# History of PME

The International Group for the Psychology of Mathematics Education came into existence at the Third International Congress on Mathematical Education (ICME-3) in Karlsruhe, Germany in 1976. It is affiliated with the International Commission for Mathematical Instruction.

# Goals of PME-NA

The major goals of the North American Chapter of the International Group for the Psychology of Mathematics Education are:
1. To promote international contacts and the exchange of scientific information in the psychology of mathematics education.
2. To promote and stimulate interdisciplinary research in the aforesaid area, with the cooperation of psychologists, mathematicians, and mathematics teachers.
3. To further a deeper and better understanding of the psychological aspects of teaching and learning mathematics and the implications thereof.

# Preface

These Proceedings are the product of the 31st Annual Conference of the North American Chapter of the International Group for the Psychology of Mathematics Education held in Atlanta, Georgia, September 23-26, 2009. They are a written record of the research presented at the conference.

The theme for the conference was *Embracing Diverse Perspectives*, an appropriate one for Atlanta as a home to Dr. Martin Luther King, Jr. and the civil rights movement in the USA. This theme, which speaks to meeting the needs of all learners in mathematics education, is a worthy goal and researching issues around this goal is of critical importance.

*Lynn C. Hart*
*Conference Co-Chair*

We are pleased to present the Proceedings for the 31st Annual Meeting of PME-NA. The Proceedings CD includes 2 plenary papers, 67 research reports, 113 brief research reports, 42 posters, and 9 working group papers. Users can access these papers by selecting specific authors or particular topics. Additionally, users can view all conference papers in a book format. Editing the Proceedings has been a great opportunity, and I would like to thank my co-editors, David Stinson and Shonda Lemons-Smith, for their significant efforts in the editing process.

# ALGEBRA IS SYMBOLIC[1]

Jeremy Kilpatrick
University of Georgia
jkilpat@uga.edu

*The symbolic nature of algebra is addressed from three angles: branch of mathematics, object of curriculum, and theme of research. As a branch of mathematics, algebra deals in symbols, and their manipulation poses sometimes daunting problems of learning and teaching. As an object of the mathematics curriculum, algebra symbolizes barrier and stepping-stone among other things. As a topic of research in mathematics education, algebra poses many of the problems of meaning and interpretation that mathematics itself poses, while allowing some special characteristics to be explored. Each angle has implications for researchers, and each touches on questions of diverse perspectives in our research.*

The title above as well as the paper that follows can be seen as a response to a doctoral student who a few months ago asked why algebra seems to be the only part of school mathematics that people are talking about these days. Certainly, algebra is much in the news.

Last year, for example, the California State Board of Education, by an 8 to 1 vote, approved a policy that as of 2011, all eighth graders in California public schools would be required to take the Algebra I course and the accompanying California Standards Test for Algebra I (Asimov, 2008). Algebra I has been a high school graduation requirement in California since 2004, but only about half of California students have been taking it in eighth grade. The others have been taking a test in general mathematics. Prompting the new policy was the ruling by the U.S. Department of Education in 2007 that the latter test was out of compliance with the No Child Left Behind Act because it measured no more than sixth- and seventh-grade mathematics content. Last December, the California School Boards Association and the Association of California School Administrators, joined by the state Superintendent of Public Instruction and the California Teachers Association, got an injunction to prevent the state board from implementing the Algebra I requirement (Garrett, 2009). Given California's continuing budget woes, it is difficult to see the policy being implemented anytime soon, but it certainly got people's attention.

As another example, how did the American Diploma Project (2004) decide on Algebra II to anchor its expectations for readiness in mathematics for college and the workplace? The Algebra II course was never intended to be a course for all students, let alone a requirement for high school graduation. Did research showing a correlation between completion of Algebra II and both college completion and employment in high-paying professional jobs (Adelman, 2006; Carnevale & Desrochers, 2003; Pelavin & Kane, 1990) lead people to make the causal inference that requiring Algebra II for high school graduation would send everyone on to college or into those jobs?

Finally, one has to wonder why the President's executive order of April 18, 2006, establishing the National Mathematics Advisory Panel (2008) contained the following, as the first item on which the panel was to make recommendations:

> "(a) The critical skills and skill progressions for students to acquire competence in algebra and readiness for higher levels of mathematics" (p. 71).

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

Did George W. Bush, having decided that he needed to convene a panel to advise him on how the United States might implement the policy of fostering "greater knowledge of and improved performance in mathematics among American students" (p. 71), wake up one morning and say, "Competence in algebra ought to be the first order of business"? As Danny Martin (2008) notes, the president's choice of algebra was far from politically neutral, and one can raise questions about it: "Why algebra? Who decides? Algebra for whom and for what not-so-apparent purposes? Whose interests are served by these choices? Whose interests are not served?" (p. 393).

Algebra can be seen as symbolic in several ways. In this paper, I discuss three of those ways in an effort not simply to suggest why algebra seems to have taken center stage but also to relate that prominence to some of the diverse perspectives to be embraced in our research.

## Algebra as a Branch of Mathematics

Algebra is one of the main branches of mathematics, one that studies structure, relation, and quantity and in which symbols are used to represent numbers or members of a specified set. In the elementary algebra of school mathematics, the most prominent symbols are letters of the alphabet that are used, along with symbols for numbers, operations, and relations, to express relationships among known and unknown quantities. In fact, for many learners, algebra may appear to be entirely about symbolism. Because of its heavy use of alphabetic symbols, *x* in particular, school algebra has been facetiously defined as "the study of the 24th letter of the alphabet" (Mason, Graham, Pimm, & Gowar, 1985, p. 38).

The activities of school algebra have been characterized using various category schemes (e.g., Kilpatrick, Swafford, & Findell, 2001, pp. 294–295, note 4). Carolyn Kieran's (2004) recent formulation is as useful as any; she divides those activities into generational activity, transformational activity, and global/meta-level activity. Generational activity concerns the formation of the expressions and equations that are the objects of algebra; transformational activity involves rule-based manipulations of equivalent expressions and equations, and global/meta-level activity uses algebra as a tool for mathematical processes such as problem solving and reasoning that are not exclusive to algebra but that make it useful. Kieran devotes much of her discussion to the transformational activity of algebra, pointing out that technology is providing "a lens . . . for researching students' emergent conceptualisations of algebraic transformations" (p. 31). Two chapters in the 12th ICMI Study volume (Stacey, Chick, & Kendal, 2004, chs. 6 & 7) in which Kieran's paper appears deal with the learning of algebra in technological environments.

The increasing availability and use of computing technology in mathematics classes is complicating the role to be played by symbol manipulation in school algebra. The very term *symbol manipulation* seems pejorative, suggesting a procedure carried out by hand or machine and not involving thinking (for a sophisticated, generous analysis of manipulation in school mathematics, see Pimm, 1995). Because technology is now available to carry out algebraic symbol manipulation, questions are arising as to how much effort should be given to such manipulation when teaching algebra. The release in May 2009 of the Web site Wolfram|Alpha, an online service built on Mathematica that makes a supercharged computer algebra system (CAS) free and easily available to the general public, has touched off discussion, and some consternation, among high school and college mathematics teachers. They recognize that students will be able to use the system to solve any transformational problem of school or college algebra (Young, 2009). Given that potential, where is elementary algebra headed, or where should it be headed?

One perspective one might take is that of the technology enthusiast, arguing that CASs, and Wolfram|Alpha in particular, can be powerful teaching tools, removing the drudgery and mindlessness from much of algebra learning. Another perspective might be that of the technology skeptic, pointing out that we do not know very much about the potential cognitive benefits of symbol manipulation. Even Tony Ralston (2009), an unabashed proponent of doing away with pencil-and-paper algorithms in the arithmetic curriculum, argues that the question of what value there might be to teaching symbol manipulation in secondary school and college is not as simple as it is for elementary school arithmetic. It might also be pointed out that countries vary considerably in how much practice is given in symbol manipulation (Kendal & Stacey, 2004, p. 337) and that, even though the situation is changing, Asian countries that have been high-achieving in mathematics have long refrained from much technology use in mathematics instruction (p. 342). Perhaps there are benefits to manipulation by hand rather than by machine that are not so readily apparent.

Lest I be misunderstood, let me immediately add that I applaud efforts to incorporate CASs into curriculum materials in mathematics. But I also think it worthwhile to probe further and deeper into the effects of using CASs and other software. An example would be the work by French researchers (Artigue, 2002, 2005; Guin & Trouche, 2002; Laborde, 2001), who have been studying some of the ways in which technological tools can be integrated into teaching practice. Particularly relevant to the example of CASs is the work of Michèle Artigue and her colleagues, "who have developed the construct of *instrumental genesis:* the way in which users shape the artifacts they use, and the artifacts shape the users, and that yields instruments" (Artigue & Kilpatrick, 2008, p. 6). Artigue has noted that although one might expect a CAS to free students from the technical burden of symbol manipulation and thus allow them "to focus on conceptual thinking and understanding" (p. 8), she did not see that happening in the classrooms she observed in the early 1990s. She came to realize that mathematical techniques have "both an epistemic and a pragmatic value. A pragmatic value because they are operational; they produce results. And an epistemic value because they contribute to our understanding of the objects they involve" (p. 8). She could then see resistance to the use of technology in classrooms from a new perspective:

> The ordinary use of digital technology plays on the pragmatic power of technology, doing more things more quickly at the expense of its epistemic power. But what makes a technique legitimate at school cannot be its pragmatic power only, which is an essential difference between school and the outside world. Making technology legitimate and mathematically useful at school requires modes of integration that allow a reasonable balance between the pragmatic and the epistemic power of instrumented techniques. This balance . . . requires tasks and situations that cannot be reduced to simple adaptations of paper-and-pencil tasks. (p. 8)

The construct of instrumental genesis appears to have considerable promise for researchers looking into the ways in which technology is and is not being used in mathematics teaching.

My point in bringing technology into the discussion of symbol manipulation is to observe that every technology has both costs and benefits. Because researchers who are technology advocates are likely to be looking primarily for benefits, it is important to have some researchers with a different perspective looking at costs. This example illustrates the value for the research we do of promoting diversity in the perspectives we employ. Seen as a branch of mathematics, algebra may appear well defined, but research into its learning and teaching depends on the position from which the researcher views algebra and the symbols it uses.

