestures can be taken as a form of *visual mediator* to complement word use. According to Sfard (2009), *utterances* and *gestures* inhabit different modalities that serve different functions in communication. Gestural communication ensures all interlocutors "speak about the same mathematical object" (p.197). Gestures are essential for effective mathematical communication: "Using gestures to make interlocutors' realizing procedures public is an effective way to help all the participants to interpret mathematical signifiers in the same way and thus to play with the same objects" (p.198). Gestures can be realized *actually* when the signifier is present, or *virtually* when the signifier is imagined. Sfard (2009) illustrates how a student uses "cutting", "splitting", and "slicing" gestures to realize the signifier "fraction". Since these gestures were performed in the air, where the signifier "fraction" is imagined, they provide an instance of virtual realization. Therefore, the same signifier "fraction" may be realized differently with different kinds of gesture or word use.

Routines are meta-rules defining a discursive pattern that repeats itself in certain types of situations. In learning situations, learners may use certain words or gestures repeatedly to model a discursive pattern, such as looking for patterns and what it means to be "the same". Drawing on Ng (2014), dragging is taken as a significant form of communication in this study; it is taken as both a routine for defining a discursive pattern that repeats itself in activities with touchscreen-based DGE, and a visual mediator as a multimodal feature of the students' discourse. A student may use dragging to explore (routine) and signify (visual mediator) the variation of the tangent slope. Using this notion, it is possible for students to incorporate *dragging-gesturing* to respond to each other in communications. Indeed, it was found that as one student suggested that the secant line will get "closer" to the tangent line, another student seemed to have responded by her *dragging-gesturing* to bring the lines "together". These gesture-utterance correspondences were also noted in the analysis of other pairs of bilingual learners' routine involving dynamic sketches (Ng, 2014).

Methodology

The participants of the study were three pairs of 12th grade students (aged 17 to 18) enrolled in a calculus class in a culturally diverse high school in Western Canada. All participants were bilingual learners and self-volunteered to participate from a class of 25, in which roughly half of the class were also bilingual learners. They were regular partners during assigned pair-work activities and were described by their teacher-researcher (also the author) as motivated and comfortable working with each other. The study took place at the end of the first trimester of the school year in the participants' regular calculus classroom, outside of school hours. At the time, the participants have just finished learning key concepts in differential calculus where the iPad-based DGE, *Sketchpad Explorer* (Jackiw, 2011) was consistently incorporated into the lessons. During these lessons, students were invited to explore dynamic sketches in pairs for roughly ten minutes followed by teacher-led classroom discussions about the activities. Therefore, the participants were experienced with exploring and discussing, in pairs, concepts in differential calculus with dynamic sketches.

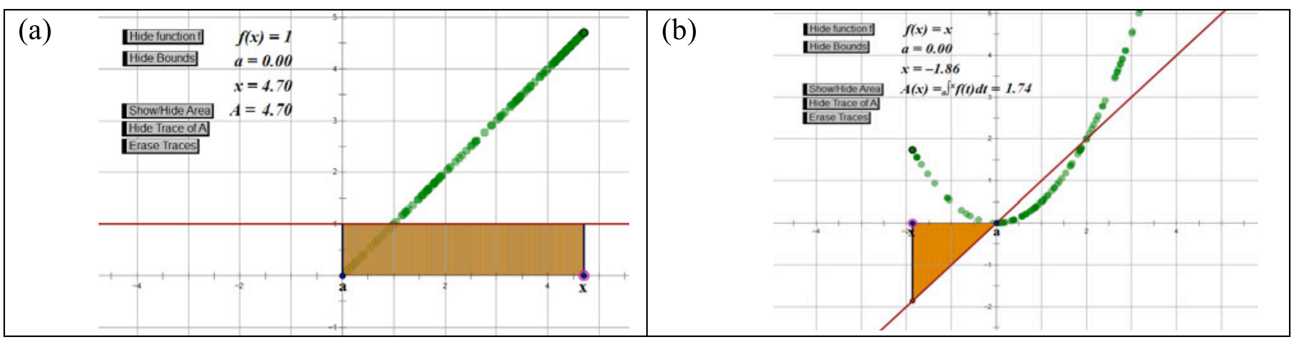

Figure 1(a-b): Screenshots of the DGE used in the study (with all buttons, "*Show function*", "*Show bounds*", "*Show Area under f*", and "*Show Trace of A*" activated). The bounds "a" and "x" are draggable; the green traces represent $A(x) = \int_a^x f(t)dt$.

The task used in this study invited the students to explore and discuss a sketch in *Sketchpad Explorer* that they had not previously seen. The sketch contains five pages all related to the concept of area-accumulating functions (Figure 1a, b). The participants were not told what concept the sketch was related to, but they were told that this concept was new to them (at the time of study, they had just spent one lesson related to integral calculus, that of indefinite integrals in their regular classroom). The participants were asked to "explore the pages, talk about what you see, what concepts may be involved" on all pages of the sketch before reporting back to the teacher as a pair. Before they began, they were ensured that their teacher would check in with them from time to time in order to make sure that they understood what they were expected to do and could ask questions that were related to the sketch. In total, 70 minutes of video data were collected in the study.

Analysis of Data

In this section, I provide detailed analyses of one participant pair, Sam and Mario's communications over the aforementioned task. Sam and Mario, whose home languages were Mandarin and Cantonese respectively, do not share a common home language. A 10-minute episode is chosen from the 30 minute discussion and analyzed in detail. The episode was chosen to highlight the different resources: language, dragging, and gesturing used by the student pair within the 10-minute discussion.

At the start, the students seemed unsure about what to do with the points *"a"*, *"x"*, and the green point in the sketch. They questioned the functions of the DGE with question markers "what" (eight times) and "how" (once) in the first two minutes of the episode. Most of these questions were formulated as Sam used the dragging modality to investigate the behavior of different points. For example, Sam asked "what" repeatedly as he tried to drag the green point which was not draggable. Although he had acknowledged that he had previously pressed a button which showed "an area", he had not realized that the green point had plotted the area in terms of *"x"*, evident in his questions "what's trace of A" and "how do we drag this trace". Then, upon dragging "*x*" around, he finally concluded "oh, oh, it's this one. Ok, make sense." His confusion seemed to have resolved perhaps because his dragging of *"x"* made the green point move; hence he realized the green point was a dependent and non-draggable object. However, it appeared that he remained unsure about what the green point meant, stating that he did not yet "understand this".

At 00:53, Sam and Mario took turns *dragging-gesturing* in a conversation-like manner, beginning with Sam's *dragging-gesturing*, which spanned 30 seconds (Figure 2a). During this occurrence, Sam dragged *"x"*, then *"a"*, and finally *"x"* again. Observing the students' word use and dragging actions, it seemed that both students made some progress in their learning of area-accumulating functions during this span. For example, as Sam was dragging *"x"*, he uttered, "*as* we drag this, the area *becomes*…" This utterance-dragging combination suggests that Sam was thinking about area as having dynamic qualities. It shows how dragging mediated the way Sam thought of the area as a becoming. The use of "become" implies something is happening, in particular, the area was changing *as "x"* was dragged. Furthermore, Sam's statement structure resembled an "if… then…" statement structure which calls upon a causal or functional relationship between *"x"* and the area. It was interesting to note that Sam never finished his sentence after uttering "become", perhaps because he had yet to *realize*, in a Sfardian sense, the simultaneous change in the variables despite noticing the area is changing. Similarly, Mario used a hedge word in his utterance, "it's *like* the area," suggesting a degree of uncertainty about whether or not the green traces meant the area.

Following Sam's prolonged dragging, different draggers and speakers were observed in the episode. For example, as Mario dragged *"x"* back and forth, Sam was responding verbally and simultaneously, "You see how this one moves? So it's like the area." A similar exchange was also noted earlier, where Sam was the dragger, as Mario spoke, "is that the area?" These two instances where the dragger and speaker were different people seemed effective for having the students communicate mutually and simultaneously. Although it may seem impolite and unconventional for one student to "talk over" another student, the presence of "talking over someone else's dragging" was not an issue here. Indeed, Sam's utterance did not interfere with Mario's dragging and vice versa; rather, from the way one talked about area while the other was dragging, they seemed to have made significant progress as a result of this concurrent communications.

Also observed in the first two minutes was the consistent use of gestures by the students in mathematical communications. Namely, Sam used three types of gestures, which in Sfard's terms, functioned quite differently in each usage. In the beginning, Sam used a pointing gesture as he talked about the bounds to make sure both interlocutors *spoke about the same mathematical object* (Figure 2b). Later, he used his hand to signify the linear pattern of the green traces, an instance of *actual* *realization* (Figure 2c). Finally, he flipped his right index finger left and right while uttering, "No you can't. You can only go like", which was another actual realization of the possible movement of the green point (Figure 2d). Moreover, this gesture was not accompanied by any speech, which suggests that Sam relied on gestures as a visual mediator, or a multimodal feature of his mathematical discourse, to communicate in the absence of word use.

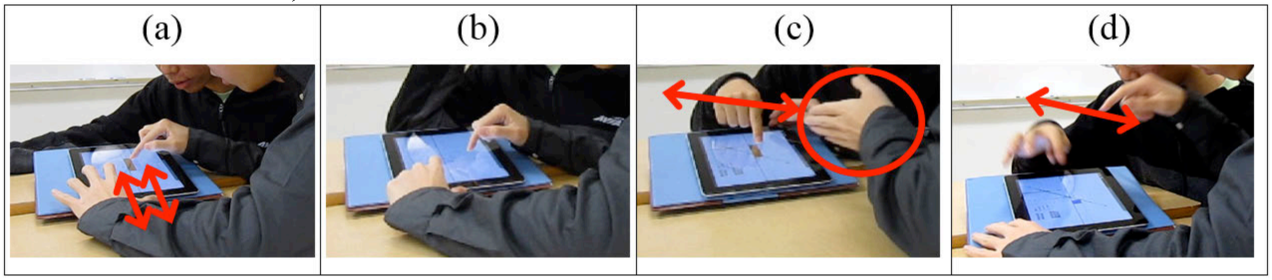

Figure 2: Screenshots of Sam's (a) dragging actions and (b-d) gesturing in the excerpt.

From 02:00 to 05:00, Sam and Mario consistently utilized dragging and gesturing to communicate mathematically. For example, as Sam took on the role of dragging and asked the question, "is that how the area is changing?" Unlike earlier, Sam was able to describe exactly that *the area is changing* with no hedge words at the 02:02 mark in the episode. He continued to drag for a span of 9 seconds without speech before letting Mario also tried dragging for another 6 seconds without speech. The switching of draggers suggest that both students were communicating mathematically while dragging. If speech was analyzed alone, some important analyses about the students' thinking in between speech would have been missed.

At 03:02, Sam and Mario performed a series of hand gestures. Initiated by his own dragging of *"x"*, Sam suggested that "oh, wait a sec. This is actually, the derivative of the graph, function," while he used a hand gesture to signify the shape of a linear function. To restate what he had said, he then used his index finger and traced a "U" shape in the air as he continued to conjecture that the line was "probably the derivative of x, x-squared". Mario responded with a similar "U" shape gesture as he asked "is this x-squared", suggesting that they verified Sam's conjecture. These gestures and word use pairings, which provide strong evidence that the students were engaging in *conjecturing* about the shape of the green traces, help identify Sam and Mario's competence in the mathematical activity.

It was noted that the deictic pointing word "this" was used extensively, appearing five times in this part of the episode. Using deictic words, the speakers no longer need to refer to the mathematical objects by describing them verbally, but they can use deictic words along with different gestures to replace the descriptions completely. This was found in Sam's "*this* is actually, the derivative", "no matter how you move, *this* one always", and "*this* is probably x, x-squared". As Sfard explains, gestures help ensure that the interlocutors speak about the same mathematical objects. Significantly for Sam and Mario, gestures served a complementary function to language in communication. The two students were able to use a combination of utterances and gestures to communicate about the mathematical objects effectively.

The students' realizations of the area-accumulating function could be observed in their discourse after the 05:00 mark of the episode. First, the questions posed hereafter were markedly different from before 05:00. Recall that previously, Sam had asked repeatedly, "what", at times without finishing his questions. It is possible that Sam's "what" questions reflected his uncertainty of what each point or button meant in the sketch. In contrast, having explored the sketch for some time, Sam asked three questions that began with "why". He asked, "why is there something to do with area" twice, and "why is it". By asking these "why" questions, it seemed that Sam was looking for the reason as to why the relationship of the two graphs were related to the area under a function. Considering Sam has only learned the topic of indefinite integral at the time of study, this was a valid question because Sam had yet to learn the idea of "definite integral as area" in his class. Regardless, asking "why" implies investigating the reasons of something that is clearly existential. In this case, Sam seemed to be investigating the reason why the *area* under a function had to do with its antiderivative.

At 05:17, a prolonged dragging action was performed by Sam, while the two students exchanged comments verbally back and forth. In particular, by far the longest spoken sentence was said by Sam within his own dragging action: "Ya. So the graph we have *here* is *specifically* the derivative of the… what we just graphed *here*, like the function *here* is *basically* the derivative of what we just graphed *here*." The sentence was very rich in a multimodal sense because it was spoken while the speaker was dragging, and gestures were used simultaneously as the speaker uttered "the function here". Some interesting word use was also observed. For instance, the word "here" was used four times, and the words "specifically" and "basically" each once. In line with a previous analysis of the use of deictic words, the use of locative noun "here" accompanied by gestures allowed the speakers to talk about the same mathematical object. Although Sam used the same word "here" four times, he actually meant to refer to two different mathematical objects, the function and its derivative. This could be why Sam used different gestures to specify which object he was talking about as he said "the function here". Secondly, the contrasting use between "specifically" and "basically" by Sam was also fascinating. Since Sam used the word "basically" quite frequently throughout the task, his word use "specifically" as opposed to "basically" in this sentence drew attention to the analysis. Consistent with his usage of "basically" in other parts of the transcript, it seemed that Sam used the word to suggest a generality or invariance that exists outside of the sketch. In contrast, it is speculated that he used "specifically" in the context of the specific page of the sketch to refer to the particular "graph" that was the derivative of another. According to this speculation, Sam was able to talk about area-accumulating functions both in its generality and particularity, which is a highly valued practice in the mathematics community.

Discussion

The analysis provides strong evidence that Sam and Mario, both bilingual learners, utilized a variety of resources in communication, with visual mediators in the form of gestures and dragging taking on a prevalent role. These included gestures accompanying deictic words and gestures for communicating geometrical notions of calculus. Moreover, the *dragging-gesturing* action emerged in the touchscreen dragging action and fulfilled the dual function of dragging and gesturing. These actions were repeatedly demonstrated by both students for communicating temporal relationships in calculus as well as in their routine of developing the mathematical discourse. In the presence of a dynamic visual mediator, the students' routine evolved from typical utterance-utterance sequences. Gestures-gestures and gestures-utterances sequences were observed in the conversation. Related to this, I observed one student *dragging-gesturing* simultaneously as the other spoke; this allowed two students to communicate simultaneously without interfering with each other. These observations support the claim that bilingual learners make use of gestures and dragging as important forms of communication. Using Sfard's communicational framework to define gestures as communicational acts is especially useful for understanding the mutual communications involved in these new communication routines.

The analysis shows that dragging and gestures transformed the students' word use. Initially, the students seemed unsure of what to make of the sketch; they used dragging to formulate their questions about the behavior of the sketch. Then, they began to explore and conjecture the relationship of the two functions in both geometrical and algebraic terms through dragging and gesturing. Sam and Mario made extensive use of verbs such as "become", "move" and "go," which imply change or motion while they used the dragging modality to change the area under a function. Moreover, gestures in the form of actual realizations were accompanied by the use of locative nouns "here" and deictic word "this". These gestures and word use pairings could potentially reduce the number of words to be spoken in a sentence.

The results of the study were encouraging not only in that the pair of bilingual learners was able to grasp quickly the functions offered by the touchscreen and DGE, but also in the way they communicated significant calculus ideas effectively incorporating linguistic and non-linguistic features in communications. These results have important implications towards the mathematics teaching and learning for all learners at large and bilingual learners in particular. For example, the study points to the use of DGE in pair-work activities for facilitating students' communications. At the beginning of their explorations, Sam and Mario did not use the functions of the DGE purposefully. As they began to learn to use the functions of the DGE, they began to engage in calculus ideas, and the DGE began to take on an important role in the communications. This implies that the role of the DGE is not a static one, but rather *dynamic* that is constantly evolving during the activity.

Also, it could be said that the design of the dynamic sketches played a significant role in facilitating the students' mathematical communications. The *Hide/Show* buttons allowed the students to talk about their ideas gradually, one button at a time, while the *dragging* affordance enabled them to attend to dynamic relationships and connect algebraic with geometric representations of calculus. In tune with previous studies on DGE-mediated student thinking (Falcade, Laborde & Mariotti, 2007), the students may have exploited these functionalities offered by the sketch and hence communicated about area and derivatives geometrically and dynamically as a result. Furthermore, the touchscreen-based DGE seemed to offer a haptic environment for learners to interact with dynamic relationships, where the nature of gestures and dragging is re-conceptualized (see Sinclair & de Freitas, to appear).

This study argues for an expanded view of bilingual learners' communication that includes utterances, gestures, dragging and diagrams. Due to their complementary functions, these elements must not be accounted for in isolation but as a full set of resources in mathematical communication. Although Sfard has not specifically addressed the distinction between dynamic and static visual mediators, the distinction is important for this study because of the potential for the dynamic visual mediators such as gestures and DGEs to evoke temporal and mathematical relations (Ng and Sinclair, 2013), particular for the study of calculus (Núñez, 2006). As shown in my analysis, *dragging-gesturing* emerged as a significant form of communication, and this was facilitated by the dynamic visual mediator presented on the touchscreen-based DGE. Future studies should consider extending the notion of visual mediators and routines to include gestures and dragging on touchscreen-based DGE. In particular, this paper calls for more studies in the area of DGE-mediated learning to investigate the role of *dragging-gesturing* in other types of mathematical activities and within other branches of mathematics.

This paper focuses on student learning in the context of a curricular module on pawnshops piloted with 15 students in an urban high school. The paper describes pedagogical frameworks guiding the development of the module and summarizes key features of its curriculum. Analysis focuses on student growth with respect to mathematical understanding of percent and opinions about pawnshops. Findings include student adoption of ratio strategies indicative of conceptual understanding of percent, and development of critical opinions about pawnshops as a lending system.

Keywords: Equity and Diversity

Introduction

Percent is a concept fundamental to the middle school mathematics curriculum. The Common Core State Standards indicate that by 8th grade, students should be able to solve multistep percent problems and apply proficiency with percents to any array of marketplace applications. In addition to being a focal point of middle grades mathematics, the concept of percent undergirds a variety of topics in secondary school mathematics, like scaling, probability, statistics, and modeling.

High school students are known to have difficulties with problem-solving related to percent (Lembke & Reys, 1994; Moss & Case, 1999; Parker & Leinhardt, 1995). Common errors include ignoring the percent sign; difficulties translating between decimals, fractions and percents; and confusion about multiplicative and additive relationships (e.g., Moss & Case, 1999; Parker & Leinhardt, 1995). Finding a given percent of a specific amount is considered the most straightforward for students; however, even at age 17, most students have difficulty with, for instance, finding 4% of 75 (Parker & Leinhardt, 1995).

Percent is prominent across an array of common marketplace transactions (Parker & Leinhardt, 1995). Banking transactions routinely communicate percents, which is essential for any consumer. Beyond its importance in terms of functional literacy for borrowers, percent is necessary for critical literacy (Apple, 1992), enabling citizens to evaluate quantitative information or analyze quantitative relationships. For example, percent figures prominently and broadly as a mathematical tool in teaching mathematics for social justice (e.g., Gutstein, 2005).

Despite its ubiquity in the marketplace, adults are known to have difficulty with percents. In an investigation of adult learners, while most knew that 100% represents the whole and 50% means half, their understanding of 25% was limited; fewer than a third of the adults could find the sale price of an $80 coat on a 25% off sale (Ginsburg, Gal, & Schuh, 1995). Pre-service teachers were successful at answering a multi-step word problem involving percents but had difficulty explaining why particular operations made sense in the task's solution (Lo & Ko, 2013).

An explanation for difficulty with percent tasks is that it has traditionally been taught strictly using procedural methods. Even though students with pictorial representations of percent are known to be more successful at problem-solving on percent tasks (Lembke & Reys, 1994), classroom instruction is traditionally unaccompanied by mathematical representations that can support conceptual understanding. Representations that can link procedures for solving percent problems to conceptual understanding of percent are area models (e.g., Haubner, 1992), halving or doubling models (e.g., Moss & Case, 1999), 100-board models (e.g., Wiebe, 1986) dual-scale number lines (e.g., Dole, 2000), or ratio tables (e.g., Middleton & Van den Heuvel-Panhuizen, 1995).

This paper explores the teaching and learning of percent within the context of a larger project. The larger project adopts perspectives that integrate culturally relevant pedagogy (Ladson-Billings, 1994) and place-based education (Gruenewald, 2003). The next section briefly describes these frameworks and their correspondence with the project's curriculum.

Guiding Frameworks

Culturally relevant mathematics pedagogy (CureMap, Rubel & Chu, 2012) is based on Ladson-Billings' (1994) theory of culturally relevant pedagogy and Gutstein, Lipman, Hernandez, & de los Reyes' (1997) application of culturally relevant pedagogy to mathematics. CureMap is comprised of teaching mathematics for understanding, centering instruction on students, and providing students with opportunities to think critically about and with mathematics. The three dimensions are interrelated and guide this project's curriculum design. The larger project, of which this study is a part, takes pawnshops as a familiar phenomenon from the city streetscape and uses it as a guiding theme for the investigation. Mathematics helps students to understand how pawnshops, as local and visible features of a spatial landscape, work.

Teaching for understanding denotes an emphasis on connections between mathematical concepts, procedures, and facts. Classroom instruction that supports teaching for understanding includes rigorous tasks, representational tools, and norms for participation (Carpenter & Lehrer, 1999). Understanding the concept of percent is fundamental to interest and to being able to model a pawnshop loan. To build this understanding, 4% simple interest was organized as a \$4 amount for every \$100 dollars borrowed in a ratio table (e.g., Middleton & Van den Heuvel-Panhuizen, 1995). Figure 1 shows an example of tables used by the teacher in our project. The table sets up students to conceptualize percent as a ratio and use a ratio table to calculate 4% of various amounts. The table has multiplicative properties (i.e., 4% of 700 is 7 times 4) and additive properties (i.e., 4% of 150 is 4+2). A ratio table can be used to calculate any percent of any quantity but is especially efficient for benchmark values.

Organizing lessons for students to be central participants is an essential component of culturally relevant pedagogy. This module emphasized student participation, particularly emphasizing whole-class discussions to build shared understanding. For example, in one of the beginning lessons, the teacher performed a skit to clarify with students the vocabulary and elements of a pawnshop transaction, and collectively defined the transaction as a collateral loan with a monthly, simple interest rate.

Centering instruction on students can be accomplished in terms of content that connects to students' lives (e.g., Moll, Amanti, Neff, & Gonzalez, 1992). There is an additional, place-based interpretation of centering: taking a spatially local phenomenon and studying it, at various levels of scale, in students' local places. Focusing on a specific context, in place, and using mathematics to make sense of that context is an explicit stance that differs from focusing on percent as a theme with applications across multiple contexts.

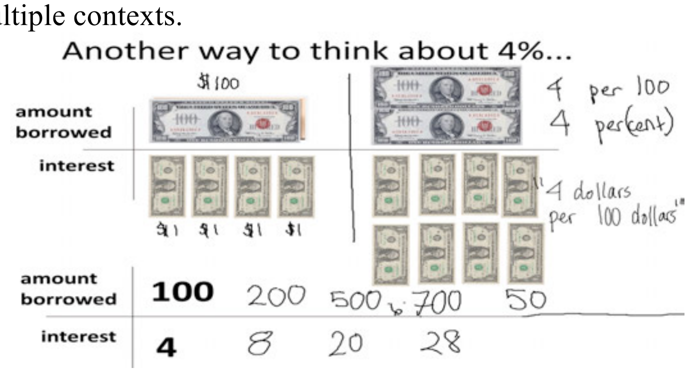

Figure 1: Ratio table used in classroom (11/6/2014)

Real-world contexts with social justice ramifications can motivate mathematics and mathematics enables better understanding of the real-world context (e.g., Gutstein, 2005). In this case, percent is a tool with which to model and compare loans toward exploring critical notions of pawnshop loans as a form of predatory lending or dominant notions of alternative financial institutions (AFIs) as important financial resources for low-income people. Drawing again on notions of local space and place, to investigate spatial patterns in the distribution of financial institutions in the local city, one lesson invited students to consider how to normalize the distribution to analyze which neighborhoods have more AFIs, since numbers of AFIs could be compared to households, land area, or to numbers of banks. Students explored data-rich spatial distributions on interactive, digital maps in the context of understanding the relative cost of different types of loans, set in terms of spatial representations of demographic statistics. Students conducted field research in the school neighborhood to explore the distribution of financial institutions and to interview pedestrians about their experiences as customers of these businesses.

An assumption is that students will develop critical opinions about pawnshops and their role in students' lives, the local community, and the broader city, and that this development is predicated on an understanding of the concept of percent. This paper explores that assumption by asking two research questions:

- Did students develop conceptual understanding of percent through their participation in this project?
- Did students develop critical thinking about pawnshops through their participation in this project?

Research Context

This module was piloted in a high school in a large Northeastern city in the United States. The school is located in one of the city's lowest income neighborhoods and provides free lunch to 100% of its students. Students identify as "Hispanic" (75%) and "Black or African American" (25%). Despite an appearance of uniformity across just two broad categories, the student body includes recent immigrants from the Dominican Republic, second or third generation of immigrants from Puerto Rico or the West Indies, and African Americans. About 20% of the students are classified by the school district as English language learners, and about 20% as needing special education (data was obtained from the school district about the previous school year).

Students are required to pass through metal detectors staffed by police personnel to enter school because of its district classification as "persistently dangerous." Incoming students test scores, on average, are "below proficient" and below city average, and the school has a six-year graduation rate just below the city average. The school suffers from low attendance; about half of its students are categorized as "chronically absent." Despite the statistics that portray the students and school as struggling, the school consistently receives high marks on its district progress report that factors parent and student surveys heavily in its metrics because parents and students express enthusiasm and positivity about the school and its teachers.

The classroom teacher in this study was in her 8th year of teaching, all at this school, and identifies as a white woman. She collaborated on classroom implementation of another curricular module as part of the larger project and had been previously involved in two cohorts of professional learning communities around culturally relevant mathematics teaching. The teacher participated in a 4-day summer training institute and collaborated with the design team to pilot the curricular module in the fall of 2014 in her advisory class, comprised of 16 tenth-grade students (who are in her geometry class). Fifteen of these students participated in the research; one was present in the sessions but could not consent to participate in the research because of disability status. Seven of 11 students took and passed the state's entry-level algebra test the previous year, but only three students' scores exceeded the "college-ready" threshold.

Data Sources and Methods

All 10 class sessions of the module were observed and audiotaped by three researchers, and student written work was collected. Fieldnotes were taken during the observations and were coordinated with corresponding audio to enable detailed memos about each session. Engagement was rated independently by three researchers using a 5-point rubric from Kitchen, Depree, Celedon-Pattichis, & Brinkerhoff (2006) and averaged. A post-focus group session was conducted with five student volunteers from the class and audiotaped.

Analytical memos were produced for every class session and the focus group session. To answer the first research question, students' written responses on assessment items were categorized in terms of correctness and strategy type. Three lessons that focused on percent as function to determine monthly interest and a 15-minute section of the post-focus group that focused on students' self-reflections about the mathematics they learned in this project were included in this analysis.

To answer the second research question, fieldnotes and written work from an introductory class session and audio of whole-class discussion portions from six lessons, totaling 132 minutes, was used to create transcripts. A coding tree was created and used to code transcripts line by line in terms of speaker and reference to pawnshops. Dedoose, a software for coding qualitative data, was used to aggregate students' ideas about pawnshops by speaker, date and in terms of whether the perspective expressed critical or dominant perspectives about pawn shops.