## Algebra as an Object of Curriculum

Algebra is symbolic not merely in its use of symbols but also in the way, as a course or curriculum strand, it symbolizes academic success. School algebra is "higher" mathematics in a way that school arithmetic is not. A simplified metaphor for the school mathematics curriculum that I am fond of using portrays its justification as arising from the collision of two tectonic plates (Kilpatrick, 2003, pp. 319–322). The first plate developed within primary school education and treats mathematics as a tool for solving practical problems. The second plate developed within secondary and tertiary education; it arises from the liberal arts tradition and treats mathematics as a means of achieving intellectual growth. Over the centuries, the line separating the two curriculum plates has shifted considerably so that now it cuts across the grades, with mathematics in the primary grades taking on some of the intellectual character of higher mathematics, and secondary and tertiary mathematics becoming more oriented toward the solution of practical problems. Nevertheless, algebra has long been seen as justified primarily for its intellectual rather than its practical value. Recent efforts to teach algebra at all grades and to all students have run into stereotypic views of what the subject is and who should be learning it.

As a symbol, school algebra has many different interpretations. When Andrew Izsák and I wrote a history of algebra in the curriculum (Kilpatrick & Izsák, 2008), we took the following quotation as the epigraph because it captures so well how school algebra has been regarded for decades:

> If there is a heaven for school subjects, algebra will never go there. It is the one subject in the curriculum that has kept children from finishing high school, from developing their special interests and from enjoying much of their home study work. It has caused more family rows, more tears, more heartaches, and more sleepless nights than any other school subject. (Anonymous editorial writer quoted by Reeve, 1936, p. 2)

In this view, algebra is an evil force wreaking havoc across the land. In contrast, Fran Lebowitz (1981) advises, "Stand firm in your refusal to remain conscious during algebra. In real life, I assure you, there is no such thing as algebra" (p. 27).[2] Algebra does not exist outside school.

The title of the April 2000 issue of *Mathematics Education Dialogues*—"Algebra? A Gate! A Barrier! A Mystery!"—captures some of the varied symbolism attached to algebra. It has long been seen as a principal gatekeeper to educational and career opportunities, which is one reason the teaching and learning of algebra from kindergarten through Grade 12 was chosen by the RAND Mathematics Study Panel (2003) as one of three focus areas (along with teachers' mathematical knowledge for teaching and skills in teaching and learning mathematical thinking and problem solving) for a long-term research and development program, "three domains in which both proficiency and equity in proficiency present substantial challenges, and where past work would afford resources for some immediate progress" (p. xv). In recent years, Bob Moses (1994), through his Algebra Project, has been instrumental in shifting the dominant metaphor from gatekeeper to a new civil right for all:

> Algebra, once solely in place as the gatekeeper for higher math and the priesthood who gained access to it, now is the gatekeeper for citizenship; and people who don't have it are like the people who couldn't read and write in the industrial age. . . . [Lack of access to algebra] has become not a barrier to college entrance, but a barrier to citizenship.

That's the importance of algebra that has emerged with the new higher technology. (Moses & Cobb, 2001, p. 14)

Politicians, however, have not ordinarily looked on algebra as a civil right. For them, it is more likely to provide an opportunity for grandstanding. What better or cheaper way to "raise standards" and "promote reform" in school mathematics, and get applause while doing it, than to require students to take "algebra" regardless of what that might entail? The examples cited above from California, the American Diploma Project, and the executive order establishing the National Mathematics Advisory Panel all reflect political uses of algebra. George W. Bush's education advisor Tom Luce, who served on that panel while he was an Assistant Secretary of Education and currently heads up the National Math and Science Initiative, was one of the first to recommend that all students "take and pass algebra in eighth grade" (Luce & Thompson, 2005, p. 170), which may help explain how algebra landed at the top of the panel's agenda. Luce and his coauthor Lee Thompson characterized algebra as "the principal gatekeeper for more advanced math and science studies in high school" (p. 170)

In the public's eye, studies in algebra, along with "more advanced" mathematics, symbolize not just a hurdle but also accomplishment and validation. In L. Frank Baum's (1900/1999) book, *The Wonderful Wizard of Oz*, when the Scarecrow asks the Wizard for brains, he gets bran mixed with pins and needles ("a lot of bran-new brains"). In the movie version, in contrast, the Wizard hands out a diploma.[3] (The Tin Woodman gets a testimonial, and the Cowardly Lion gets a medal.) The writer Yip Harburg, who wrote the movie scene, said, "[I] devised the satiric and cynical idea of the Wizard handing out symbols because I was so aware of our lives being the images of things rather than the things themselves" (quoted in Harmetz, 1997, p. 58). In other words, symbols are our reality.

On receiving the diploma, the movie Scarecrow responds with a garbled version of the Pythagorean theorem: "The sum of the square roots of any two sides of an isosceles triangle is equal to the square root of the remaining side." Although the Scarecrow's "theorem" is more geometry than algebra, it makes my point: The Scarecrow does not get brains; instead, he gets a piece of paper. And rather than knowledge leading to certification, certification leads to knowledge. In popular culture, the important thing is not the algebra you have learned but the presence of "Algebra II" on your transcript.

As a curriculum object then, algebra, like the rest of school mathematics, has multiple symbolic meanings for learners, teachers, parents, politicians, and the public. Researchers should do more to recognize, explore, and attempt to understand those meanings. Research into the teaching and learning of mathematics that avoids attending to how the curriculum object is being interpreted by the participants in the educational encounter and the society in which they are situated is quite likely to yield useless or even invalid results.

## Algebra as a Topic of Research

Algebra is also symbolic as a topic of research into the teaching and learning of mathematics. As a presumably well-defined curriculum entity, algebra is studied by researchers around the world. Are they studying the same thing?

> Curriculum issues have apparently seemed relatively easy to discuss in international forums because they could be discussed in a manner that attended strongly to rather universal, mathematical characteristics and only weakly, if at all, to more local, sociopolitical characteristics. It is not surprising, therefore that the resulting conversations often bypassed subtle, yet important, curriculum issues related to variations

> in educational traditions and practices across countries. . . . To what extent can all important research questions be lifted out of the contextual details so that they can be considered within a broad international community of researchers? (Silver & Kilpatrick, 1994, pp. 249–250)

One characteristic that distinguishes researchers in the community of mathematics education from those outside that community who "use mathematics as a vehicle for their research into learning and instruction" (Kilpatrick, 1996, p. 33) is that the latter take mathematics as unproblematic, a black box whose performance characteristics can be studied without asking what is inside. In contrast, when mathematics education researchers study a topic like algebra, they do not—or should not—assume they know exactly what is being taught and how. An excellent example can be found in the chapter by Margaret Kendal and Kaye Stacey (2004) that ends the 12th ICMI Study volume. The chapter convincingly demonstrates that algebra is not the same school subject across educational jurisdictions. There are striking differences in who takes it; whether it is integrated or layered across years; how much emphasis is put on matters of generality and pattern; how much attention is given to symbolism, formalism, and abstraction; whether it is approached through functions and multiple representations; and what role is played by technology. Kendal and Stacey conclude, "Don't take your country's curriculum and approach to teaching algebra for granted and don't assume all other educational jurisdictions operate in a similar way—they conspicuously do not" (p. 345). Researchers interpreting national and international assessment studies involving algebra, therefore, should analyze how the term is being understood in the assessment items and how well that understanding applies to the issue in question (Kilpatrick, 2009; Kilpatrick, Mesa, & Sloane, 2007). Of course, that admonition applies equally well to other branches of school mathematics.

The National Mathematics Advisory Panel (2008) defined algebra in a conservative fashion with a list of what they deemed to be major topics of school algebra (Table 1, p. 16). They developed that list by reviewing state standards, current textbooks, 12th-grade objectives of the 2005 National Assessment of Educational Progress, the American Diploma Project's benchmarks, and the Singapore standards. Brian Greer (2008) characterizes the list of topics as

> a subset of what I learnt at grammar school in Northern Ireland nearly 50 years ago, with two exceptions, namely (a) fitting simple mathematical models to data, and (b) combinations and permutations, as applications of the binomial theorem and Pascal's Triangle. (p. 426)

Roschelle, Singleton, Sabelli, Pea, and Bransford (2008) point out:

> The Panel chose not to broadly and critically examine the relevance of (lowercase) algebra to modern economic life, its role in scientific activities, and its function in a highly technological world. Instead, the Panel defined Algebra I and Algebra II in the most conservative way (based on the intersection of the content of international curricula for such courses) and then further restricted its focus to "addressing the teaching and learning of mathematics from preschool to Grade 8 or so." (p. 610)

Pat Thompson (2008) observes that "the vision of algebra reflected in the Panel's content recommendations is a skills-based foundation for advanced symbolic manipulation and abstract algebra (especially the algebra of polynomial forms)" (p. 585).

The National Mathematics Advisory Panel (2008) notes in a footnote that their list of major topics "is meant as a catalog for coverage, not as a template for how courses should be sequenced or texts should be written" (p. 15). By cataloging topic coverage rather than suggesting approaches or offering interpretations, the panel assumed that school algebra is school algebra now and forever here and everywhere. Listing a topic such as "logarithmic functions" without considering how it might be introduced, understood, or used is equivalent to taking algebra itself as a black box. Also, as Greer (2008) noted, by ignoring the work of researchers such as Carolyn Kieran and Jim Kaput, the panel missed the opportunity to recommend "a more productive approach to the teaching of school algebra" (p. 424).

The draft mathematics standards from the Common Core Standards project of the National Governors Association and the Council of Chief State School Officers (Cavanagh & Gewertz, 2009) that were unexpectedly released in July suggest that, so far, that project is providing some context for the treatment of topics and not just a list. The argument can still be made, however, that the inclusion of more mathematics education researchers in the standards development process, as well as more attention to the work they do, would yield a better product. Anyone who has taken school algebra as a research topic should understand its problematic quality.