Results

Development of Conceptual Understanding of Percent

On the written pre-assessment, nine of 14 students computed 4% of 150 correctly, but they were limited to decimal-based strategies, mostly with a calculator. During the class sessions, students who had computed 4% of 150 correctly using a decimal strategy demonstrated difficulty articulating a conceptual understanding of 4%. For example, several students who had used a decimal strategy and arrived at a correct answer on the pre-assessment conjectured in class that 4% might mean one-fourth, or a quarter.

Students readily took up the ratio-based strategy initiated by the teacher in the class session that introduced the ratio table. In written work during the lesson in which the table was introduced, eight of 12 students present showed that they could use ratio tables to compute given percents of multiples of 100. Some students could use ratio tables using doubling and halving to compute 8% of multiples of 50 (i.e., 8% of 50, 8% of 150), and few students computed 8% of 75, a slightly more challenging example.

The next day, empowered with a conceptual understanding of percent, students were tasked with using mathematics to model a pawnshop loan in a story problem that required them to extend the monthly interest over 4 months and to factor in the one-time fees. This lesson's engagement was rated at 4.33 (serious/widespread), one of only two lessons with highest student engagement. Our interpretation of this engagement is that students had been carefully introduced to the elements defining the transaction, possessed conceptual tools with which to approach the problem-solving task, and were interested in being able to interpret the mathematics of this pawnshop scenario.

On the post-assessment with 11 students present, six correctly computed 6% of 800 and four demonstrated a ratio approach. Nine students attempted to answer a second question, which asked them to model a pawnshop loan, and five had the correct answer. On this problem, five students used a ratio strategy toward computing 4% of 250. These results on the written assessments might seem underwhelming to readers, but should be considered in light of the context of struggling students. One student in the focus group described how her participation impacted her mental mathematics strategies and her confidence about those strategies. In response to the question, “Did you learn any math?”, Tacee declared:

> I learned a lot. Because, like, before, when I was finding percent, I would only know how to find 50% like, oh -I’d be like- oh it’s half. But then like, now, I know how to find, like for any number (11/25/14).

Use of ratio-table strategies became more efficient and sophisticated for some students by the end of the project. When asked to demonstrate how to compute 6% of 250, four of the five students in the focus group quickly arrived at a correct answer, in some cases without writing anything down. When asked how to accommodate this strategy to a problem like 6% of 280, two of the students in the focus group (the two students with the highest scores on the previous year’s state algebra test), demonstrated strategies that extended beyond the halving, doubling, and combining that had been worked on in class with the teacher. One student scaled 100 to 280 by a factor of 2.8, and correspondingly scaled 6 by a factor of 2.8. A second student first found 6% of 250 using doubling and halving, and then used the entry for 50 to scale to 5 by dividing by 10 and reasoned that “as the money increases by five dollars, the interest also increases by 0.3.” He then used this rate to scale up to 30 dollars toward finding the correct answer (see Figure 2).

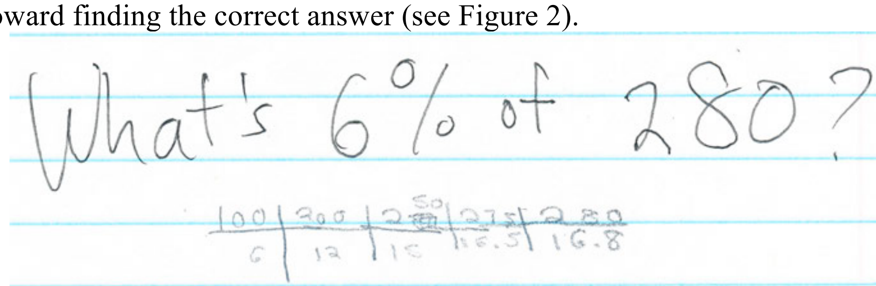

Figure 2: Sample ratio used by student to compute 6% of 280

These examples demonstrate how the ratio table approach was effective as a remedial tool and functioned as a springboard for students with stronger mathematics backgrounds toward more sophisticated strategies.

Development of Critical Thinking About Pawnshops

Critical thinking with mathematics about pawnshops can refer to the phenomenon at increasing levels of complexity (see Figure 3). At the scale of individual transactions, it is possible to use mathematics to analyze a transaction in terms of its high interest rates compared to other loans, or the way that its appraisal system might undervalue items from the perspective of the borrower. Dominant perspectives might dictate that pawnshops are legal enterprises, with published interest rates and, like any business, need to make sufficient profit.

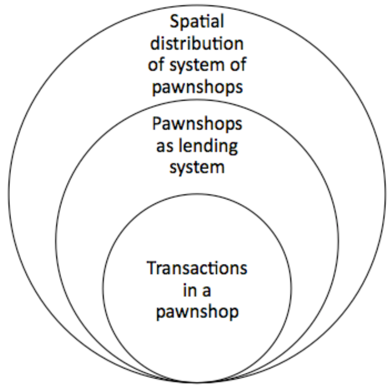

Figure 3: Levels of complexity for thinking about pawnshops

Beyond individual transactions, pawnshops can be considered as a system within the financial landscape. A critical perspective might examine that system as one that, by virtue of its extremely high rates relative to other options and the quick access it provides to small loans, is a system that preys on low-income people. A dominant perspective is that pawnshops form one choice among many options and are a financial resource for those who have poor credit or need small sums quickly.

A spatial perspective on pawnshops considers distribution across places. Patterns in that spatial distribution of mainstream and alternative financial institutions might provide evidence to suggest that the AFIs target geographical neighborhoods that have more unemployed people, immigrants, or low-income families. A dominant perspective about the spatial distribution is that pawnshops, with banks, are located in heavy shopping areas.

On the first day with the module, students were asked to name associations with pawnshops, and the teacher penned contributions on a word wall. Forty-nine words or phrases were named; 34 were related to the pawnshop transaction, with most referring to the appraisal process (25). Students less frequently (12) offered associations that might be indicative of critical perspectives about pawnshops as a lending system, with statements like "advantage," "power," and "they get over on you." One comment hinted at a spatial, critical perspective: "the 'hood."

At the end of the module, in a whole-class discussion organized to elicit student opinions, students made 30 references to pawnshops. These 31 references (made by 8 students) mostly (20) were oriented toward pawnshops as a lending system, though some (8) referred to aspects of individual transactions, and few (3) referred to the spatial distribution. This demonstrates greater sophistication in the students' thinking about pawnshops; prior to the module, their references were concentrated tightly around aspects of the transaction, and by the end of the module, their references had shifted largely to focus on pawnshops as a lending system.

For example, when the class was asked to agree or disagree with the statement, "Pawnshops prey on our community by charging much higher annual interest rates than banks," one student, Lina, disagreed, providing a dominant perspective about pawnshops as a system, explaining, "*I don't think they [pawnshops] do it intentionally, I think they just do it as a choice. Like, if you don't have the credit then you, like, it's their, like it's someone's fault if they have bad credit 'cause it's you're fault if you didn't pay all your debts or whatever… they're helping you out by at least letting you borrow money…*" Another student, Bo, disagreed, offering a critical perspective: "*I only see pawnshops inside, like, poor neighborhoods. So I feel like they, like, preyin' on the poor neighborhoods, because, like, they don't have nothin' so if they come, then they gonna take they money*." Bo continued, recalling examining the posted interest rates and fees inside a check-cashing store during the field research session, "*since it's so expensive, right, then like the people who can't afford it have* *to, like, do that because if they really need the money then they gonna have to raise all they money and then, to get that, then they gonna be broke"* (11/20/14). In that summative whole-class discussion in general, more statements had critical orientations (18) than dominant (13).

Discussions and Further Questions

Findings include student interest in and adoption of ratio models for percent calculations. For struggling students, with weak scores on standardized tests, this topic remediated a central focus of middle school mathematics. At many points in the module, students pointed out that it is important for a consumer to be savvy in terms of the individual transaction, because "pawnshops get over on you." Students felt that understanding mathematics would help them to better navigate an appraisal or loan process. One student, Sheeda, shared in the focus group that she found learning about the mathematics to be more useful to her than she had at first expected:

> But then when we started like, going more in deep into the project we was like oh that's what they really be doing, so like we really have to have that skill of math to, you know, to, pursue… like, that. Like, if we ever went to a pawnshop. (11/25/14)

In other words, mathematics would enable a position of strength instead of weakness for students as consumers. In response to a follow-up question as to whether the mathematics they learned was new, she elaborated:

> *Sheeda*: cuz basically we learned it, but basically we, didn't, like pursue more into it. Like, we just like, oh that's something that we learned in school, like, we-we like…
> *Lina:* to learn it, just to learn it…
> *Sheeda*: Yeah, it felt like, we felt like…
> *Lina:* ...we did, applied learning.
> *Sheeda:* yeah, it felt like — exactly, that's like what I was saying — like, it felt like we really needed to, like, pursue it*."*

These two students made the point here that the context was not only motivating for them, but that learning this mathematics felt necessary.

By the end of the module, students expressed points of view that demonstrated that the module had opened up space for thinking more broadly than about individual transactions in pawnshops. Those points of view became more critical in orientation, and it is our interpretation that that students' learning how pawnshops work, an element of which is how to use percents to calculate interest, was a key factor in this growth. Although the module included a focus on using maps and data to make spatial arguments, such arguments were rarely assimilated into students' opinions. An interpretation of this finding is that the students' map and data analysis was done individually or in pairs at laptops computers, without time for interpreting or layering those observations in whole-class discussions. Collectively building understanding in whole-class discussion competed for time with individual investigations that focus on single-user technologies.

This investigation of pawnshops used mathematics of percent in different ways. This paper has a central focus of understanding how to use percent as a function and as a proportion to model a pawnshop loan and to compare loans. Yet percent was used in other parts of the module to represent demographic data as a statistic. Using percent as a function to model loan interest typically scales *up* from $100, while using percent as a statistic typically scales *down* to 100 people. Future research could focus on relationships between conceptual understanding of percent as a function, proportion, and statistic, in mathematical investigations that draw on data that pertain to demographics and place.

STUDENTING IN THE SECONDARY MATHEMATICS CLASSROOM: MARIA

Darien Allan
Simon Fraser University
dariens@sfu.ca

Studenting is comprised of the behaviors that students perform or exhibit in a learning situation, such as the mathematics classroom. These may or may not be intended to help themselves learn, and may or may not conform to the teacher's goals and expected actions. In this paper I report on the case of a particular student, Maria. Observations, together with excerpts of informal interviews, are used to provide a preliminary analysis using activity theory as a theoretical lens. Initial results reveal that 'good' studenting behaviors do not necessarily result in mathematics learning, nor indicate a primary motive of learning. Analysis indicates Maria's primary motive was to get a good grade and be seen as a good student.

Keywords: Teacher Beliefs; High School Education; Affect and Beliefs

Studenting

The term 'studenting' was coined by Gary Fenstermacher in 1986. Initially, he describes this concept in terms of a cohort of student behaviors including "*getting along with one's teachers, coping with one's peers, dealing with one's parents about begin a student, and handling the non-academic aspects of school life*" (p. 39). In essence, Fenstermacher describes studenting as what students do to help themselves learn. A later definition encompasses other behaviors such as "*'psyching out' teachers, figuring out how to get certain grades, 'beating the system', dealing with boredom so that it is not obvious to teachers, negotiating the best deals on reading and writing assignments*" (Fenstermacher, 1994, p. 1) and other similar practices.

Analyses have shown that the process of schooling produces a number of unintended consequences, some desirable, but also many that are patently objectionable (Engeström, 1991) and counterproductive to the goal of student learning. Preliminary studies have shown that across the board students are finding ways to subvert the expectations of the teacher in ways that the teacher is not aware of (Liljedahl & Allan, 2013a; 2013b).

Theoretical Framework – Activity Theory

Considerable research can be found looking at students' motives and behaviors, but what is lacking is a catalogue of student behavior across activity settings in the mathematics classroom. This finding drives the first research question.

Activity Theory was chosen as a framework for analysis for its ability to describe what *is* rather than what *is ideal*. Rather than categorizing students by their behaviors (e.g., on-task or off-task), presuming students behave rationally or ideally (e.g., game theory), or assuming the students' primary goal is learning (e.g., didactic contract (Brousseau, 1997)), activity theory allows for a description of what is observed and said without overlaying preexisting assumptions or judgments. These observations, taken together, can then be used to develop a hypothesis for what is driving student action: their motive, which may be something other than a desire to learn. Individual behavior and motive within the classroom collective is best viewed through a theoretical lens primarily comprised of Leontiev's Activity Theory (1978).

For Leontiev, "*[a]ctivity does not exist without a motive; 'non-motivated' activity is not activity without a motive but activity with a subjectively and objectively hidden motive*" (1978, p. 99). The object of an activity is its motive, and is something that can meet a need of the subject. Motives arise from needs, which are the ultimate cause of human activity. Figure 1, below, illustrates the relationship between the elements in Leontiev's development of activity theory.

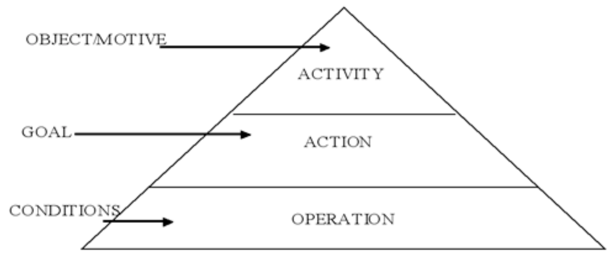

Figure 1: Pyramid Representation of Leontiev's Three-Level Model of Activity (1974)

Motives drive activity, and activities are directed at goals. People have many goals, which shift in importance and in content on the basis of both contextual and intrapersonal factors. At the very top of this hierarchy is the motive for activity. At any time an individual has a hierarchy of these motives, the order of which is determined through and as a result of one's activity.

Actions are the many steps that comprise an activity, although not all are immediately related to the motive (Kaptelinin & Nardi, 2012). Actions are directed towards specific targets, called goals. Goals are conscious; in contrast to motives, of which a subject is not usually aware.