## Diversity, Balance, and Quality

By taking the symbolic nature of algebra as a focus, I have attempted to suggest how important it is to embrace diverse perspectives in conducting our research. Diversity in background, preparation, outlook, and approach enriches the research community. Diverse approaches, in particular, make our research useful for different purposes (National Council of Teachers of Mathematics Research Committee, 2009). But diversity is not all we need.

Diversity should be accompanied by balance. Enthusiastic ideologues are important; they are the ones who push us to try new things. Also important, however, are skeptical critics, and the latter always appear to be in short supply. Speaking for myself, I tend to avoid bandwagons, whether they concern problem solving (Kilpatrick, 1981), constructivism (Kilpatrick, 1996), or "algebra for all." It is fine if some of us want to hop on the current bandwagon, but it would not be good if all of us were there. To change the metaphor, there is little use in having a diverse set of passengers if all of them sit on the same side of the boat. We need "a more balanced perspective on research and the variety of ways it can be conducted" (p. 41).

Diversity and balance, of course, need to be accompanied by quality in what we do. As Heather Hill and Jeff Shih (2009) point out, "high-quality research" in education is a contentious construct, one that people continue to debate. Nonetheless, I think the community of mathematics education researchers has taken some important strides toward consensus regarding quality over the past several decades even if we continue to disagree regarding details.

A heartening sign that we are achieving diversity in research method comes from a recent study by Lynn Hart and her colleagues (Hart, Smith, Swars, & Smith, 2009). They examined 710 articles published from 1995 to 2005 that reported research in mathematics education and found that although, not surprisingly to anyone acquainted with the recent literature, qualitative studies were the most common, studies using mixed methods were the next most common, and a nontrivial number were quantitative studies. Hart et al. looked at six journals; Figure 1 shows the results for the *Journal for Research in Mathematics Education (JRME)*, which are not too different from those for the journals taken together, although the *JRME* had by far the most articles that used mixed methods with inferential statistics. The classification of research as qualitative, quantitative, or mixed turned out to present some serious problems of interpretation. In particular, studies using mixed methods were seldom identified as such in the report of the study. Although they did not find clear trends in the fraction of studies using mixed methods, Hart et al. expect that more high-quality mixed methods research will be published in the coming years, seeing mixed methods as possibly "an appropriate response to calls for greater generalizability of results while maintaining enough detail about the processes of teaching and learning to be valid and useful" (p. 39).

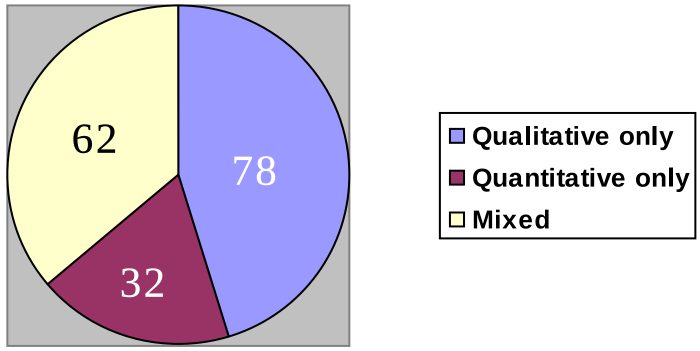

*Figure 1.* Frequencies of methods used in *Journal for Research in Mathematics Education* articles from 1995 to 2005. (*Source:* Hart et al., 2009, p. 34)

Before celebrating the diversity of methods to be found in the research literature in mathematics education, one should note that Hart et al. (2009) found much that could have been improved in the way researchers using mixed methods report their results. Hill and Shih (2009), who looked at statistical and mixed method reports in the *JRME* from 1997 to 2006 and judged the adequacy of the statistical treatment of data, also found considerable room for improvement in the quality of both analytic techniques and reporting. So we are not quite there yet.

School algebra is receiving more than its usual share of attention these days for reasons that are largely beyond the control of the North American community of researchers in mathematics education. As I have tried to suggest in this paper, they have some distinctive perspectives to contribute to the discussion. Like all research, theirs has its flaws and shortcomings. But to ignore both the research and the researchers is to limit the possibility of improving the teaching and learning of mathematics.

## Endnotes

# LITTLE BLACK BOYS AND LITTLE BLACK GIRLS: HOW DO MATHEMATICS EDUCATION RESEARCH AND POLICY EMBRACE THEM?

Danny Bernard Martin
University of Illinois at Chicago
dbmartin@uic.edu

Come round by my side and I'll sing you a song.
I'll sing it so softly, it'll do no one wrong.
On Birmingham Sunday the blood ran like wine,
And the choirs kept singing of Freedom.
That cold autumn morning no eyes saw the sun,
And Addie Mae Collins, her number was one.
At an old Baptist church there was no need to run.
And the choirs kept singing of Freedom,
The clouds they were grey and the autumn winds blew,
And Denise McNair brought the number to two.
The falcon of death was a creature they knew,
And the choirs kept singing of Freedom,
The church it was crowded, but no one could see
That Cynthia Wesley's dark number was three.
Her prayers and her feelings would shame you and me.
And the choirs kept singing of Freedom.
Young Carol Robertson entered the door
And the number her killers had given was four.
She asked for a blessing but asked for no more,
And the choirs kept singing of Freedom...[1]

## Preamble

The theme of this year's conference is *Embracing Diverse Perspectives*. This theme clearly represents an invitation for scholars in the field to consider and appreciate a wide range of theoretical and methodological perspectives on mathematics learning and participation, including those perspectives that diverge from what might be called conventional or mainstream thinking.

In my view, the conference theme also provides an opportunity to raise questions about how mathematics education research and policy have embraced and served the diversity of students who show up in mathematics classrooms, especially those students who must learn mathematics while simultaneously trying to negotiate the most difficult and oppressive life circumstances. These are often the same students who have been systematically and deliberately underserved in so many other societal and institutional contexts.

In this paper, and my accompanying plenary address, I take advantage of the conference theme to do two things that rarely occur in mainstream mathematics education contexts. First, I put Black children and their experiences at the center of the discussion. I share my perspective on how I believe mathematics education has and has not served these students. In many ways,

[1] Excerpted lyrics from the song *Birmingham Sunday* written by Richard Fariña and performed by Joan Baez.

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

Black children serve as canaries in the coal mine. If we have not, and cannot, do right by these children, it is extremely difficult for me to believe that we can accomplish the goals inherent in the conference theme.

My focus on Black children is not an exclusionary move; taking a *pro*-Black-child stance should not be interpreted as a stance *against* any other group of children given my sincere interest in insuring that all children experience mathematics learning and teaching in relevant and meaningful ways. However, I do believe that, in the context of discussing *diversity*, we should never lose sight of particularity. Similarly, when discussing particularity, we should never lose sight of diversity. Therefore, while it is important to discuss the needs of Black children as *children*, it is equally important to prioritize their needs as *Black* children (e.g., Hale, 2001; Lomotey, 1990; Martin, 2007; Perry, Steele, & Hilliard, 2003; Shujaa, 1994).

Regarding these last points, we should not lose sight of the fact that there is great diversity among Black children in the United States (e.g., Waters, 2001). There is no singular, essential characterization. They come from varied socioeconomic and family backgrounds and respond to schooling and education in multiple ways. Yet, there is a collective history and collective condition of Blacks in the United States that is clearly distinguished from other social groups. It is this history that gives partial meaning to what it has meant, and what it currently means, to be Black in America.

My focus on Black children in the United States does not deny that they are forever linked to other Blacks in the African *diaspora*, including Afro-Latins in the central and southern Americas, Afro-Carribeans in the West Indies, the Sidis in India, the Aboriginals in Australia, Afro-Arabs in the Middle East, and so on. These *diasporic* relations remind us that Black children in the United States are also children of the world. It is unfortunate that some policy makers and education researchers often lose sight of this fact by confining black children's existence to poverty-ridden communities, broken families, and low-quality schools and easily dismissing the historical and structural forces that create and maintain those conditions (D'Souza, 1991; McWhorter, 2001; Steele, 1990; S. Thernstrom & A. Thernstrom, 1997; A. Thernstrom & S. Thernstrom, 2004). Moreover, there is a disturbing trend in society that attempts to strip Black children of their childlike qualities altogether by using such labels as thugs, urban terrorists, predators, threats to society, and endangered species. Ignoring structural considerations, we are asked to believe that genetic, cultural, and intellectual inferiority account for these conditions (D'Souza, 1991; McWhorter, 2001; Steele, 1990; S. Thernstrom & A. Thernstrom, 1997; A. Thernstrom & S. Thernstrom, 2004).

While it is true that disproportionate numbers of Black children here and around the world continue to experience life conditions that not only limit their opportunities to learn but that also threaten their very lives, this is not the end of the story. It is equally true that, wherever they live and learn and no matter what their circumstances, Black children are also among the most resilient (Bowman & Howard, 1985; Gordon. 1995; McGee, 2009; Miller & MacIntosh, 1999; Sanders, 1997; Spencer, Cole, Dupree, Glymph, & Pierre, 1993). We need more studies of this resilience in mathematics education (e.g., Ellington, 2006; McGee, 2009).

Moreover, Black children in the U.S. are growing up in a time when geopolitical boundaries are being blurred by technology and globalization. Social media such as YouTube and MySpace are not only responsible for exporting and importing culture, ideology, protest, and revolution but also for exposing the human condition and helping Black children to contextualize their lives vis-à-vis the conditions in which other children live and learn. Black children can see that the struggle for a more humane existence is not confined to the boundaries of their own neighborhoods or cities.

Within this global perspective, the implication for Black children's mathematical education is clear:

> … meaningful mathematics education for African-American children should not only help them function in their local contexts in U.S. society but should also help them function as citizens of the globe, to function across boundaries of difference, and to recognize similarities in human conditions among people who wage the struggle against oppression" (Martin & McGee, 2009, p. 216).

This view on the aims and goals of mathematics education stands in sharp contrast to policy discussions that frame mathematics participation for Black children in terms of workforce participation and the preservation of U.S. international competitiveness (Committee on Science, Engineering, and Public Policy, 2007; Domestic Policy Council, 2006; National Research Council, 1989; National Science Board, 2003; U.S. Department of Education, 1997, 2008). While these may be worthy goals, they still reflect crude commodifications and self-serving concerns for Black learners, concerns that are typically couched in the easy-to-swallow language of equity and diversity (Gutstein, 2008; Martin, 2003; Martin 2009a, 2009c; Martin & McGee, 2009).

My own view is that even if larger numbers of Black Americans were to find themselves in the mathematics and engineering pipeline, they would only be absorbed into the workforce up to the point of not threatening the status and well-being of white workers. Examination of the public debate reveals the angst, resistance, and cries of racial preference that are often associated with the introduction of just one qualified African American into a given context even when that context has been historically all-white (Bonilla-Silva, 2003, 2005).

The second thing I do in this paper—in addition to centering the discussion on Black children—is to argue for racism and racialization (Miles, 1988) as central concerns in mathematics learning and participation and as lenses through which to critique mathematics education research and policy. I do so knowing that discussions of race[2] and racism are likely to produce knee-jerk negative reactions from those who have adopted a color-blind ideology and who believe that we now live in a post-racial society in which race and racism are no longer relevant, despite great evidence to the contrary (Bonilla-Silva, 2003, 2005; Macedo & Gounari, 2006; Omi & Winant, 1994; Winant, 2004). I do so also knowing that many discussions of race and racism are unproductive because they tend to aim for simplicity in framing and in solution.

In this discussion, I acknowledge the complexities of race and move well beyond the causal-factor approach utilized in mainstream research. For example, I agree with Essed (2002) who stated:

> "Race" is an *ideological construction*, and not just a social construction, because the idea of "race" has never existed outside a framework of group interest. As part of a nineteenth pseudoscientific theory, as well as in contemporary "popular" thinking, the notion of "race" is inherently part of a "model" of asymmetrically organized "races" in which Whites rank higher than "non-Whites." Furthermore, racism is a *structure* because racial

[2] Clearly, my focus on race does not diminish the importance of race, class, and gender intersections.

> and ethnic dominance exists in and is reproduced by the system through the formulation and applications of rules, laws, and regulations and through access to and the allocation of resources. Finally, racism is a *process* because structures and ideologies do not exist outside the everyday practices through which they are created and confirmed. (p. 185)

I draw on sociological theory in further characterizing racism as “the routinized outcome of practices that create or reproduce hierarchical social structures based on essentialized racial categories” (Winant, 2004, p. 126). As noted by Macedo and Gounari (2006), “Racism includes a set of ideologies, discourses, discursive practices, institutions, and vocabularies” (p. 4). These characterizations are important because they overcome the tendency to reduce racism to individual psychology (Omi & Winant, 1994). Instead, these characterizations acknowledge that racism operates at many levels—everyday, institutional, and structural—and involves all the actors, practices, and institutions in a given society.

Acknowledging sociological findings that race and racial categories are politically contested in any given sociohistorical and geopolitical context—through a process called *racial formation*[3] (Omi & Winant, 1994)—and also recognizing that racism is a global phenomenon (Macedo & Gounari, 2006), my references to race and racism in this paper is to their everyday, institutional, and structural instantiations in the United States (Bonilla-Silva, 1997; Essed, 2002). These peculiar and particular manifestations have ranged from (a) native American extermination, chattel slavery, Jim Crow apartheid, Chinese exclusion, and Japanese internment to (b) post-civil rights color-blindness to (c) a so-called post-racial context that allows for the passage of the Secure Fence Act which calls for 700 miles of physical and virtual fencing along the U.S.-Mexican border; a post-racial context that allows for the burning of Black churches and synagogues; a post-racial context that condones racial profiling of Arab Americans and Muslims; a post-racial context that allows a Republican activist to compare the First Lady of the United States to a gorilla and then issue a non-apology apology; a post-racial context that encourages a lunatic white supremacist to open fire in the Holocaust museum because of his hatred for Jews and Blacks (Macedo & Gounari, 2006).

The history and ubiquity of race offer some evidence for law professor Derrick Bell’s haunting claim that racism is permanent (Bell, 1993). This ubiquity also begs the question of how, not if, (mis)understandings of race and racism influence the ideologies and epistemologies found in mathematics education. I push this point further by asking how do race and racism structure the very nature of the mathematics education enterprise?

On one hand, there is the possibility that mathematics education is a race-neutral domain, free from racial contestation, stratification, and hierarchies, and different in character than all other racialized societal contexts. If so, how do we reconcile this neutral character with the racialized inequities faced outside of the domain by many of the students our work is intended to help?

On the other hand, I suggest that a structural analysis would show that mathematics education research and policy not only help to produce racial representations and meanings but also are themselves informed by societal meanings and representations of race. Not only do research and scholarly interpretations of children’s mathematical behavior serve to inform societal beliefs about race and racial categories, but race-based beliefs about children also serve

[3] Omi & Winant (2005, p. 16) define *racial formation* as the process by which social, economic, and political forces determine the content and importance of racial categories, and by which they are in turn shaped by racial meanings.

to inform mathematics education research and policy. Beliefs in so-called *racial* achievement gaps and attempts to close of such gaps by raising Black children to the level of white children exemplify these beliefs.

Moreover, a structural analysis would reveal that the pervasiveness whiteness—represented numerically, ideologically, epistemologically, and in material power—which characterizes mathematics education research and policy contexts bears a strong family resemblance to the manifestations of whiteness found in other societal contexts. In my view, the enterprise of mathematics education is no different than other racialized spaces and should be subjected to the same anti-racist scrutiny, especially as it pertains to the well-being of Black children.

It is in the ways just described that mathematics education research and policy can be implicated in New Right, conservative, liberal, and neoliberal *racial projects* (Omi & Winant, 1994; Winant, 2004) that shape larger racial dynamics. According to the sociological literature, a racial project is "simultaneously an interpretation, representation, or explanation of racial dynamics and an effort to reorganize or redistribute resources along particular racial lines. Racial projects connect what race means in a particular discursive practice and the ways in which both social structures and everyday experiences are racially organized, based upon that meaning" (Omi & Winant, 1994, p. 56). Consider this partial history of the *neoliberal* racial project:

> In order to win the [1992] election and reinvigorate the once-powerful Democratic coalition, Bill Clinton believed he needed to attract white working class voters—the "Reagan Democrats." His appeal was based on lessons learned from the right, lessons about race. Pragmatic liberals in the Democratic camp proposed a more activist social policy emphasizing greater state investment in job creation, education, and infrastructure development. But they conspicuously avoided discussing racial matters such as residential segregation or discrimination. The Democrats' approach, which harked back to Kennedy's remark that "A rising tide lifts all boats," aspired to "universalistic" rather than "group-specific" reforms. Thus the surprising shift in U.S. racial politics was not… the Republican analysis which placed blame on the racially defined minority poor and the welfare policies which has supposedly taught them irresponsibility and dependency. The "surprise" was rather the Democratic retreat from race and the party's limited but real adoption of Republican racial politics, with their support for "universalism" and their rejection of "race-specific" policies.…. This developing neoliberal project seeks to rearticulate the neoconservative and new right racial projects of the Reagan-Bush years in a centrist framework of moderate redistribution and cultural universalism. Neoliberals deliberately try to avoid racial themes, both because they fear the divisiveness and polarization which characterized the racial reaction, and because they mistrust the "identity politics" whose origins lie in the 1960s…. In its *signifying* or representational dimension, the neoliberal project avoids (as far as possible) framing issues or identities racially. Neoliberals argue that addressing social policy or political discourse overtly to matters of race simply serves to distract, or even hinder, the kinds of reforms which could most directly benefit racially defined minorities. To focus too much attention on race tends to fuel demagogy and separatism, and this exacerbates the very difficulties which much racial discourse has ostensibly been intended to solve. To speak of race is to enter a terrain where racism is hard to avoid. Better to address racism by ignoring race, at least publicly (Omi & Winant, 1994, pp. 146-148)

By way of example, recent reform movements and policy documents in mathematics education can be analyzed for their contributions to these racial projects. *Mathematics for All*, as one of the most egalitarian movements in the field, seeks to reorganize and redistribute access to mathematics by appealing to liberalism. In the liberal project, there is an underlying appeal to white middle- and upper-class consciousness to convince them that others must now share in the opportunities that they have long enjoyed (Winant, 2004). It also aligns well with the neoliberal racial project in that universal programs (i.e. *Algebra for All*) that work for all students are promoted in lieu of group-specific efforts and objectives (Winant, 2004). It is in this way that *Mathematics for All* rhetoric is about assimilation. In classical assimilation theory, assimilation is defined as “the decline, and at its endpoint the disappearance, of an ethnic/racial distinction and the cultural and social differences that express it” (Alba & Nee, 1997, p. 863).

Viewed more critically, *Mathematics for All* is also about nationalism because it appeals to U.S. international competitiveness in relation to real and perceived foreign threats (Gutstein, 2008; Martin, 2003, 2009c). Like assimilation, nationalism seeks to erase meaningful cultural differences among social groups and to silence internal racial identity politics in favor of collectivism.

So, while *Mathematics for All* has an equity-oriented veneer, it is clear to me that there are other ideologies at play that are not based on moral and humanistic concern for those who are marginalized in mathematics. In a paper titled *Hidden Assumptions and Unaddressed Questions in Mathematics for All Rhetoric* (Martin, 2003), I offer additional critique of this movement.

Similarly, a critical analysis of the *Final Report of the National Mathematics Advisory Panel* (U.S. Department of Education, 2008) report reveals how it, too, contributes to racial projects. In this report, the learning of mathematics in U.S. schools is linked directly to the preservation of national security. The third paragraph of the Panel’s *Executive Summary* is very clear in making this link:

> Much of the commentary on mathematics and science in the United States focuses on national economic competitiveness and the economic well-being of citizens and enterprises. There is reason enough for concern about these matters, but it is yet more fundamental to recognize that the safety of the nation and the quality of life—not just the prosperity of the nation—are at issue. (p. xi)

Considering the political origins of the National Math Panel, these security concerns can be linked to conservative Republican ideology, Islamophobia, anti-Muslim sentiments, and the globalization of U.S. racism and white privilege (Macedo & Gounari, 2006; Winant, 2004).