The fact that motive is often hidden from the subject suggests difficulty in determining the ultimate motive. This obstacle can be overcome by utilizing an "*actions first*" strategy (Kaptelinin & Nardi, 2012). The strategy begins at the level of goals, which people are generally aware of and can express, and the analysis is subsequently expanded up to higher goals and ultimately the motive. Given the primary interest of this study is the students' actions/goals and activity/motive only the top two levels of Leontiev's pyramid will be considered in this paper.

Cataloguing the observable aspects of studenting (actions) and analyzing these together with students' goals through the lens of activity theory can offer new insights into student motives and provide researchers and educators with evidence to better understand student behavior.

Methodology

The nature of the research questions requires a particular approach – an ethnographic study, though the study itself is not ethnography. In accordance with this approach, I spent significant time immersed in the classes under study observing and interacting with students, taking fieldnotes, and asking questions. Analysis occurred throughout the process of data collection whereby what was observed and recorded in one lesson provoked questions and shifted focus for the next observation/interviews. Both an etic and emic perspective were utilized.

Participants

The data for analysis are taken from a larger study conducted in three secondary school mathematics classes in British Columbia. Maria was in the Foundations 11 class.

Data Collection and Analysis

Data were collected during the 2013-2014 school year. Throughout the fall semester the class was observed for twelve periods, each period ranging from 60 to 75 minutes. Classroom lessons and informal interviews were audio recorded and transcribed for later analysis and comparison with field notes taken during the class. The data discussed here has been subjected to an initial analysis using Leontiev's activity theory in order to determine the likely primary motive underlying Maria's behavior.

Results and Analysis

The analysis is influenced by all observations, interviews, and interactions with Maria, not all of which are provided here. A selection of observations and interview transcripts are provided to render a sketch of Maria's behavior and justify the hypothesized motive.

What Maria Did (Actions)

Over the five-month period the class was visited the researcher observed Maria in many activity settings. Maria was always present, on time, and prepared for class. She tried every homework question and asked for help from neighbors or Mr. Matthews when it was needed. She was often the first to begin a new activity and remained focused for the duration of the task. She took notes during lessons and for example problems. She also stayed after class on occasion to do extra review and finish homework. Maria could often be relied on to supply answers (usually correct) if Mr. Matthews asked a question of the class during a lesson. She would follow the teacher's explanations and, if she was able, provided explanations when asked 'why'. These explanations were largely procedural. She asked questions when Mr. Matthews was doing example questions during a lesson, such as "*If you gave us those two roots, how would you graph it?*". During group work she did not actively take a leadership role but often ended up leading group presentations.

What Maria Said (Goals)

The following is a summary of some Maria's written responses to some prompts given to all students in the class regarding note-taking habits and review for tests.

She takes notes when there is a lesson, even if she has done the topic previously, and writes them in her own words, rather than exactly what the teacher says because it "*helps me remember the notes*". She wrote that she takes notes during class because it helps her "*pay attention to the lesson"* and it helps her "*to study later on when there is going to be a test*". Maria thinks her teachers expect her to take notes because they know it will be helpful to students in the future.

To review for a chapter test Maria wrote that she uses both her notes and her textbook to ensure she "*fully understands the subject/topic*". She "*looks over*" her notes both at home and in class, reading them "*to see if I can follow all the steps*". She does all the questions in the assigned textbook homework that "*I know I'll have trouble with*" and also does "*some of each type of question*". During class on the day before a test she'll work on the assigned review and if she has difficulty "*I'll ask someone who might understand*". After a particular test she said she "*should have done more practice on converting equations with the word problems*".

Discussion and Conclusion

Maria demonstrates the activity of a conscientious student. According to Mr. Matthews', Maria "*should*" be achieving a high 'A' in the class, but when it comes to the test she doesn't seem to have fully understood the material. This perplexing situation could be understood by examining Maria's actions to determine what is driving her behavior.

Figure 2 depicts the top two levels of Leontiev's (1974) triangle as applied to Maria's actions, her voiced and indicated goals and, extrapolated from these, her motive.

In all aspects Maria demonstrates qualities of what she perceives to be a 'good' student. Maria's actions demonstrate that her understanding of a what a 'good' mathematics student does includes: doing and submitting all the homework, asking for help (and being seen to do so), answering questions in class, participating, taking notes, doing practice for procedural fluency.

Maria's studenting is so successful that she seems to have fooled Mr. Matthews into thinking she is a good mathematics student – yet she seems to struggle with non-typical problems and relies significantly on 'remembering' how to do questions. Maria is very good at studenting, just not mathematics. Since her actions align with the features that Mr. Matthews appears to consider a part of being a good mathematics student, Maria's performance on assessments is puzzling.

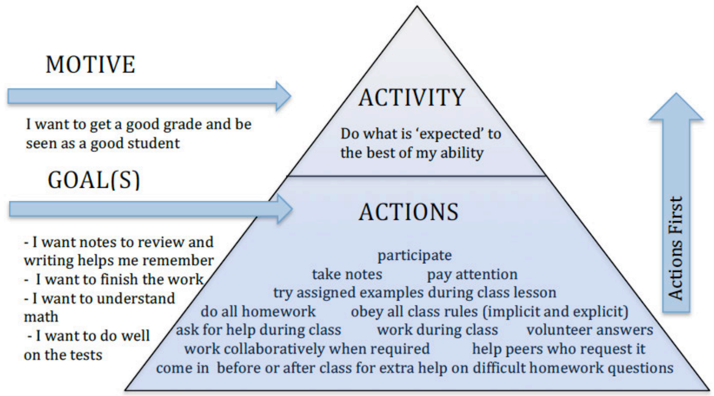

Figure 2: Using an 'actions first' approach to determine Maria's motive.

Although the teacher saw all of Maria's actions as indications of learning, they were, in fact, just proxies for learning. Thus even when students are conforming to teacher expectations, as in the case of Maria, there appears to be a gap between actual student activity and learning, the ideal outcome associated with a primary motive of learning. Frameworks like the didactic contract (Brousseau, 1997) may apply when the desire to learn drives student activity but when learning *is not* the primary motive, other approaches must be explored, such as activity theory.

Other preliminary results show that are a variety of goals that manifest in similar actions, suggesting that considered alone, a students' actions are insufficient to deduce their motive. Also, even when students do not conform to the teacher's expected behaviors, from the student's perspective there is a certain rationality to their actions. It is anticipated that extended analysis will provide further evidence to support this claim.

What the case of Maria suggests is that a deeper understanding of the perspective of the student within the classroom unit could serve to provide teachers with cause for reflective thought on their policies and practices that influence student learning.

CONNECTING INDIGENOUS AND WESTERN WAYS OF KNOWING: ALGONQUIN LOOMING IN A GRADE 6 MATH CLASS

Ruth Beatty
Lakehead University
rbeatty@lakeheadu.ca

Danielle Blair
On secondment to the Ontario Ministry of Education
dblair@scdsb.on.ca

In this study we explored the connection between Algonquin ways of knowing and Western mathematics found in current math curricula. We used a cyclical research design of consultation, co-planning, co-teaching, and co-reflection to explore the potential of grounding mathematical instruction in the traditional Algonquin activity of looming. Results suggest the activity supported students' complex mathematical thinking including patterning and algebraic reasoning, proportional reasoning and spatial reasoning. The experience also resulted in a reconceptualization of mathematics learning for both Algonquin and non-Native students.

Keywords: Equity and Diversity; Elementary School Education

Objectives

The activities in this paper come from an ongoing long-term project in which we collaborate with Elders and community members from different Indigenous communities across Ontario to explore connections between Indigenous and Western ways of knowing mathematics. The goal of this project is to explore connections between the mathematical content knowledge based on the Ontario curriculum expectations and the mathematics inherent in Indigenous cultural practices. We are also exploring connections among evidence-based teaching pedagogies founded on the principles of reform math instruction, Indigenous ways of teaching and learning, and contextual knowledge based on students' lived experiences. The work outlined here was conducted in a Grade 6 classroom at a small public school near Pembroke, Ontario. The school population comprises approximately 20% Algonquin students from the nearby Algonquins of Pikwàkanagàn First Nation, and 80% non-Native students.

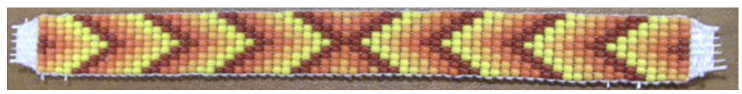
Theoretical Framework

Ethnomathematics is a theoretical framework that has generated a growing area of research of how math curricula can and should respond to local culture (D'Ambrosio, 2006). From the ethnomathematics perspective, school mathematics, which is derived from 15th century Western European traditions, is one of many diverse mathematical practices and is no more or less important than mathematical practices that have originated in other cultures (Mukhopadhyay et al., 2009). Ethnomathematics provides a foundation for developing culturally responsive education, which refers to efforts to make education more meaningful by aligning instruction with the cultural paradigms and lived experience of students (Castagno & Brayboy, 2008). Research has shown that creating connections between math instruction and Indigenous culture has had beneficial effects on students' abilities to learn mathematics (Cajete, 1994). Long-term studies by Lipka (2002, 2007) found that culturally responsive education in mathematics had statistically significant results in terms of student achievement. Recent researchers have also been exploring the insights Indigenous epistemologies and practices can provide into understanding diverse mathematical pedagogies (Barta et al., 2003).

Methods

Research Design

Our core research team for this project included two Algonquin teachers, and the operations manager of the Algonquins of Pikwàkanagàn Cultural Centre, Christina Ruddy, who is an expert loomer. The team also included three non-Native teachers from the school, including the Grade 6 teacher, Mike Fitzmaurice, in whose classroom the study took place. We followed a cyclical approach (consult, plan, teach, reflect, share) as a framework for the project, which ensured that we continually cycled back to members of the Algonquins of Pikwàkanagàn community for guidance. The cycle includes a consultation phase during which we met with community leaders from Pikwàkanagàn. A key theme raised by community members was the importance of revitalizing Algonquin culture. One focus of this cultural revitalization has been beadwork, including loomwork, which has always had significance for this community. For this study we co-planned a unit of instruction based on Algonquin looming – a type of beading that is done on a loom, and involves stringing beads onto weft threads and weaving them through warp threads. Once the lesson sequence had been designed by the team, Mike and Christina co-taught the lessons over the course of two weeks in the grade 6 classroom. All lessons were videotaped and specific classroom incidents were transcribed. The team viewed video clips to co-analyze students' mathematical thinking and cultural connections. Finally, the results of the lessons were shared with community members though parent and community meetings. In this paper, we share some of the mathematical thinking from week 1 of the sequence, which focused on pattern design.



Findings

Looming in the Classroom

Christina taught the students that looming pre-dates the arrival of Europeans to North America. Historically sinew and porcupine quills would have been used but currently plastic and sometimes glass beads and nylon thread is used. The pattern for each looming project is created on graph paper (see Fig. 1). The columns represent the weft threads, and the number of columns corresponds to the horizontal length of the beadwork. The rows represent the warp threads, and the number of rows corresponds to the width of the beadwork. The rows and columns of the design space are numbered. Below each column, the number of each colour of bead is entered (with the number representing the colour of the beads, in this case blue numbers for blue beads and red numbers for red beads). This helps the beader to know the order for stringing beads for each column, or line of beads on the weft thread. Each column should add to the total number of beads on each weft thread (so in the example in Fig. 1, each column should add up to 7).

Patterning and Algebra

Students were introduced to a pattern of chevrons that were two-beads wide and created using two alternating colours; a 2-colour 2-bead Chevron pattern (Fig. 1). To identify the unit of repeat (also referred to as the "pattern core"), some students focused on the numeric pattern and noted that even though the numbers repeated after the 2nd column, the colours were different

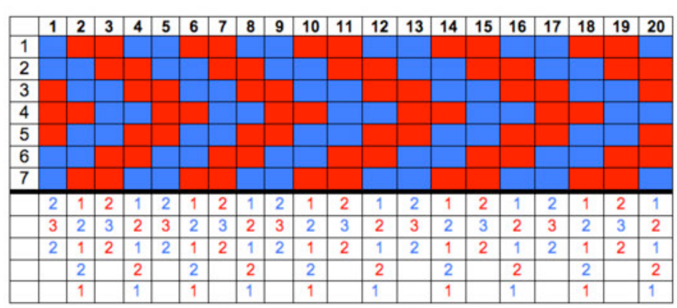


Fig. 1: 2-Colour 2-Bead

so the first 4 columns made up the core. Others identified the visual pattern of the first 4 columns and described the central blue chevron surrounded by parts of red chevrons on either side.

Students then created a 3-colour 3-bead chevron (Fig. 2) and found that column 10 was identical to column 1, and so reasoned that the core comprised columns 1-9. Students described imagining superimposing the first 9 columns onto the next 9 columns to see if they “matched.” Noticing that the pattern seemed to begin with a partial chevron, a few students wondered what would happen if they added a column “before” (to the left of) column 1 on the pattern (which they referred to as “column 0”). This inquiry was explored by the rest of the class. They discovered that the core “moved” to the left by one column, and comprised columns 0 – 8 (Fig. 3). They continued to add columns to the left of column 1, and noticed the core shifted by as many columns as were added. However, they also noticed that the number of columns in the core did not vary. For a 3-colour, 3-bead Chevron pattern the core was always made up of 9 columns.

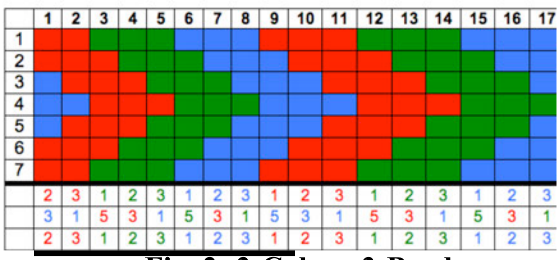

Fig. 2: 3-Colour 3-Bead

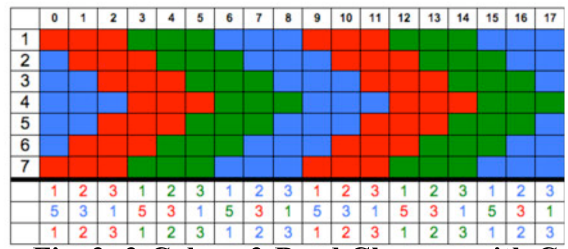

Fig. 3: 3-Colour 3-Bead Chevron with Column

Based on these experiences, the students generated an algebraic generalization to predict the number of columns in the pattern core of any Chevron pattern. The width of the core is determined by a multiplicative relationship between the number of beads that made up the chevron and the number of colours (chevron width x colour = core width). The idea of a “moving” pattern core was new to these students, as previously they had never considered that a pattern can extend to the left as well as the right of the given elements. This allowed them to recognize that the core of a pattern is not necessarily defined by the first element, however what remains constant is size of the core (in this case, the number of columns).

The students were then asked to make predictions about columns in the pattern further down the sequence, for example, what the 35th column would look like. The students identified the multiplicative relationship between the number of columns in the core, and the numbered columns of the design template. For example, if the core of a pattern comprises 4 columns, the 35th column would be the same as the 3rd column, since the core would be repeated 9 times to the 36th column (which would be identical to the 4th column) and the column before the 36th column would be identical to the 3rd column.

Proportional Reasoning

At the end of the first week, the students designed their own pattern to use as the basis of their bead creations. They learned that 5 columns on the pattern template equated to 1cm of beadwork. Students were asked to measure their wrists and calculate how many columns wide their bracelets would need to be, how many beads of each colour and in total they would need.

Some students used proportional reasoning to estimate the total length of their finished bracelets using a fixed ratio of 1 cm = 5 columns. We also saw evidence of students using the pattern core as a unit, for example, considering the core as simultaneously one core and 4 columns. For example, Wyhatt with a wrist of 17cm worked with the relationship of 5 core units = 20 columns (or 4 cm), 10 core units = 40 columns (or 8 cm), 20 core units = 80 columns (or 16cm) and one more core unit plus a single column (first column of the core unit) for 85 columns (17 cm). This is an example of using a composite unit (Lamon, 1996) for more sophisticated reasoning – the 20-column template represented 5 pattern core units and 4 cm simultaneously. Students exhibited an ability to use single or composite units as the basis for multiplicative thinking (e.g., using the unit of 5 columns for 1 cm, or using the unit of the pattern core of 4 columns with an understanding that 20 columns = 5 cores *and* 4 cm).

Spatial Reasoning. Numerous studies suggest that spatial reasoning skills, including mental manipulation and spatial visualization, are linked to mathematical achievement (e.g., Gunderson et al., 2012). We found that designing 2-dimensional patterns on a grid, and identifying components of the pattern (like the pattern core) provided an opportunity for students to engage in visuospatial thinking. As they worked to isolate the columns that made up the core of the pattern, the students were able to mentally visualize isolating the pattern core superimposing one core onto the next to determine whether it "matched".

Conclusion

Ethnomathematics, and culturally responsive teaching specifies working within the mathematical systems established within a particular culture, in this case, the Algonquin culture of Pikwàkanagàn. The connections that we made between Western and Algonquin mathematics took the form of creating a "third space" (Haig-Brown, 2008; Lipka et al., 2007) in the classroom by exploring the potential of Algonquin activities for mathematics, and bringing Algonquin culture into the classroom. This third space, merging Algonquin and Western ways of knowing, is created when the knowledge and perspectives of traditionally excluded communities are privileged alongside the dominant society's pedagogy and content.

TEACHER PERSPECTIVES ON MATHEMATICS EDUCATION FOR LANGUAGE LEARNERS: ADAPTING ELL EDUCATION MODELS

Ji Yeong I
Iowa State University
jiyeongi@iastate.edu

Hyewon Chang
Seoul National University of Education
hwchang@snue.ac.kr

Teachers in Korea have recently confronted new challenges as the population of linguistically and culturally diverse students increases. Ethnically diverse students as well as Korea-born students returning from long residences in foreign countries have great difficulties orienting themselves within Korean schools due to lack of Korean language proficiency and cultural differences. We named this student group as Korean language learners (KLLs) and investigated teacher perspectives on effective mathematics pedagogy for KLLs. Using two educational models for English language learners (ELLs)—Cummins' Quadrant Model and the Sheltered Instruction Observation Protocol (SIOP) Model—we examined survey results of a small group of elementary teachers in South Korea in terms of effectiveness and feasibility of the ELL models.

Keywords: Equity and Diversity; Teacher Beliefs; Elementary School Education

Research Objectives

The classroom culture of Korean schools has recently changed as the population of linguistically and culturally diverse students increases. We associate immigrant students and Korea-born students, returning from long residences in foreign countries, in terms of their linguistic difficulty, and name them as *Korean language learners* (KLLs). Recent studies have found that students from international marriages and immigrant families tend to academically perform at lower levels than general Korean students (Cho et al., 2006; Song et al., 2010) and mathematics is one of the subjects they have the most difficulty with (Cho & Lee, 2010; Jang & Choi-Koh, 2009). Moreover, Korean public schools have failed to provide multicultural programs or linguistic supports tailored to the needs of KLLs (Kim & Kim, 2012), and teacher preparation programs have not prepared teachers for implementing multiculturalism in their instruction (Mo & Hwang, 2007).

We investigated South Korean elementary teachers' perspectives on the use of effective mathematical pedagogies for language learners, especially KLLs. We specified several pedagogies within two educational models designed for English language learners (ELLs) and examined survey results of how teachers considered implementing the ELL pedagogies in Korean school contexts.

Frameworks

One trend of ELL research has been to highlight the distinction between academic language and everyday language (Moschkovich, 2007) although they are not exclusively separated. Two ELL education models were chosen to address the importance of considering both language development and academic context: Cummins' Quadrant Model (Cummins, 2000) and the Sheltered Instruction Observation Protocol Model (SIOP Model: Echevarria, Vogt, & Short, 2004). We adapted and connected these models in a mathematical context.

Cummins' Quadrant Model

Cummins (2000) considered a degree of context and a degree of cognitive demand in language tasks or activities to create a two-dimensional model (see Figure 1). Quadrants A and B include instructions that may be appropriate for language learners because contextual clues help them overcome language barriers. In the context-embedded instruction, students actively negotiate meaning through scaffolding and feedback provided by their teacher (Cummins, 2000). Further, students need to be challenged cognitively as well as provided with appropriate contextual and

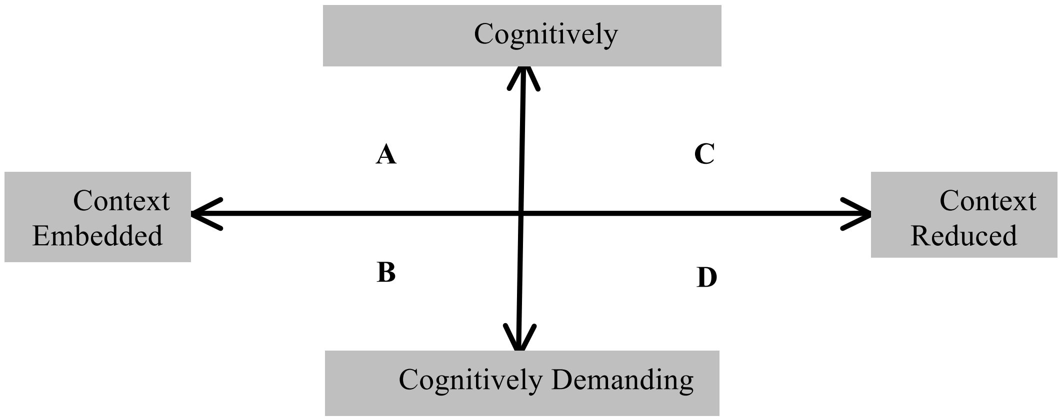

Figure 1: Four - Quadrant Model (adapted from Cummins 2000, p. 68)

linguistic supports as emphasized in Quadrant B (Gibbons, 1998; Vincent, 1996).

The SIOP Model

We chose the SIOP Model as one of the approaches to be placed in Quadrant B. The SIOP Model was designed to teach content subjects for ELLs. The eight components of SIOP Model are: lesson preparation, building background, comprehensible input, strategies, interaction, practice/application, lesson delivery, and indicators of review/assessment (Echevarria et al., 2004). Because we were interested in the strategy component, we chose five strategies that have potential for teaching mathematics to KLLs: Higher-order thinking questions, visual/physical activity, scaffolding, graphic organizer, and group activity.

Methods

Participants and Setting

We conducted a survey with 27 Korean elementary teachers in a large urban area where the population of multicultural students was relatively high compared with other places in South Korea. Due to the location, some participants had taken multiculturalism courses in various forms, although none of the trainings specialized in mathematics education. The survey asked them to evaluate a lesson plan designed by the SIOP Model developers (Echevarria et al., 2010) to teach geometric figures for second grade ELLs. Because the lesson included all five SIOP strategies mentioned above, we examined how Korean teachers identified and valued those strategies for teaching KLLs.

Data Sources and Analysis

The objectives of the survey were (1) to examine if teachers identify the strategies designed for language learners, (2) to examine whether they consider the cognitive demands and contextual aspects, and (3) to see how they would choose to implement the lesson for their students. The first part of the survey asked about previous experiences and beliefs on KLLs, and the second part included open-ended questions about teachers' insights on the SIOP lesson plan. To analyze the data, we used the constant comparative analysis method (Fram, 2013), which employed open coding, axial coding, and selective coding (Strauss & Corbin, 1990). Finally, we built a map of all categories and found themes that emerged in and across categories.

Results

Teacher Beliefs on KLLs

Differentiation of mathematics instruction. More than 90% of respondents agreed that they should differentiate their mathematics instruction for KLLs. The more experiences teachers had with KLLs, the deeper and richer the insights in their responses were. For example, one teacher who had a long-term experience teaching KLLs pointed out the difficulty of teaching conceptual knowledge to KLLs rather than teaching procedural knowledge. In addition, there was no relation between the beliefs on differentiating instruction and the multicultural trainings they received. One reason for the small influence of training might be that the multiculturalism courses were not specialized in mathematics.

Appropriateness of the storytelling mathematics textbooks. Recently, the Korean government issued storytelling mathematics textbooks, which included sufficient pictures and contextual clues. One of the survey questions asked how appropriate the storytelling textbook was for KLLs. The responses were prevalently negative. The teachers disagreed that the storytelling textbook was suitable for KLLs because it required teachers to use complicated discourse in order to make sense of the story contexts in the textbook. This reveals that teachers perceive language as a barrier for KLLs to understand mathematics. Even if pictures and contexts support word problems, teachers believe more sentences yield more difficulties rather than more contextual clues.

Evaluation on the SIOP Lesson

Most teachers responded that the SIOP lesson would be effective for KLLs. They identified various types of linguistic supports: linguistic objectives, graphic organizers, or practicing sentence patterns. They thought these strategies were different from their typical mathematics lessons. One teacher articulated that linguistic supports would be useful, not only for KLLs, but all students, as follows:

> I have seen many students who are capable in mathematics have great difficulty expressing their ideas in language. Particularly lower-grade boys have trouble with verbalizing an image in their head. This lesson is impressive in the sense that it guides students to learn how to express their understanding in sentences in concrete ways.

Among the five strategies, teachers identified visual/physical activities, group activities, (verbal) scaffoldings, and graphic organizers. However, none of them noticed the higher-order thinking question, although it was written at the top of the lesson plan. The series of teacher questions that explicitly appeared in the lesson plan multiple times were not mentioned either. In short, they were able to identify the SIOP strategies and generally agreed that the lesson would be effective for teaching KLLs. However, little recognition was found on cognitively demanding aspects such as the higher-order thinking question. Moreover, it should be noted that the Korean education system or Korean teachers' pedagogy has its own features and structures that could be an obstacle when implementing the ELL strategies in the classrooms in South Korea.

Discussion

Although the teachers in Korea had not received any official training to teach mathematics for KLLs, it was a positive sign that they could identify important strategies that support language learners. However, the results imply that their understanding is limited because they did not pay attention to the aspects of cognitive demand and they heavily focused on language difficulty rather than providing contextual clues or scaffoldings. This view might be related to the conception that language learners are deficit learners (Moschkovich, 2007).

This study provides an international lens on teacher perspectives and openness towards multicultural education. Diversity is becoming prevalent internationally, so it is important to recognize other countries' situations and efforts in educating diverse learners because we can learn from their experience and also find some possible collaboration. This study contributes to teacher educators' understanding of the needs of language learners in mathematics education and teachers' adaptability of a linguistic education model in content areas. Based on the results of this study, the efforts of applying ELL education models can give a meaningful indicator for future education models for other language learners and teachers of language learners if there are adequate considerations about cultural and political situations.

FOSTERING LEARNING-BASED CONVERSATIONS IN MATHEMATICS

P. Janelle McFeetors
University of Alberta
janelle.mcfeetors@ualberta.ca

Conversations can be communicative moments in which there is an interpersonal and intimate nature of turning round ideas for the purposes of growth. Interactions among grade 12 students demonstrates the possibility of learning to learn mathematics through conversation. In exploring opportunities for learning-based conversations, constructivist grounded theory sponsored the development of a Model for Fostering Learning-based Conversations in Mathematics. The four features of preparation, presence, mode, and pace represent a space where students engaged in talking about their learning through conversational moments. This report will use student data to demonstrate how conversations which focus on ways of learning mathematics empower students.

Keywords: Classroom Discourse; Learning Theory; High School Education; Metacognition

Purpose of the Study

Mathematics education reforms (NCTM, 2000, 2014; Western and Northern Canadian Protocol, 2008) have emphasized students' personal development of mathematical ideas through conversation (e.g., Chronaki & Christiansen, 2005; Herbel-Eisenmann & Cirillo, 2009). As an enduring challenge, absent from these reforms and from many students' experiences is explicit discourse about processes of learning–identifying strategies students use to learn (e.g., homework, taking notes) and how to adapt strategies. Current scholarship could respond by addressing how students engage in conversation about their processes of learning and how learning-based conversations support improved mathematical learning.