Beyond the policy arena, the frequent use of a race-comparative approach to examine mathematics achievement differences among U.S. students makes its own contribution to racial projects. This approach supports the normalization of whiteness and the subordination of poor, African American, Latino, and Native American students. Specifically, this approach has served to reify a racial hierarchy of mathematics ability that is now taken for granted by the general public and by many scholars and policy makers (Martin, 2009a, 2009c). Belief in this hierarchy contributes to the interpretation and representation of race and racial categories by supporting negative societal meanings for what it means to be poor, Black, Latino, and Native American. For example, in most of these studies, the resulting analyses often suggest that to *be Black* is to be mathematically illiterate and inferior relative to those who are identified as White and Asian.

## Researcher Identity

Having provided the extended preamble above, I do feel it is important to pause and provide a better sense of my motivation for raising these issues and where they fit into my life as a scholar. Readers who are familiar with my research and teaching know that my focus on Black children and issues of race and racialization is not a novelty for me. My efforts are not an attempt to jump on the equity and diversity bandwagons that have emerged in mathematics education over the last several years or an attempt to urbanize my research. Nor does my focus represent a sudden realization that it might be valuable to study the mathematical lives of Black children and to be explicit about attempts to construct them as less than ideal learners.

My research and teaching over the last twenty years have focused exclusively on the life and mathematical experiences of Black children and adults in school contexts ranging from middle school to community college. In my work, I have detailed aspects of their racial and mathematical socializations and characterized the identities they co-construct in light of their experiences. Moreover, rather than studying only underachievement and failure in mathematics, I have devoted a great deal of attention to documenting success and agency among African American children and adults. Up until a few years ago, little attention was given to this success and little was known about how students defined, achieved, and maintained it. My own studies have revealed a number of sociohistorical, community, school, and intrapersonal forces contributing to resilience and success in mathematics (Martin, 2000, 2006a, 2006b). This work has consistently highlighted issues of racism, racial identity, and racialization not because I impose these issues but because the participants in my research cite them over and over again as being both central and salient (Martin 2000, 2006a, 2006b, 2007, 2009a, 2009c).

So, although this paper has been composed to address the conference theme, it is clear that I also have a political agenda. This goes against the idea that research and scholarship should not drift towards advocacy. However, all research and scholarship are political. Moreover, the production of knowledge cannot be disconnected from who we are as people, what we have experienced, and what we believe. My multiple identities—racial, scholarly, mathematical, and otherwise—have informed, and continue to shape, my scholarly perspective. I am an African American through self and societal identification although these asserted and assigned identities do not always overlap. My own experiences with mathematics both mirror and diverge from those of other African Americans. Experiences with poverty and racism are not unfamiliar to me nor are experiences with academic and mathematics success.

I am also a scholar. I do not hesitate in identifying myself as an African American scholar in a field numerically dominated by white scholars. Identifying in this way does not limit or essentialize my perspective or discount the perspectives and experiences of others. Paraphrasing Supreme Court nominee Sonia Sotomayor:

> I would hope that a wise [African American man] with the richness of [his] experiences would more often than not reach a better conclusion than a white male who hasn't lived that life…. [However,] I… believe that we should not be so myopic as to believe that others of different experiences or backgrounds are incapable of understanding the values and needs of people from a different group. Many are so capable…. However, to understand takes time and effort, something that not all people are willing to give. For others, their experiences limit their ability to understand the experiences of others. Others simply do not care. Hence, one must accept the proposition that a difference there will be

by the presence of women and people of color. (http://feministlawprofessors.com/?p=10952)

In the remainder of this paper, I discuss Black children and issues of racism and racialization by structuring my comments around four inter-related topics which, admittedly, will be devoid of mathematics content[4] and may come across as sociological in nature, far afield of mathematics education.

First, I explore the meaning and significance of the title of this paper.

Second, I briefly discuss the representation of Black children in mainstream mathematics education research and policy so as to reveal the form and substance of these representations and to show how they have contributed to the construction of Black children as inferior to other children. Continued rhetoric around the so-called black-white or racial achievement gap is one example where Black children are told explicitly and matter of factly that they are inferior to white children.

Third, I briefly outline my own research theoretical perspective that conceptualizes mathematics learning and participation as racialized forms of experience, not just for African American children but also for all children. Within this perspective, I characterize mathematics education research and policy as instantiations of white institutional space, where pervasive myths and stereotypes about African American children have their genesis and are allowed to persist as common sense.

Finally, I present of a set of axioms for researching Black children and mathematics; these axioms have served as the foundation of my research and I believe they should inform all future work on Black children, helping to counter the masternarrative that has dominated discussions of these children.

## Little Black Boys and Little Black Girls?

My focus on little Black boys and little Black girls is simultaneously historical, present-day literal, and metaphorical. First, it recognizes the historical significance of this conference taking place in Atlanta, a key city in the United States civil rights movement as well as being the birthplace of reverend Dr. Martin Luther King, Jr. and the final resting place of Dr. King and his wife, Coretta Scott King. In his famous *I Have a Dream* speech, delivered on August 23, 1963, Dr. King envisioned a day when little Black boys and little Black girls would be able to experience full and humane lives, free from racism and subjugation and all that accompanies those oppressions.

Yet, on September 15, 1963, less than one month after that clarion call for social progress, four little Black girls—11-year-old Carole Denise McNair and 14-year-olds Addie Mae Collins, Cynthia Wesley, and Carole Robertson—were murdered by a bomb placed under the steps of the 16th Street Baptist Church located in Birmingham, Alabama. The ground floor of the church collapsed, killing the girls and injuring some twenty others. The lyrics that opened this paper are taken from the song *Birmingham Sunday,* which was performed by Joan Baez to mourn the girls' deaths.

[4] Although studies of Black children learning specific mathematics content are critically important, I do not dwell on this topic because I do not wish to suggest that there is something peculiar about these children's learning or that some content is especially problematic for them to learn. The fact is that normal, healthy Black children can learn whatever mathematics they are given the opportunity and necessary supports to learn.

Robert "Dynamite Bob" Chambliss, a member of the Ku Klux Klan, was identified by witnesses, arrested, and charged with murder and possession of dynamite without a permit. Other Klansmen were also identified but not initially charged. In his first trial on October 8, 1963, Chambliss was found not guilty of murder but received a small fine and sentenced to six months in jail for possessing dynamite. It was later revealed that FBI director J. Edgar Hoover interfered with prosecutions in the cases. In 1971, the case was re-opened by the Alabama attorney general. A grand jury indicted Chambliss for the murder of Denise McNair on September 24, 1977. In November 1977, Chambliss was retried, found guilty of murder, and sentenced to life in prison. It was not until 2001 and 2002 that two of the remaining suspects were convicted.

Although the murders of four little black girls punctuated September 15, 1963, two other murders of black children occurred in Birmingham on that day:

> James Robinson, a black 16-year-old, became involved in a rock-throwing incident with a gang of white teenagers. As he fled from the scene, Robinson ran down an alley near the Sixteenth St. Church and was promptly shot in the back and killed by a white City of Birmingham police officer. A few hours later, on the outskirts of the city, 13-year-old Virgil Ware was riding on the handlebars of a bicycle with his older brother. From the opposite direction, a red moped, decorated with the Confederate flag, quickly approached the two boys. Without warning, the operator of the motorbike, a white 16-year-old, pulled out a gun and shot Virgil twice in the chest, killing him instantly.
> http://www.trutv.com/library/crime/terrorists_spies/terrorists/birmingham_church/5.html

Why do I bring up civil rights history in a contemporary discussion of mathematics learning and participation? I do so because history reminds us that society has always had a high threshold for Black pain. Moreover, the lives of Denise McNair, Addie Mae Collins, Cynthia Wesley, Carole Robertson, James Robinson, and Virgil Ware were taken not because they were just any children. Their lives were taken because they were *Black* children. As I stated earlier in this paper, when discussing diversity, we should not lose sight of particularity. Any analysis of Black children's behavior in the world, including mathematics education, that fails to contextualize or appreciate what life was like, or is like, for these children is shortsighted and bound to be limited in its explanatory power.

There will be some who read this paper and say, "Get over it. Stop whining. Stop playing the race card. That's ancient history. Things have gotten better." and so on. However, these dismissals and resistance only amount to a desire to maintain the status quo and to avoid the work of understanding how society's laws, policies, and practices routinely continue to converge in subjugating Black children.[5]

### Representing and Constructing Black Children in Mathematics Education

My focus on little Black boys and little Black girls is present-day literal because I contend that even in a post-civil rights, color-blind era highlighted by the election of a President with biracial African heritage and the identification of mathematics literacy as a 21st century civil right, there is little reason to believe that the well-being of little Black boys and little Black girls

[5] As pointed out by educational anthropologist, studies of education for Black children should consider forces at many levels: societal, community, family, institutional, school, individual. I acknowledge that there are many internal, community- and family-based forces to consider. Those forces are not addressed in this paper. See Martin (2000).

is a priority in America or in mathematics education, in particular. We still live in a society where blackness and black life are denigrated. Just a few months ago, Bonnie Sweeten, a white woman from Philadelphia claimed that she and her 9-year-old daughter had been abducted by two Black men and thrown into the trunk of a Cadillac. In response to her 911 calls, massive local and national media attention was given to her abduction. Crisis intervention teams were sent to her daughter's school. Only after more careful police work was it revealed that Sweeten had faked the abductions and had flown to Disneyworld after withdrawing more than 12,000 dollars from her bank accounts. This is a repeat episode of earlier cases involving Susan Smith and Charles Stuart in which the villainous Black man was blamed for killing four white children and a white wife, respectively. In these two instances, Smith and Stuart were the guilty parties. Yet, in all these cases, society was quick to accept the accusations that were put forward. The media attention and concern for the well-being of white children, men, and women stands in stark contrast to the attention given to the alarming numbers of murders of Black children in my own city of Chicago. As of mid-May, 36 schoolchildren, most of them Black, had been killed, an average of more than one a week. National media attention was slow in coming.[6] In the eyes of many, each time a Black child's life is taken, it is just "another one gone."

A cursory examination of the ways Black children have been researched and represented in mainstream mathematics education research and policy further shows how Black children are devalued.