The empirical research presented in this report is part of a larger study that addressed the question: *What is the nature of students' learning when they engage in conversations to shape their personal processes of learning mathematics?* The purpose of the study was to understand how high school students learn to learn mathematics (McFeetors, 2014). This report focuses on one facet of the study: how students engaged in conversations about their ways of learning mathematics. The conversations were "learning-based" because they foregrounded *learning* in the students' awareness (Polanyi, 1964/1969) and students improved their learning through discourse. In the presentation, I examine conversational features which afforded students opportunities to experience growth in awareness of their learning processes, improve their approaches to learning mathematics, and view themselves as capable learners of mathematics.

Mode of Inquiry

Constructivist grounded theory (Charmaz, 2006) returns to the symbolic interactionist root of grounded theory while looking through a constructivist lens as an interpretive process for inquiring into dynamic phenomena. Theory is constructed on a provisional basis and contingent to the context. The researcher moves from rich empirical data through abstraction toward developing a mid-range interpretive theory through guiding processes like coding, memoing, categorizing, theoretical sampling, saturation, and sorting. The researcher's reflexivity results in theorizing as both process and product enabling other researchers to apply and extend the work.

The study was situated in an academically-focused suburban school in a Western Canadian city. Thirteen grade 12 students who were taking a pure mathematics course volunteered to participate in the study. Students were enrolled concurrently in a course, *Mathematics Learning Skills*, that provided support for their mathematical learning. Within the *Learning Skills* course, I assisted the teacher in coaching students to improve their approaches to learning mathematics while simultaneously collecting data.

I recorded field notes after observing each class over four months. Students took part in: 1) bi-weekly interactive journal writings (Mason & McFeetors, 2002) about how they were learning mathematics; 2) one of three small groups where they developed a learning strategy that supported understanding (three to five sessions of approximately 30 minutes each); and, 3) two informal interviews focusing on approaches to learning mathematics for understanding (each approximately 30 minutes long). In addition to generating data, the interactions also afforded students moments to be in conversation about their approaches to learning mathematics. Using line-by-line coding and the constant comparative method (Glaser & Strauss, 1967), data analysis involved developing codes for characteristics of student conversations. Categories of analysis were constructed by grouping codes related by conceptual qualities of conversation. Category names, like "pace", are descriptive of conversational features students valued and are abstracted from the data. I constructed the Model for Fostering Learning-based Conversations in Mathematics by exploring the interrelationship of the categories.

Perspective

Rather than using an interpretive framework, I adopted Blumer's (1954) notion of sensitizing concepts to "merely suggest direction along which to look" (pp. 7-8). *Conversation* was used as a sensitizing concept in this study. Surveying the uses of *conversation* in curriculum inquiry (Bakhtin, 1986; Belenky, Clinchy, Goldberger, Tarule, 1986; Gadamar, 1965/1975; Gee, 1996; Noddings, 1994; Varela, Thompson, & Rosch, 1991) and mathematics education (Bauersfeld, 1995; Cobb, Boufi, McClain, & Whitenack, 1997; Davis, 1996; Ernest, 1993; Gordon Calvert, 2001; Sfard, Nesher, Streefland, Cobb & Mason, 1998) pointed to a particular form of communication in which there is an interpersonal and intimate nature of turning round ideas for the purposes of growth, as well as a way of being in the world. The related literature served to sensitize me as a researcher to five particular conversational features – including *withness*, *listening*, *dynamic*, *uncertainty*, and *form* – which guided my attention to the ways in which students were in conversation about their processes of learning and informed generating a model.

Results

The four features of fostering learning-based conversations include: preparation, presence, mode, and pace. The features represent qualities of providing opportunities for students to talk about and improve their learning strategies. It is more explanatory of the occasioning of learning-based conversations, rather than of the qualities of conversations themselves. As such, it demonstrates ways in which teachers could provide opportunities for students to talk about how they learn. The features were created by looking at the range of examples from the study and attending to what the students emphasized when they identified conversations about their learning and what I noticed in their conversations through interpretation of data that the students did not explicitly identify as conversational moments. Students' quotes are included below.

The *preparation* feature points to the varying degrees of advanced planning that took place in providing opportunities for the students to attend to their learning. This feature has a temporal dimension, from spontaneous to deliberate interactions. In offering help in class, I recorded a field note where Teresa "asked me if it was like a question in her notes … I encouraged her that she had used a great strategy" for getting unstuck—an example of being alert to a spontaneous moment to shift the focus to learning. When I deliberately showed students a list of learning strategies they used during an interview, Grace exclaimed, "That's a lot! … I thought I only had two or three ways to learn math." The deliberate planning for learning-based conversations allowed for deep exploration of the processes and meaning of learning for the students.

The *presence* feature refers to the composition of members of a learning-based conversation, ranging from internal dialogue to including teachers and peers. While self-talk often focused on mathematical thinking, Danielle described "sitting on the bus, and I was thinking … how would I be able to separate my ideas and stuff" as a catalyst for a new learning process. In small group sessions, students suggested and considered different ways of learning mathematics content. Students valued different perspectives on learning processes, not looking for experts to inform them but rather a responsiveness to turning round ideas in conversation with fellow inquirers.

The *mode* highlights the dialogic nature of learning-based conversation through various forms, including spoken interactions, textual artifacts, and a hybridity of these two modes. Spoken discourse occurred mainly through one-on-one interactions and small groups. It required moving students from noticing content to identifying how learning occurred. Interactive journal writing, as a textual artifact, gave students time to pause and consider deeply their approaches to learning. It was a safe space to share emergent thoughts about learning and as I wrote back I could draw learning into view. Upon returning a journal, Kylee exclaimed, "This idea for the cue card is great! I'm going to try it tomorrow"—a hybrid of student, me, and text.

The *pace* feature indicates a shift in classroom rhythm that allowed for a suspension of time from content to explore issues of learning. When Shane explained that "sometimes I just think about how I learn", it was within a relaxed feeling of learning-based conversations contrasted with the rapidity of mathematics content. Opening up brief moments mattered to students. For instance, Ashley identified "the [small] groups that we're doing, it's mostly concentrated there" for conversations where learning strategies were developed that helped her succeed in mathematics. The different intensity fostered students' choice to engage in learning-based conversations where they inquired into ways of learning mathematics.

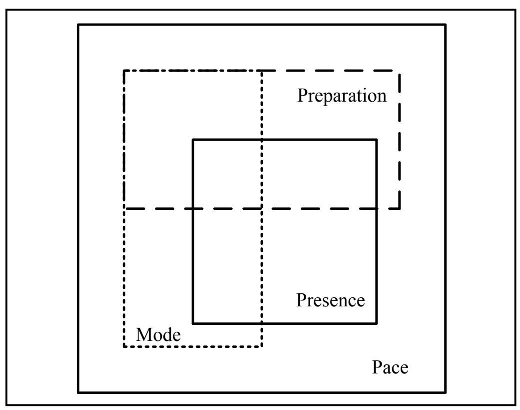

Figure 1: Model for Fostering Learning-based Conversations in Mathematics

Discussion: Integrating the Features into a Model

The Model for Fostering Learning-based Conversations in Mathematics, in Figure 1, represents a space highlighting the complexity of students' opportunities to be in conversation about their learning. Pace, diagrammed as the exterior square, situates the other three features of preparation, presence and mode, in a particular moment. Each of the conversational moments within the study could be placed within the space created by the rectangles. The placing of the conversational moments is what creates the space in which the students were talking about their learning and shaping their learning strategies through conversation. By explicating features which identify ways to foster learning-based conversations with students, I hope to invigorate mathematics education research to draw learning processes into view to empower students to improve and succeed in learning mathematics.

LEARNING FROM FAILURE: A CASE STUDY OF REPEATING A MATHEMATICS COURSE FOR PRESERVICE ELEMENTARY TEACHERS

Michelle Ann Morgan
University of Northern Colorado
Michelle.Morgan@unco.edu

The following paper is a description of a qualitative case study of a student as she attempted a course for the second time. This study took place at a four-year university in the first of a three-course sequence of mathematical content courses for preservice elementary teachers. Data was collected over the course of a single semester using a combination of interviews and short-response, reflection questionnaires and was analyzed using an open-coding process. A rich description of the student's experiences includes a discussion of how the course curriculum, instructor feedback, ability to seek help, and having "the right team" contributed to the student's negative and positive experiences in the course.

Keywords: Teacher Education-Preservice; Affect and Beliefs

Introduction

The National Council of Teachers of Mathematics, in their *Principles and Standard for School Mathematics*, argued that preservice teacher preparation programs have a significant impact on school mathematics through their instruction of future teachers (NCTM, 2000). Echoing that sentiment, Campbell et al. (2014) claimed that elementary teacher preparation programs have "a core responsibility for enhancing the content and pedagogical knowledge of prospective and practicing teachers as well as influencing their beliefs regarding mathematics teaching and learning" (p. 455). As a result, Clark et al. (2014) called for increased research to better understand potential influences on teachers' beliefs and how experiences impact mathematical views.

The research study presented in this paper took place a four-year university in the Rocky Mountain region. At this particular university, all elementary education majors are required to complete a three-course sequence of mathematical content courses. This research study focused on the first course of that three-course sequence. To continue to the next course in the sequence, students must achieve a grade of 70% or higher in their current course. Some students (henceforth called *repeaters*) fall short of this expectation and find it necessary to repeat at least one of the courses. In order to explore ways to better serve these repeaters, the purpose and goal of this research study was to explore the experiences of current repeaters. To achieve this goal, I sought to answer the following research questions: from the student's perspective (1) what circumstances contributed to the student needing to retake the course? and (2) what circumstances contributed to the student being successful in their current attempt at the course?

Methodology

The purpose of this case study was to develop a holistic view of the experiences and circumstances surrounding students as they attempted to repeat the entry-level mathematics content course for preservice elementary teachers.

The Setting and Course

The research study presented in this paper took place during the 2014 fall semester at a four-year university in the Rocky Mountain region. The participants were enrolled in an entry-level mathematics content course for preservice elementary teachers and all were repeating for the first time. According to the course description, the purpose of this course was to explore the real number system and basic arithmetic operations. Specifically, the course focused on mathematical structures,

Bartell, T. G., Bieda, K. N., Putnam, R. T., Bradfield, K., & Dominguez, H. (Eds.). (2015). *Proceedings of the 37th annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education*. East Lansing, MI: Michigan State University.

patterns, and properties through a format of problem solving and exploration. All classes utilized a combination of direct instruction, whole-class discussion, and small-group exploration.

Participants

I administered a demographic questionnaire to approximately 230 students enrolled in multiple sections of the course. From those surveys, I invited six repeaters to participate in the research study, three of which agreed to participate. The case study presented in this paper will focus on one of the student's experiences as she attempted to complete the course for a second time.

Data Collection and Analysis

I conducted semi-structured interviews and collected short-response reflection surveys over the course of the semester during which the students were repeating the course. During the interviews, I asked the students questions about their experiences in their previous attempt to pass the course as well as their experiences in their current attempt. To gather information for the interviews, an online, short-response self-reflection questionnaire was administered. Each questionnaire included questions about the student's current experiences in the course. Administration of these questionnaires occurred the week prior to the second and third interviews. I used an open coding process to separate the interview data into key parts: (1) description of the case and (2) emergent themes.

Results and Discussion

In the following section, I will present a detailed description of the experiences of a single student, Quinn, as she attempted to repeat the course. The choice to focus on this student was a result of the rich, illustrative nature of her case record.

About Quinn

During the semester of this research study, Quinn was a sophomore majoring in Special Education with an emphasis in English as a Second Language (ESL). She moved to the United States approximately 8 years ago and attended an American junior and senior high school prior to attending the university. While English was not her first language, she expressed enjoyment from studying the subject. She also admitted that mathematics was her weakest subject. She believed that she learned best when she had a clear procedure in front of her, that included clear pictures and diagrams, emphasizing that "the steps [are] really important to [her]." When asked about questions that do not have a clear procedure, she argued that there is always a procedure to solve the problem. However, she blamed her language barrier for her difficulties in solving such problems. She appeared to have a very procedural view of what it means to study mathematics.

At the time of Quinn's first attempt, the fall semester of her freshman year, the expectation to pass the course was that all students needed to achieve a 75% or higher. Quinn achieved a low 70% which indicates that she almost passed the course the first time. In a study focusing on a course similar to the course in this study, Harkness, D'Ambrosio, and Morrone (2007) found that students, who struggled with the content of the course, "struggled to make sense of the mathematics, to value group work as an opportunity to socially construct knowledge, to understand the role the teacher played in shaping the learning through her enactment of teaching, and to change their self-concept and self-efficacy with mathematics" (2007, p. 251). This did not appear to be the case for Quinn. She claimed that it was not the mathematics content that caused her problems, but rather the process of explaining of her reasoning. She also valued group work and had a strong belief that her instructor and group members should help her learn the material. However, she found that the situation in her first attempt at the course, was not a supportive learning environment and, therefore, not conducive to this type of learning.

Course Curriculum

A key portion of the course curriculum is an expectation that students explain their reasoning when solving mathematics problems. Additionally, students are expected to analyze examples of incorrect student thinking in order to practice dealing with student misconceptions. As a result of her previous mathematical experiences, Quinn argued that she was at a disadvantage since she had never been asked to explain and justify her reasoning. In addition, her language barrier resulted in a greater challenge to achieve the expectations of the course.

After initially struggling, she eventually changed her perspective on the importance of explaining her reasoning as well as her role as a future elementary teacher. She argued that there should be an emphasis on explanations in elementary mathematics curriculums. She was motivated to emphasize this practice when she becomes a teacher. Research has shown that the perceptions of mathematical learning held by teachers have strong influences on their students' views of learning mathematics as well as their academic achievement (Campbell et al., 2014; Hadfield & McNeil, 1994; Bekdemir, 2010; Clark et al., 2014). Campbell et al (2014) found that, when teachers believed that mathematics learning consisted of focusing on procedural skills and the teacher had low mathematical abilities, student mathematical achievement decreased. Therefore, while it is difficult for students to achieve, it is important the course curriculum continues to place high importance on student explanations of their reasoning.