The dominant story line, or masternarrative, in research and policy contexts is one that normalizes failure, ignores success, and uses white children's mathematical behaviors and performance as the standard for all children. This masternarrative has helped to support negative social constructions of these children. Mathematics education policy reports dating back 25 years have explicitly labeled Black children as mathematically illiterate. More recently, African American 12th graders have been told, in a very public fashion, that they are only as skilled and demonstrate math abilities at the level of white 8th graders (Education Trust, 2003). After their comprehensive review of over 16,000 studies, the members of the National Mathematics Advisory Panel reduced their research recommendation for Black children to issues of motivation, task engagement, and self-efficacy. These areas are important but they focus attention on Black children as though they are unmotivated, inclined to disengagement, and lacking in agency. Institutional and structural barriers inside and outside of school, including racism, that affect student mathematics achievement, engagement, and motivation received little, if any, attention in the report (Martin, 2008). Resistance and disengagement among some students may, in fact, be rational responses to oppressive schooling practices.

In other research contexts, it has been claimed that poor (Black) children enter school with only *pre*-mathematical knowledge and lack the ability to mathematize their experiences, engage in abstraction and elaboration, and use mathematical ideas and symbols to create models of their everyday lives (e.g., Clements & Sarama, 2007). Left unanswered is whether researchers who report these findings understand, even partially, the "everyday lives" of Black children. As I have stated in other writings (Martin, 2009c):

> Because the tasks, assessments, and standards for competence used to draw these conclusions are typically not normed on African American children's cultural and life

[6] For an interesting mathematical analysis of media coverage on crimes against Black and White children see the Appendix to this paper or go to: http://www.thedefendersonline.com/2009/05/14/36-children-of-color-dead-in-chicago/

> experiences, one could also argue that … the preferred ways of abstracting, representing, an elaboration called for in these studies and reports are based on the normalized behavior of white, middle-class and upper-class children…. Very little consideration is giving to exploring patterns in the ways that [poor] African American children do engage in abstraction, representation, and elaboration to determine if these ways are mediated by their cultural experiences in out-of-school settings and whether the preferred ways of engaging in these processes serve useful functions relative to those experiences. (p. 15)

Moreover, despite these claims about Black children's mathematical knowledge, little seems to be known about their metacognitive and racial awareness during mathematical problem solving, particularly in contexts that are meaningful to them and where they are likely to demonstrate a range of mathematical behaviors. Research in these areas would not only provide insight into Black children's reasoning processes and strategy choices (e.g., Malloy & Jones, 1998) but also about their awareness of how they are socially constructed, and how they socially construct themselves, as mathematics learners.

Finally, those who choose to study Black children in high-poverty contexts must first acknowledge, and understand, that ghettos are not natural or normative contexts for Black children but, like slavery and Jim Crow, they are "race making institutions" (Wacquant, 2006, p. 103) designed to dehumanize and inflict material, structural, and symbolic violence (Bourdieu & Passeron, 1977) on those who are forced to live in them. As noted by Wacquant (2006):

> The ghetto, in short, operates as an ethnoracial prison: it encages a dishonoured category and severely curtails the life chances of its members in support of the 'monopolization of ideal and material goods or opportunities' by the dominant status groups dwelling on its outskirts. (p. 101)

Only recently have researchers begun to directly examine the mathematical *experiences* and *identities* of Black children versus a narrow focus on their achievement (Martin, 2007). Researchers doing this work have explored several important areas related to these students' mathematics learning and development: (1) their beliefs about their ability to participate in mathematical contexts, (2) their motivations to learn or do mathematics, (3) the ways in which they define the importance and value of mathematics knowledge and success in mathematics, (4) their mathematics socialization experiences in school and non-school contexts, and (5) the co-construction of mathematics identities and other social identities that are important to these students. Research in these areas supports the assertion made Theresa Perry, Claude Steele, and Asa Hilliard (2003) in their book *Young, Gifted, and Black: Promoting High Achievement Among African American Students:*

> African American students face challenges unique to them as students in American schools at all levels by virtue of their social identity as African Americans and of the way that identity can be a source of devaluation in contemporary American society…. Before we can theorize African-American school achievement, we need to have an understanding of what the nature of the task of achievement is for African Americans *as African Americans*. (pp. vi-9)

Readers are urged to consult the recent volumes *Mathematics Success and Failure Among African American Youth* (Martin, 2000), *Mathematics Teaching, Learning, and Liberation in the Lives of Black Children* (Martin, 2009b) and *Culturally Specific Pedagogy in the Mathematics Classroom: Strategies for Teachers and Students* (Leonard, 2008) for more details about some of this recent work.

### Racialized Forms of Experience and White Institutional Space

One of the most defining feature of the masternarrative on Black children and mathematics is that it frequently cites or implicates *race* as a causal variable in their achievement but just as frequently fails to define this concept or acknowledge that *racism*, not race, should be the key area of focus. I have argued elsewhere (Martin, 2009a) that:

> Within mathematics education, *race* remains undertheorized in relation to mathematics learning and participation. While race is characterized in the sociological and critical theory literatures as socially and politically constructed and with structural expressions, most studies of differential outcomes in mathematics education begin and end their analyses with static racial categories and group labels for the sole purpose of disaggregating data. One consequence is a widely accepted, and largely uncontested, racial hierarchy of mathematical ability. Rather than challenging and deconstructing this hierarchy, many math educators take it as their natural starting point. Disparities in achievement and persistence are then inadequately framed as reflecting race effects rather than as consequences of the *racialized* nature of students' mathematical experiences. (p. 295)

My own considerations of racism and racialization have led me to develop a conceptualization of mathematics learning and participation as *racialized forms of experience* for all children (Martin, 2006a, 2009a). I claim that these experiences are shaped and structured by the meanings and representations of race and racial groups that exist in the larger society. A summary of this perspective is provided in Figure 1. A more detailed discussion can be found in Martin (2009a).

I argue that this conceptualization of mathematics learning and participation may be more relevant to the mathematical experiences of African American learners than the dominant perspectives which typically characterize learning and participation as cultural, situated, or cognitive because this conceptualization situates the realities of racism and racialization at the center of these experiences (Martin & McGee, 2009).

| | **Conceptualizations of race** | **Conceptualizations of learners** | **Research, policy, and practice orientations to race** | **Aims and goals of mathematics education research, policy, and practice** |
|---|---|---|---|---|
| **Mainstream mathematics education research, policy, and practice** | Races as biologically determined. Race as a way to disaggregate data. Race as a causal variable for mathematics achievement. | Those who know mathematics. Those who do not. Those who are mathematically literate. Those who are | Resistance to realities of racism. Color-blindness. Racial apathy. Solution on demand. Interest convergence. | Close the racial achievement gap. Maintain white privilege and United States international |

| | | | | |
|---|---|---|---|---|
| | | mathematically illiterate. Students belong to a racial hierarchy of mathematical ability. | | competitiveness. |
| **Mathematics learning and participation as racialized forms of experience** | Race as a sociopolitical construction. Historically contingent nature of race. Consideration racism and racialization. | Consideration of the negotiated nature of identity with respect to mathematics. Asks what does it mean to be African American, Latino, Native American, white, and Asian American in the context of mathematics learning? | Consideration of everyday, institutional, and structural racism. Mainstream mathematics education research and policy contexts as instantiations of white institutional space. | Empowerment and liberation from oppression for marginalized learners. |

*Figure 1.* Contrasting approaches to race in mathematics education research, policy, and practice

I have utilized this race-critical perspective to address the production of knowledge about African American children and mathematics and to reframe the conversations about these children in several areas including mathematics teacher knowledge and teacher selection (Martin, 2007) and assessment (Davis & Martin, 2008). I have addressed questions such as: What is the study of African American children the study of? What should the study of African American children be the study of? Why should African American children learn mathematics? Who should teach mathematics to African American children? What does it mean to be African American in the context of mathematics learning? and What does it mean to be a learner of mathematics in an African American context?

*White Institutional Space*

Returning to the masternarrative on Black children, I contend that it is only within certain kinds of ideological and material spaces—contexts that sociologists have called *white institutional spaces*—that so-called *racial* achievement gaps and the mathematical illiteracy of Black children can assume common-sense status. The term *white institutional space* comes from the work of sociologists Joe Feagin (1996) and Wendy Moore, who, in her book *Reproducing Racism: White Space, Elite Law Schools, and Racial Inequality* (2008), examined the white space of law schools and how the ideologies and practices in these schools serve to privilege white perspectives, white ideological frames, white power, and white dominance all the while purporting to represent law as neutral and objective.

White institutional spaces are characterized by (1) numerical domination by whites and the exclusion of people of color from positions of power in institutional contexts, (2) the development of a white frame that organizes the logic of the institution or discipline, (3) the historical construction of curricular models based upon the thinking of white elites, and (4) the assertion of knowledge production as neutral and impartial unconnected to power relations.

In Martin (2008), I provide a more detailed discussion of how mathematics education research and policy contexts represent instantiations of white institutional space. For example, I offered a critique of the composition of the National Mathematics Advisory Panel as well as its failure to draw on the most insightful recent research about Black children and mathematics. My critique was not only directed at the Math Panel but also at scholars in the field who, from recognized positions of power, failed to object to the absence of African American math education researchers on the Panel. This kind of inaction, despite progressive rhetoric about equity and diversity, was noted by Macedo and Gounari (2006) as being characteristic of liberal approaches in white spaces:

> … many white liberals (and some black liberals as well) fail to understand how they can embody white supremacist values and beliefs, even though they may not embrace racism as prejudice or domination (especially domination that involves coercive control). They cannot recognize how their actions support and affirm the very structure of racist domination and oppression they profess to wish to see eradicated….By not understanding their complicity with white supremacist ideology, many white liberals reproduce a colonialist and assimilationist value system that gives rise to a form of tokenism parading under the rubric of diversity…. That is why many white liberals prefer to promote "diversity" to the extent that diversity as a cultural model not only fails to interrogate the white privilege extracted from a white supremacist ideology but also allows for white liberals to have blacks and other oppressed cultural groups as mascots in their Benetton color scheme of diversity. This form of diversity promoted through multicultural programs, for example, represents a mere reorganization of knowledge through which diversity is presented as a naturalization process whereby different ethnic and cultural groups (white groups are never associated with ethnicity, even though their ethnicity provides a yardstick against which all other groups are measured) are represented and their asymmetrical power relations with the dominant white group are never interrogated (p. 32)

These sentiments were echoed by Liz Appel (2003) in her focused critique of liberal white participants in the movement against the prison industrial complex:

> … many well-intentioned white folks wish to incorporate an anti-racist approach in their work. Seeking a quick resolve, the problem of racism is often superficially addressed, however. Focusing on tangible and visible solutions, they tokenize individual people of color, perhaps by bringing in a few nonwhite people into public spaces and circles of power (as board members, speakers, etc.), in an attempt to demonstrate the "diverse" nature of the struggle and those that make up the fight. This is not to say that every attempt to incorporate people of color is inherently racist and self-serving…. [But does] not the fact that whites are able to select people of color for inclusion… reaffirm our power and privilege? (p. 84)

It is through my analysis of mainstream mathematics education research and policy contexts as instantiations of white institutional space, and my understandings of other such spaces, that my focus on little Black boys and little Black girls in this paper becomes metaphorical. Sociologists tell us that when someone or something is socially blackened, it or they are relegated to marginalized status and thought of as inferior. Similarly, when something is whitened, it or they are elevated in social status or importance. In terms of racial dynamics of the United States, this has been documented in books with such provocative titles as *How the Irish Became White* (Ignatiev, 1996) and *The Price of Whiteness: Jews, Race, and American Identity* (Goldstein, 2006). This whitening has also been witnessed in the education arena where Asian Americans, collectively, have been given *model-minority* and *honorary white* status (Lee, 1996, 2005; Martin, 2009). Blackening, on the other hand, has most recently happened to Arab Americans and Muslims who are now are subject to racial profiling and other forms of subjugation. Blackening also explains how the diversity among those from the African diaspora is muted so as to create a singular perception and construction of these groups. Blacks from Caribbean, West Indian, and African backgrounds are all labeled by the dominant society as Black when they come to the U.S.

So, it is interesting to ask the following about the United States mathematics education enterprise: Who are the little Black boys and little Black girls in mathematics education and how are they, and their perspectives, embraced? Are they the scholars who take up race, racism, and power; issues that only occasionally find their way into mainstream mathematics education research and policy discussions? Are these scholars and their perspectives tolerated but also marginalized? Is it assumed that they are less-informed about mathematics content, teaching, learning, curriculum, and assessment to the degree that they are largely absent from key discussions in the field; called on only when issues of equity and diversity are considered?

In a field that purports to be committed to equity for all children, why are there no explicit discussions of the pervasive whiteness in mathematics education research and policy contexts or of the fact that the norms and values of these white institutional spaces are increasingly being applied to populations of other people's children? Why are there no discussions of how we continue to blacken some children by producing research that implies their inferiority? Is it that the characteristics of white institutional spaces are so strong that they lead us to believe this state of affairs is normal and acceptable?

**Where do we go From Here? Axioms for Researching Black Children and Mathematics**

In so far as Black children are concerned, I remain hopeful that mathematics education research and policy, if done right, can benefit these children. Clearly, what constitutes "right" is subject to much debate. Yet, little that constitutes right for these children will emerge from an enterprise that fails to understand its own complicity in these children's subjugation and negative social construction. Moving forward, I want to propose adherence to a set of *sociocritical* "axioms" for addressing Black children, in particular. An axiom is defined as a self-evident or universally recognized truth that is accepted without proof as the basis for argument. In mathematics, proofs of various conjectures and claims are essentially a function of the axioms upon which the system is organized. If you change the axioms, you change the system, and you also change what constitutes valid proof and what is regarded as true. My own research, as well as the comments and analysis in this paper, are premised on these axioms[7] and I believe they should undergird all future inquiry to the mathematical experiences of Black children:

- Axiom I: Black children are brilliant; researchers should not overly concern themselves with documenting how Black children differ from white children and reifying racial achievement gaps but with how black children can best attain and maintain excellence in mathematics;

- Axiom II: Black children possess the intellectual capacity to learn mathematics as well any other child; they do, however, often lack sufficient opportunities to engage in meaningful mathematical experiences;

[7] It is true that these are not axioms in the strict mathematical sense. I am appropriating the term to serve sociological and political purposes.

- Axiom III: *Race* is not a causal variable in determining mathematical achievement among Black children or any other group of children; research and policy purporting to cite *race* effects should be dismissed as scientifically invalid;

- Axiom IV: Racism, racial identity, and racialization are important considerations in mathematics learning and participation; Mathematics education research and policy are deeply involved in the production and reproduction of racial meanings;

- Axiom V: Mathematics education research and policy are simultaneously sites of oppression and liberation for Black children.

These statements are not meant to romanticize Black children nor do they ignore their struggles. However, they require attention to Black children's social realities and how forces, discourses, and projects in the larger society influence those realities. They also require reconsideration of the assumptions about the competencies and capacities of Black children in ways that move us beyond default characterizations of mathematical illiteracy and inferiority with respect to other learners.

As I stated earlier, Black children serve as canaries in the coal mine. If we cannot do right by these children, it is difficult to believe that we can accomplish the goal inherent in the theme of *Embracing Diverse Perspectives*.

## Conclusion

The discussion in this paper hints that a more thorough structural analysis of mathematics education would reveal that the discipline is no different than other racialized contexts in the larger society where issues of power and stratification are prominent. The analysis would confirm the racialized character of mathematics learning and participation not only for Black children but also for all children. I conjecture that a structural analysis would also show that mathematics education research and policy contribute to, and constitute, racial projects. Yet, the hopeful side of me continues to believe that mathematics education can simultaneously be a sight of, and means to, liberation for Black children, helping them to combat the negative consequences of these racial projects.

## Appendix

Retrieved on July 12, 2009 from: http://www.thedefendersonline.com/2009/05/14/36-children-of-color-dead-in-chicago/

By Stacey Patton

Megan Kanka. Amber Hagerman. JonBenét Ramsey. Elizabeth Smart. Caylee Anthony. Sandra Cantu.

When these six cute, middle-class white girls, ranging from age 2 to 14, went missing or were horrifically murdered, national news outlets devoted hours, days and weeks of coverage to their cases. But when children of color are victimized in similar ways, the mainstream media often remains conspicuously silent or provides scant coverage at best.

A quick GOOGLE news archive search illustrates my point.

There are 3,670 articles on the 1994 murder of 7-year-old Megan Kanka, who was raped and abducted by a twice-convicted sex offender who lived next door. The 1996 murder and abduction of 9-year-old Amber Hagerman produced 2,570 headlines. An astonishing 13,500 news stories helped sensationalize the 1996 murder of JonBenét Ramsey, a 6-year-old beauty pageant contestant found bound and strangled in her home. Between June and November of 2002, 8,300 new stories were printed about the abduction and recovery of 14-year-old Elizabeth Smart. Since last October, 1,570 stories have discussed the murder of 2-year-old Caylee Anthony, whose skeletal remains were found a month later. And in one month, 424 articles have appeared on 8-year-old Cantu, who was raped, killed, stuffed in a suitcase and thrown in a pond in northern California on April 11.

Do the math. Six young white girls. One abducted and later returned. Five killed. 30, 134 news stories and nearly two million total web hits. And with the exception of the Ramsey case, suspects have been captured, indicted, tried, and even sentenced to death for the brutal crimes against these innocent children.

Each of these girls has her own Wikipedia entry, which discusses their lives, details of their investigation, and archives media references and external links to various websites, talk shows, and made-for-TV documentaries and movies as well as child and victims advocacy sites.

Now enter the names of the following children: Corey Hatter, Ordero Hillard, Marcus Washington, Andre Malcolm, Arthur Tyler, Sameer Conn, Shaun Brown, Shaun Bowens, Kiyanna Salter, Daniel Calderon, Ernest Williams, Julian King, Brian Murdock, Quentin Buckner, Devour Robinson, Dushawn Johnson, Isiah Stroud, Andre Stephens, Esteban Martinez, Itzel Fernandez, Johnel Ford, Rachael Beauchamp, Johnny Edwards, Kendrick Pitts, Raheem Washington, Carnell Pitts, Franco Avila, Gregory Robinson, Lee Ivory Miller, Rakeem Washington, Tommie Williams, Marquell Blake, Juan Cazares, Christina Campos, and Alex Arellano.

All 36 of these schoolchildren, mostly black and a few Latinos, were killed in the streets of Chicago during the past nine months. They were shot, stabbed, beaten with bats, kicked to death, burned and run over by cars.

GOOGLE their names and you won't get a return of hundreds of national news stories or thousands of web hits discussing their deaths. The only child of all these victims to gain a great deal of media attention was 7-year-old Julian King, the nephew of singer and actress Jennifer Hudson, killed last October by his mother's estranged husband.

For the rest of the children, there are no Wikipedia entries. No documentaries. No made for TV films. And there won't be. They'll be remembered in a few grainy YouTube video tributes posted by friends and family members. And if there are more shootings, all of these children will be lumped together and described as statistics and tragic victims of urban warfare, even though most were not high school dropouts, gang members, or criminals. They were killed during day-to-day activities: walking to the store, playing in a park, waiting for a bus, or riding in a car with a parent.

# DISCURSIVE ROUTINES AND ENDORSED NARRATIVES AS INSTANCES OF MATHEMATICAL COGNITION

*The purpose of this research is to investigate the cognitive processes utilized by students when accessing mathematical knowledge while completing homework. In particular, we focus our attention on the ways in which students use distinctive features of mathematical discourse, as mathematical cognitive processes (i.e., "mathematical" mental functions based upon the function being performed), to support their own learning. Our findings suggest that there may be an important connection between discursive routines and endorsed narratives in student learning.*

## Purposes of the Study

Students' inability to complete mathematics homework has been linked to achievement (Cooper, Robinson, & Patall, 2006). In some instances, motivation and social circumstances may contribute to students' inabilities to complete mathematics homework. The curriculum and how it is experienced, understood, and subsequently accessed by students may also be important contributors to students' inability to complete homework. Nesher, Hershkovits, and Novotna (2003) contend that the ability to access mathematical knowledge, independently by a student, is significantly influenced by a student's *initial* ability to make sense of mathematical texts. Surprisingly, little research exists documenting the ways in which students access mathematical knowledge while completing homework, although research does exist in simulated settings (e.g., Berger, 2004).