Instructor Feedback

During her first attempt, Quinn claimed that she received very little feedback beyond simply right or wrong, on her work. However, the feedback she received during her current attempt helped in several ways: (1) it helped her understand *what* she did right and wrong, (2) it helped her better understand what she needed to work on, and (3) it helped her build her confidence with the material she did understand. As a result, Quinn believed that she was better able to learn from her work. This confirms the findings of Harks, Rakocsy, Hattie, Besser, and Klieme (2014) who found that students perceived process-oriented feedback positively contributed to student understanding and motivation.

While receiving helpful feedback appeared to have a positive impact on Quinn's success, she seemed to make a connection between receiving feedback on a problem with the importance of completing that problem. She argued that if a problem was not going to be graded, then it was unfair to ask the student to complete the problem. There appears to be a disconnect between Quinn's belief that she obtained most of her understanding from completing the assignments and a lack of importance of a problem if no feedback was to be received.

Ability to Seek Help

During both attempts at the course, Quinn sought help from multiple places with mixed results. She admitted that she should have done a better job of seeking help the first time she took the course. However, she described a feeling of fear about having to ask for that help. This perception of asking for help is common among students (Butler, 1998). Butler suggested that students avoid asking for help because "they perceive help seeking as evidence of incompetence and thus as threatening to their perceptions of ability" (p. 630). When she did ask for help, she did not find the type of help she needed to be successful. For example, Quinn sought help by going to the on-campus, mathematics tutoring center. She encountered a tutor who, according to Quinn, treated her poorly and made her feel like helping her was not worth their time. She identified this as a key moment in her failed attempt at the course. Quinn expressed fear when asked if she would ever return to the center. She claimed that the experience rattled her confidence so significantly that she would never return. This suggests that a single event outside of the classroom may have a significant impact on a student's ability to seek help as well as on their mathematical confidence.

Having "the Right Team"

According to Quinn, her cooperative classroom structure consisted of "the right team." Her first "team" consisted of members that she perceived as not supportive of her learning. She expressed feelings of discomfort in asking them for help as well as decreased motivation and confidence in completing her mathematics as a result of interacting with her "team." This was in significant contrast to her second "team." During her second attempt she felt she had a supportive relationship with her instructor, small group members, as well as outside study partners. Each of these "team" members played a key role in contributing to Quinn's success.

Conclusion

Swars (2005) claimed that the previous mathematical experiences of preservice elementary teachers play an important role in shaping their current views of mathematics teaching and learning. As such, Swars argued that teacher preparation programs must provide preservice elementary teachers opportunities to reflect on and become more self-aware of negative mathematical experiences. As demonstrated by Quinn's story, it is clear that a course as well as outside experiences can have significant impacts on preservice teachers' attitudes and motivation towards mathematics. This is an important consideration for preservice elementary programs as they design and implement their programs.

WIDENING THE VISION OF MATHEMATICS: CHALLENGES, NEGOTIATIONS, AND POSSIBILITIES

Nirmala Naresh
Miami University
nareshn2@miamiOH.edu

Lisa Kasmer
Grand Valley State University
kasmerl@gvsu.edu

Teachers' views about mathematics greatly impact the way they teach. Research indicates that many teachers project mathematics as a linear subject, and view mathematics teaching as about teaching a set of formulated procedures concerned with developing skills. Teachers' traditionally-held views of mathematics may constrain their ability to perceive and present mathematics as a human activity. Limited modes for curricular resources, professional development, or models exist to help support teachers to attend to the social, cultural, and political dimensions of mathematics education. In this paper, we draw upon the theoretical fields of ethnomathematics and its subset culturally responsive mathematics education to describe curricular efforts that were aimed to promote meaningful connections between mathematics content, context, culture, and the society.

Keywords: Equity and Diversity; Teacher Education-Preservice; Curriculum; Classroom Discourse

Introduction

In a traditional school setting, mathematics is mostly perceived and presented as an elite body of knowledge stripped of its rich social, cultural, and historical connections. We oppose this view and argue for countering the narrow vision of mathematics that confines it to the school walls. When thinking about mathematics, seldom does one consider culture, context, diversity, history, or politics. Many individuals, including educators believe that there is no place for such constructs in mathematics classrooms. Thus, it is necessary to institute a change at the teacher education level to challenge teachers' traditionally-held perceptions of mathematics and its pedagogy. We, the authors, are involved in a broader research project aimed to identify more meaningful ways to promote connections between ethnomathematics theory and practice as it applies to the preservice teacher education (PST) context. In this paper, we present part of the findings - in particular, we describe curricular efforts specific to two mathematics teacher education courses that were helpful in addressing the broader research goal.

Theoretical Underpinnings

The research field of ethnomathematics (D'Ambrosio, 1985) contributes to the theoretical base. The foundation of ethnomathematics rests in its "openness to acknowledging as mathematical knowledge and mathematical practices elements of people's lives outside the academy" (Mukhopadhyay, Powell and Frankenstien, 2009, p. 75). An ethnomathematics curriculum with a critical perspective will help generate a meaningful dialogue centered on a culturally responsive mathematics education (CRME) (Gay, 2000), which is aimed to empower and transform learners. The key tenets include: helping students connect academic mathematics to other forms of mathematics, connecting school mathematics to the socio-cultural-ethnical aspects of home culture, enabling teachers to practice equitable practices that cater to all learners, and allowing both students and teachers to acknowledge and celebrate their own and each other's cultural background (Gay). A critical ethnomathematics curriculum draws on the principles of a CRME and addresses the challenges that it poses to a traditional mathematics curriculum. It challenges the "Eurocentric narrative", confronts "what counts as knowledge in school mathematics", and attends to the disconnect between "mathematics education and social and political change" (Mukhopadhyay et al., 2009, p. 72).

Methodology

We chose narrative inquiry as a methodology to frame and present our research findings. It is our work as teacher educators and researchers that we find interesting and this is the story we are compelled to tell. From this perspective, our work shifts from a mere analysis of concrete data to an introspection and deep reflection of the complexities of our practices. In our narratives, we consciously choose and present episodes from our professional and practical knowledge base that will best help us attend to the central theme of this paper. The episodes are drawn from two distinct professional experiences aimed to challenge and broaden PSTs views of mathematics and teaching through a) Content-focused coursework offered in an on-campus setting and b) an immersive early field experience facilitated away from campus.

Content-Focused Coursework

The contextual setting for university A is a mathematics content course *Patterns and Structures through Inquiry (PSI*) for PSTs. This is a three credit-hour course, which a PST completes near the end of their program of study. PSTs pursuing licensure to teach middle school mathematics typically enrolled in this capstone course in their fourth year at the university. The PSI course is designed to foster critical thinking, solving complex problems, engaging with other learners, and communicating mathematical ideas. The course was designed in line with the principles highlighted in Presmeg's (1998) ethnomathematics course "mathematics of cultural practices". Course content was delivered using practical and research components. As part of the practical component, each week, PSTs participated in at least one content exploration activity set in a social/cultural/historical/political context. The research component required participants to identify and investigate a personally meaningful practice, which emphasizes that mathematics is a human activity.

Practical Component (Content Explorations)

For content analysis, participants (re) examined mathematical topics (while accessible to school students and teachers) that typically lie outside the focus of the traditional K- 8 mathematics curriculum. An overview of the content exploration tasks is available at http://bit.ly/17H2DiA. As part of content explorations on geometry, we studied the Kolam geometry of the women of South India (Siromoney, 1978). Kolams are interesting and intricate art forms created in the threshold of their homes by women in South India. PSTs engaged in the art of Kolam drawing and investigated the potential it held for teaching and learning mathematics. Some of the student-identified teaching ideas include the following: a) Geometry– Polygons & Transformations (e.g., Identify and name polygons in a given Kolam, Identify the symmetries and transformation in a given Kolam) b) Algebra – patterns & sequences (e.g., Determine the patterns & sequences in a series of Kolams, c) Combinatorics (e.g., Decorate Kolams using a set of colors subject to specific constraints), and d) Discrete Mathematics (Investigating graphs, paths, circuits in a given Kolam). Prospective teachers enjoyed learning about (and doing) the mathematics inherent in the Kolams and socio-cultural activities of other cultural groups (e.g., Islamic Star patterns, Sona drawings). In light of their exposure to such mathematical investigations, PSTs were more willing to look for and acknowledge forms of mathematics that exist outside the realms of the academia. Evidence to this fact was exemplified in the enactment of the research component of the course.

Research Component (Course Project Investigations)

All participants completed a course project that required them to identify and investigate a personally meaningful practice, which highlights the fact that mathematics is a human activity. Each participant developed a mathematical activity and engaged in both content and pedagogical explorations. Here is a quick overview of one of the projects: PST Heather's late grandmother taught her the art of cross-stitching. Heather developed this activity as a tribute to her grandmother. She incorporated technology to (e.g., geogebra) to replicate some of the patterns and discussed underlying mathematical ideas. She used this cultural art form to enhance students' understanding of graphing on a Cartesian plane. This activity enabled students to create colorful and intricate patterns on a Cartesian grid and uncover the connections between art and mathematics.

Early Field Experience in an International Setting

Currently, teaching in the United States remains a homogeneous profession; the majority of teachers and PSTs are of European American descent; PSTs tend to be cross-culturally inexperienced, live within 100 miles of where they were born, and desire to teach in schools similar to those they attended with fewer than 10% hoping to teach in either an urban or multi-cultural setting (Cushner and Mahon, 2009). Heyl and McCarthy (2003) suggest that experiences in international education have the potential to be the most influential factor in developing cultural awareness in PST education. In order to gain a more global perspective and culturally responsive teaching of mathematics, an early field experience was developed at University B to address the PSTs inexperience relative to a CRME.

Setting and Background

At University B mathematics majors seeking teaching certification are able to fulfill their senior capstone requirement through a month long field experience in Arusha, Tanzania. (The fieldwork is completed in one month, while the coursework is completed over 8 months, 2 months prior to travel and 6 months post travel). Prior to departure, students attended six orientation meetings in which they read and discussed articles about Tanzanian culture, history, and education, and learned basic Kiswahili in preparation for the program. During their month long experience in Tanzania the PSTs taught mathematics in elementary and secondary English medium schools for 60-75 hours. The PSTs were responsible for developing the lessons, teaching the lessons, and designing assessments, often without textbooks, materials or resources. In the following discussion we provide an example of how this experience addressed some of the key tenets of a CRME.

Parallel Lines and Kangas

Over the course of the month long experience the PSTs had numerous opportunities to infuse African culture and mathematical context. However, at the onset of this experience the PSTs in an attempt to contextualize the mathematics they were teaching, provided contexts which were unfamiliar or irrelevant to the Tanzanian students. For example, one PST taught a lesson about parallel and perpendicular lines. She provided the context of roads "that run parallel to one another" and roads "that are perpendicular to each other". It was evident to the PST that the students were confused by her explanation, and she attempted to provide another context which did not provide clarification for her students. When she debriefed with her peers at the conclusion of the day, she came to realization that her attempt to contextualize the mathematics was a meaningless (and western) context. In order to make the concepts of parallel and perpendicular lines meaningful to her students, she decided that it would be necessary to provide a context that was familiar and relevant to her students. She accomplished this by situating parallel and perpendicular lines with kanga fabric. (Kangas are brightly colored rectangular fabrics often with geometric patterns that African women wear as dresses, skirts, and headpiece). Using a familiar context to the students, they were easily able to see the meaning she was trying to convey of parallel and perpendicular lines. The PST then realized the power of situating her instruction of rotations, translations, and reflections using kanga fabric, rather than the pen and paper demonstration she originally planned. In this way, the PST connected school mathematics to the socio-cultural-ethnical aspects of her students' home culture.

Discussion

In both settings (on campus and away from campus courses), PSTs were provided ample opportunities to learn about the social constructions of mathematics that highlighted the contributions of people who were not necessarily from the mainstream academia, mathematical ideas of people from all walks of life. In their weekly journal entries and debriefing sessions PSTs noted that such activities greatly "challenged their perceptions of mathematics", "enhanced mathematical understandings", "offered a glimpse into cultures and societies and the mathematical activities that live and thrive in such contexts".

During class discussions and field experiences our PSTs examined questions such as: What is mathematics? If and how informal mathematics is different from formal mathematics? How are mathematical ideas exemplified in the activities of just plain folks? From a dominant Eurocentric view, which forms of mathematics is acknowledged and valued? Why might this be the case? What can we do about this? Many of the course activities were geared towards helping them think deeper about plausible responses to such questions. We readily acknowledge that some of these responses are at best emergent, yet powerful; we hope that, in their quest for deeper answers to these questions, PSTs will further broaden their perceptions of mathematics and its teaching. Consequently, we hope that they will be able to engage in a "two-way dialogue in which [the different forms of] knowledge (community knowledge, school knowledge) and their associated values are brought into the open for scrutiny" (Civil, 2002, p. 146).

NON-DOMINANT STUDENTS' AND THEIR PARENTS' MATHEMATICAL PRACTICES AT HOME

Miwa Takeuchi
University of Calgary
miwa.takeuchi@ucalgary.ca

In response to the global mobility of populations, there have been growing international interests in mathematics learning and teaching in linguistically and ethnically diverse classrooms. In order to better support mathematics learning at school for non-dominant students, I examined informal mathematical knowledge they accessed at home. Focusing on Filipino immigrant mothers and their children in Japanese schools, this paper highlights how these mothers' informal mathematics knowledge attached to everyday practices can influence their children's development of mathematical literacy at school.

Keywords: Equity and Diversity; Informal Education

Purpose of the Study

There have been growing international interests in mathematics learning and teaching in linguistically and ethnically diverse classrooms (Barwell, 2009). Supporting linguistically and culturally non-dominant students in the current globalized mathematics classrooms is a multi-layered process to address languages, ways of knowing, and cultural practices. One of the central research agendas is to challenge the prevailing deficit views towards non-dominant students including English language learners (Moschkovich, 2007). This paper examines everyday mathematical practices unique to transnational families, who live across and beyond national borders (Kitchen & Civil, 2011). Drawing from perspectives of parents and children, this paper considers whether and how participants' everyday mathematical practices are connected with children's development of mathematical literacy.

Internationally, the Organisation for Economic Co-operation and Development (OECD) promotes *mathematics literacy* as "reasoning mathematically and using mathematical concepts, procedures, facts, and tools to describe, explain and predict phenomena" (OECD, 2013, p. 17). Providing access to mathematics literacy for all students is a pressing issue, especially in linguistically and ethnically diverse mathematics classrooms.

Theoretical Framework

Sociocultural theory maintains that learning and development are fundamentally social and cannot be reduced to the phenomenon closed within an individual (Vygotsky, 1978). One of the central tenets of sociocultural theory is to highlight capabilities and competencies that people exhibit in the cultural practices they engage in everyday lives (Saxe, 2012; Scribner & Cole, 1981). These competences are often neglected in the school contexts, especially for non-dominant students and families. One of the key concepts to highlight their resources is "funds of knowledge," which is defined as "historically accumulated and culturally developed bodies of knowledge and skills essential for household or individual functioning and well-being" (Moll, Amanti, Neff, & Gonzalez, 1992, p. 133). Drawing from the *funds of knowledge* perspective, Civil (2007) demonstrated ways in which Latino/a parents' and children's mathematical knowledge exhibited through their everyday practices (i.e., gardening) could facilitate academic mathematic learning. This paper builds on the sociocultural theory while carefully paying attention to the aspect of power dynamics, which is essential to interrogate the legitimacy of knowledge exchanged in school contexts (Nasir & Hand, 2006). Examining the aspect of power is also essential in rethinking the relationship between school knowledge and knowledge gained through non-dominant students' family practices.

Methodology

Based on Vygotsky's idea, Newman and Holzman maintain that method is simultaneously both a tool and a result and propose the *tool-and-result methodology*. Tool-and-result methodology conceptualizes the method as an activity or a search that simultaneously explores and generates tools and results that are "elements of a dialectical unity/totality/whole" (Holzman, 2009, p. 9). In this study, interview data with 12 Filipino mothers and 10 of their school-aged children was used to gauge the needs of Filipino mothers and their children (all the names used are pseudonyms). Workshops were organized subsequent to the interviews with mothers, as an attempt to address some of the issues raised in the interviews.

In the interview, parents undervalued their mathematical knowledge, compared to the mathematical knowledge taught at schools. Parents expressed their feeling of powerlessness, to support their children for their school learning, due to a language barrier and also a perceived hierarchy between Japanese mathematics curriculum and Filipino mathematics curriculum (please see Takeuchi, in press). In order to address this issue, one of the workshop themes was set out to collectively reflect on their everyday practices involving mathematics. The workshop was video recorded, content-logged, and transcribed in part. For this paper, I will introduce narrative descriptions generated based on video-recorded interactions and interviews.

In order to examine how children understood the concepts learned at home, in the children's interview, I included a modified word problem used for PISA 2009 assessment on the international currency, which asked to convert 35,000 Japanese yen to the Philippine peso (at the exchange rate: 1 YEN=0.52PHP).

Results

In this section, I will first introduce transnational families' mathematical practices focusing on calculating international currency conversion. I will then show how children applied the concepts learned at home, in order to solve a word problem.

Parents' Everyday Mathematical Practices: Calculating International Currency Conversion

During the workshops with parents, the participants and I explored some of the mathematical practices that they engaged in their everyday lives. One of the commonly reported practices was calculating international currency conversions. Five Filipino mothers attended the first workshop and all of them stated that they would constantly engage in computing international currency conversions. All the Filipino mothers I interviewed said that they were from a big family of lower SES and financially supporting their family was the main reason they initially came to Japan. Many of them were still sending money back to their family members in the Philippines.

When converting between the Japanese yen and the Philippine peso, participants had a strategy of doubling the Philippine pesos (to convert to yen) and halving yen (to convert to Filipino pesos), to get an approximate value. The following narrative description of the workshop shows this point.

> A researcher asked an average price of a picture book in the Philippines and participants answered "About 300 pesos. They are cheaper." A researcher asked, "Then, how much would that be in Japanese yen?" Evelyn and Michelle in unison said "double it." Iren said "600 yen." A researcher said, "Then, can we say 1 yen = 0.5 peso?" Multiple participants immediately responded, "That was before." Janice said "It's now 1 yen = 0.45 peso."

The subsequent conversation addressed the meaning of this fluctuation. Filipino mothers used common sense reasoning, which is strongly connected to their everyday experiences. The conversation described in the following narrative depicts some of the ways in which Filipino mothers answered the question, "what does this change in conversion rate mean to you?"

> Irene said, "For us, if the peso is 0.5, it's good for us and it's good for my family in the Philippines too." Everlyn said, "In my case, I send 100,000 yen (note: approximately $1,000 USD) but I need to add 10,000 yen to fill the loss. So, for my family in the Philippines, the price is the same."

As seen in this narrative description, participants presented the informal knowledge of doubling and halving to convert between the Philippine peso and Japanese yen. They also demonstrated an understanding of the concept of fluctuating currencies and the consequences of this fluctuation.

Children's Mathematical Literacy: International Currency Conversion

Half of the child participants reported that they learned about calculating international currency conversions and talking about time differences since when they were young (as young as Grade 2), because they are the practices specific to transnational families. For example, one parent, Grace, explained, "When we went abroad, my son asked me how to calculate the currency. Because he's very good at managing money, so he's interested." On the other hand, some parent participants said that they would not teach children these practices. A parent, Christine, said, "At home, I don't teach my kids anything about the Philippines."

When given a word problem that requires understanding of international currencies, two Grade 6 participants accurately solved the word problem. Four other participants reported that they knew the doubling and halving strategy to covert Japanese yen to the Philippine peso but could not complete the word problem. The majority of students (five out of six students) who demonstrated partial or complete problem solving were those who learned about international currencies at home, from their mothers.

Grade 6 students who solved the problem performed beyond the grade level expectation, as the original PISA problem targeted for Grade 9 students. The following excerpt describes how a Grade 6 student, Mary, engaged in this problem.

> Looking at the word problem, Mary was mumbling, "I know about the exchange rate but I don't know how to solve this." She looked at the problem for a while and suddenly said, "I got it." She then wrote down vertically "35000 yen = ? 1 yen=0.52." She stared at what she wrote for a while and said, "Got it." She wrote "35000 x 0.52=" She then identified the answer, 182,000 pesos.

This example implies that the informal knowledge of doubling and halving for converting two currencies could be used to solve a word problem used at school. In contrast, those who reported not having learned about international currencies at home tended not to be able to interpret the meaning of the word problem, even when they were able to decode its texts.

Discussion and Conclusion

This paper highlighted Filipino mothers' mathematical understanding, attached to their everyday practices. By drawing from children's interviews, I explored the possibility of connecting non-dominant students' mathematical practices at home with their development of mathematical literacy in school. This finding is particularly significant to the discussion on how to design educational practices which can meaningfully bridge out-of-school resources to in-school learning by considering non-dominant students' and their parents' positionality (Gutiérrez, 2013). These Filipino mothers raising children in Japan perceived their mathematical resources to be less valuable, compared to the school knowledge. This positionality was internalized to their children, who also perceived their mothers' mathematical knowledge to be less valuable.

As previously discussed, countering the deficit views toward non-dominant students will be an essential challenge to create more equitable learning opportunities in mathematics education

(Gutiérrez, 2007; Moschkovich, 2007). This study highlights the mathematical understandings of non-dominant parents and students, focusing on everyday mathematical practices that are familiar to them. As indicated through children's interviews, there is a potential that informal mathematical knowledge can facilitate mathematical literacy, for instance, in PISA assessments. To further draw from non-dominant parents' and children's expertise identified in this paper, designing a school-based lesson to bridge in and out-of-school practices will be necessary as global mobility increases worldwide.

In this paper, we discuss students' images of mathematics constructed through their experiences of school mathematics learning. We draw from data collected within our project, which investigates students' experiences learning mathematics in Canadian schools and the ways that these experiences contribute to students' images of mathematics and their mathematical identities. In doing so, we point to the ways in which schools engender a particular image of mathematics for students. We conclude by positioning the students' images of mathematics with respect to the mathematics curriculum and teaching practices in schools.

Keywords: Affect and Beliefs; Curriculum; Elementary School Education; Middle School Education

Purpose of the Study

In this paper, we explore images of mathematics held by Kindergarten to Grade 9 students in Canada. We examine data collected in one Canadian province (Alberta) and relate our findings to different groups' images of mathematics, as documented in the literature, and to the local curriculum guiding teaching practice in the participants' jurisdiction. From this analysis, we examine ways in which particular images of mathematics are developed through students' experiences in schools.

Theoretical Framework

The theoretical frame underlying this research is enactivism—a theory of embodied cognition that emphasizes the interrelationship of cognition and emotion in learning and that troubles the positioning of self and identity as purely individual phenomena (Kieren & Sookochoff, 1999; Maturana & Varela, 1992). Learning in this frame is seen as reciprocal activity—the teacher brings forth a world of significance with the learners within a cultural milieu (Maturana & Varela, 1992). Students' mathematical images and understandings are therefore not determined solely by the teacher or by the learner; rather, they are dependent on the kind of teaching experienced and the (mathematical) culture within which students are immersed. Educators have focused on better and better ways to transmit content, all the while forgetting that the content is not primarily what the students have been learning. Instead, we suggest that they have been learning a culture of mathematics—a particular vision of, and way to be with, mathematics. Our frame, then, prompts us to seek to understand how students come to have particular relationships with mathematics and what mathematics means to them.

Review of the Literature: Images of Mathematics

Images of Mathematics in the Media

Western media tend to portray mathematics as a difficult subject only understood by a select few who are often portrayed in negative, stereotypical ways, such as being socially inept, unattractive, and mentally ill related to their obsession with mathematics (Mendick, Epstein, & Moreau, 2007). Mathematics is usually portrayed narrowly, typically as numbers and arithmetic (e.g., basic operations, counting) or as financial mathematics (e.g., money, consumerism) (Hall, 2013). Other researchers' explorations of popular culture representations of mathematics and mathematicians have found mathematics portrayed as "a secret language, possibly a code, which is difficult to 'crack'" (Epstein, Mendick, & Moreau, 2010, p. 49) and only occasionally as beautiful or utilitarian (e.g., used to solve crimes).

Mathematicians' Images of Mathematics

Many mathematicians have discussed their views of mathematics. For instance, Furinghetti (1993) argues that people's views of mathematics are almost wholly based on their in-school experiences, and that in-school experiences must therefore portray mathematics as a set of human activities that are highly related to "real world" experiences. The subtitle of Lockhart's (2009) book, *A Mathematician's Lament,* declares mathematics to be "our most fascinating and imaginative art-form." Similarly, Taylor (2014) notes that mathematics is that which is "eternal and has beauty and structure to die for" (p. 34).

Elementary and Secondary Students' Images of Mathematics

Research regarding elementary and secondary school students' views tends to focus on students' feelings about mathematics, as opposed to their views on what mathematics is. Perkkilä and Aarnos (2009) addressed the latter topic by exploring the views of Finnish children, aged six to eight, by asking them to draw themselves in the "land of mathematics." The findings indicate that students view mathematics as a solitary pursuit involving only certain types of mathematics. Young-Loveridge, Taylor, Sharma, and Hawera (2006) found that students tended to view mathematics as being related to number and/or operations, as opposed to other topics.

Methodology and Research Design

The data on which we focus for this paper were gathered in the province of Alberta, which is located in Western Canada. The study's participants are Kindergarten to Grade 12 students, post-secondary students, and members of the general public, but we focus here on data collected in the first phase of the study, which includes students from Kindergarten to Grade 9. Forms of data include semi-structured interviews, drawings (that represent participants' ideas about what mathematics is and their feelings when doing mathematics), and written and oral mathematics autobiographies (accounts of participants' histories of learning mathematics).

To date, 94 interviews with Kindergarten to Grade 9 students (41 girls and 53 boys) have been conducted. In order to reveal students' images of mathematics, in this paper we focus primarily on data related to one of the interview questions: "When you hear the word mathematics, what images come to your mind?" These data are considered with supplementary data that further explain and explore participants' responses. Elsewhere (e.g., Hall, Towers, & Martin, 2015), we explore other aspects of the data.

All of the interviews were transcribed verbatim. To answer the aforementioned question, the data were analyzed through emergent coding, primarily using in vivo coding to stay as close as possible to participants' own words. Then, codes with more than one response were entered into a Wordle, a visual representation of response frequencies (i.e., a larger font size indicates a more frequent response). To explain and contextualize this interpretation of the data, we supplemented our analysis by drawing on additional information from the student interviews.

Findings

As shown in the Wordle in Figure 1, the participants' images of mathematics were narrowly focused on number sense and numeration.

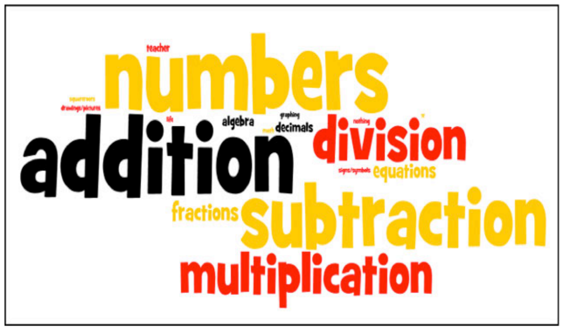

Figure 1: Wordle Representation of the Students' Responses

Responses aligning with the top five categories of response—numbers and the four basic operations—were ten- to twenty-fold more common than most of the other responses. Even the next most common responses, such as "fractions" and "equations," still align with this mathematical topic area. This pattern was observed from Kindergarten through to Grade 9 students. For example, Kindergarten students described mathematics as: "Numbers, five and six and stuff," or "How many numbers makes more numbers." Primary grade elementary students described mathematics as: "Adding and subtracting," and "Counting." Similarly, upper-grade elementary students depicted mathematics as: "Like, numbers and letters and, like, the adding and subtracting signs and, like, the multiplying and dividing signs and all that stuff," and "Numbers and additions, subtraction, multiplication, division." This tendency to associate mathematics with numbers and the basic operations was common across all grade levels.