Therefore, the purpose of this research is to investigate the cognitive processes utilized by students when accessing mathematical knowledge while completing homework. In particular, we focus our attention on the ways in which students use distinctive features of mathematical discourse, as mathematical cognitive processes (i.e., "mathematical" mental functions based upon the function being performed), to support their own learning. Four features of distinctive mathematical discourse are drawn from Ben-Yehuda, Lavy, Linchevski, and Sfard (2005) and thus include:

> (1) *uses of words* [authors' italics] that count as mathematical; (2) the use of uniquely mathematical *visual mediators* [authors' italics] in the form of symbolic artifacts that have been created specifically for the purpose of communicating about quantities; (3) special *discursive routines* [authors' italics] with which the participants implement well-defined types of task; and (4) *endorsed narratives*[authors' italics], such as definitions, postulates, and theorems, produced throughout the discursive activity. (p. 182)

We adopt for this analysis an elaborated view of mathematical discourse to include "all forms of language, including gesture, signs, artifacts, mimicking, and so on" (Lerman, 2001, p. 87).

For this research, six eighth grade children were invited to document their mathematical cognitive processes using at-home video diaries (i.e., "mathcams") while completing their homework to capture aspects of their mathematization that are causing problems, pause, and reflection. Students' verbalizing their thinking has been shown in multiple settings to improve mathematical performance (Mercer, Wegerif, & Dawes, 1999; Sfard & Kieran, 2001), and thus may be a real and tangible benefit for the students participating in this study. Beyond individual achievement, however, this research reporting data occurring in real-time has the potential to raise important insights and questions about classroom practices and student learning. Currently, "real-time analysis" of mathematical cognitive processes utilized by students during homework is scant amongst the literature.

## Research Questions

1. Which mathematical cognitive processes (i.e., mathematical words, visual mediators, discursive routines, and endorsed narratives) do students utilize when accessing mathematical knowledge while completing homework?
2. How does the interaction of mathematical cognitive processes suggest about the nature of student learning?
3. How can this knowledge inform teaching of mathematics?

## Theoretical Framework

In order to examine verbalized process as instances of mathematical cognition, we adopt the theoretical framework of Ericsson and Simon's (1993, 1998) work on talk- and think-aloud protocols. Ericson and Simon contend that verbal reports as data can, depending on the conditions of the verbal reports, be viewed as instances of cognition. This view is also supported by other theorists (Lerman, 2001; Radford, 2004; Sfard & Kieran, 2001). For example, Vygotsky (1962) describes talking aloud as the manifestation of inner thought or cognition (p. 149). Vygotsky theorizes that as children "solve practical tasks with the help of their speech, and action, which ultimately produces internalization of the visual field" (p. 26). Cognition "is not merely expressed in words; it comes into existence through them" (Vygotsky, 1962, p. 125). Ben-Yehuda et al. (2005) also suggest that "thinking can be regarded as a special case of the activity of communication [authors' italics]" (p. 181). Comparison between child and researcher-observer reports in a study by Wu et al. (2008) investigating verbalized reports of cognition showed high consistency (Kappa=.948). Wu et al.'s results suggest suggests that children can report on their cognitive processes accurately.

Particularly relevant to the present research are Ericsson and Simon's (1993; 1998) protocols associated with *Level 3 verbalizations*, which are verbalizations linked to instructions to explain or describe thinking, and thus employ intermediary cognitive processes by virtue of the instruction to "explain" or "elaborate." Ericsson and Simon also make the distinction between verbalizations that are given retrospectively or concurrently to task completion. In the present research, both applications apply. Students may be verbalizing their cognitive processes as they concurrently with homework completion or may retrospectively describe their cognitive processes associated with prior learning.

Faithful appropriations of Ericsson and Simon's (1993, 1998) talk- and think-aloud protocols occur exclusively in experimental settings. In later explications of their model for analyzing thinking and talk, Ericsson and Simon proposed that everyday situations can be reproduced in controlled laboratory settings. Indeed, many researchers simulate classroom learning with laboratory “training” (Anderson, Reder, & Simon, 2000, Summer). As Anderson, Reder, and Simon explain, learning as a complex skill is hierarchical in structure with multiple nested components that require both analyses in the laboratory and in real-world settings. Our research is poised to make important contributions in terms of real-time analysis of mathematical cognition and its relationship to teaching and learning, based upon what students tell us about their own thinking versus what a standardized test might show.

## Methods

Data for this paper were drawn from a year-long study investigating the home-school connection in mathematics learning in an eighth grade classroom. The teacher involved in the research (the third author), was a mentor mathematics teacher in his school board (Kotsopoulos & Heide, in press). At the time of this research, he had been teaching 12 years and had completed a master’s degree. He was approached to participate in this study and he agreed.

The school was located in an economically, socially and culturally diverse urban setting. For example, there were a reported 52 languages spoken amongst the student population, with 195 out of 960 students identified as English Language Learners (ELL). Only approximately 10% of the English Language Learners were born in Canada or resided in Canada for more than three years.

Duane’s class consisted of 28 students, 14 male, and 14 female. All students were either 13 or 14 years of age. From these 28 students, a purposive sample of six students (three males and three females) was selected and invited to participate in this study. In consultation with the grade-seven teacher, students were selected based upon the following considerations: (a) perceived ability of the student by the teacher to engage in thinking aloud, (b) perceived level of responsibility of the student to maintain continued engagement with the student and to care for the home equipment, (c) gender, and (d) ability. The goal in terms of ability and gender was to ensure mixed representation. In addition to the six students that were selected, two alternates were also selected in the event that a student had to withdraw from the study, which was the case with one of the initial student cohort.

Observational video data were gathered from the students and also daily from the classroom during mathematics instruction. The six students, their parents, the classroom teacher, and the research team, met to engage in a training session with the students and distribute the computers. Students at this time were trained on (a) how to video record their verbalizations using cameras built-into the laptop computers, (b) how to transfer their recordings using secure email or memory sticks, and (c) how to engage in the task of talking aloud about their mathematical thinking. We encouraged students to document everything they were thinking and doing in order to assist themselves with the understanding and completion of the mathematical homework. We anticipated one to five submissions from each student per week. Additionally, Amanda, the fourth author, video-taped the daily mathematics lesson for the duration of the school year.

All video data from the classroom and the students were transcribed by two different transcribers to ensure accuracy and then coded. There were four codes used. These codes were adopted from the four features of distinctive mathematical discourse from Ben-Yehuda et al. (2005) and thus include: identifying uses of words that count as mathematical, use of uniquely mathematical visual mediators, use of discursive routines, and use of endorsed narrative. Also appropriated from Ben-Yehuda et al. is the use of *high-resolution descriptive methods* to report our data. This method is intended to focus on detailed qualitative accounts of students’ cognitive process through transcription and, in our case, video analysis. The detailed qualitative accounts also aimed at ascertaining relationships between the four codes used. Thus, the codes were examined both individually and in relation to one another.

For this paper we analyzed 34 mathcam videos (mean length 4.79 minutes) from the six students (mean number of submissions 6 during the month of October 2008, in which the topic of study in the classroom was numeracy (e.g., exponents, factors, prime numbers, and square roots). In this paper we present specifically data emerging from one student—Kara who is 13 years old. We selected this case for its explanatory potential.

## Results

Our results across all six students suggested that the there were particular forms of interaction between the four mathematical cognitive processes under examination: uses of words use of uniquely mathematical visual mediators, discursive routines, and endorsed narratives. Use of words, specifically those mathematical words used in the homework sheet from which the students referred to, created some source of difficulty for each of the six students during one or more mathcam videos analyzed. In all cases, students indicated on the video that they would ask for assistance from their teacher. In one case, Kara, the student we will be discussing shortly, referred to the internet.

Mathematical visual mediators were used very infrequently by students (n=4) in an effort to support their understanding (see line 10). In all but one instance, the visual mediators used replicated those in the classroom by Duane during a lesson on integers (i.e., the use of counters to understand negative and positive numbers). Across all six students, an interesting interaction was observed between discursive routines and endorsed narratives. We illustrate this with two examples from mathcam videos submitted from Kara.

Instances where there were mathematical challenges exhibited by the students, discursive routines did not function in concert with endorsed narratives across all students. For example, Kara made inappropriate connections between her prior knowledge of finding the perimeter of a perfect square with square roots (line 2). She used a visual mediator to assist her but does not move forward in her trying to support her own understanding. Despite the fact that she is unsuccessful, she still viewed her approach as "cool" (line 4).

| | | |
|---|---|---|
| 1 | So today in math class we did the perfect square problem again, and while everybody else was doing the systematic trial system, I decided that I was gunna [SIC] try to figure out the perimeter, because if I could figure out the perimeter, I could divide it by four, and then I'd be able to find out the outside, then I could find out the width and the length for each side, and then from there I could multiply it and get the answer to the area. | Discursive routines |
| 2 | So, I was trying to figure it out, and I was trying to…first I made the rectangle, with the twenty square centimeters as the area, and then I cut off the four extra… um, squared centimeters that made it into a rectangle, and then I tried dividing that up. | Visual |
| 3 | And though it would have taken me a long time to figure it out, I'm pretty sure it would have eventually worked. But my um, other members of my group found it quickly by us—well not quickly, but they found it eventually by using the systematic trial system, but it took 'em [SIC] a while. Um, other people figured out a formula, and it turned out the entire thing was about roots, and I wish I would've thought about it because square root, it means the root of the square. If you think about it, it just kind a sounds like a big fancy word, but if you look at the word it makes sense to what it means. So if I thought about using the buttons on the calculator, maybe I could a figured it out. | Words<br>Endorsed narratives |

| | | |
|---|---|---|
| 4 | But, um, I definitely thought the way I decided to find the answer was kind of a cool way to try and do it. | Discursive routines |

A major source of misconception for Kara was from prior knowledge from previous classroom instruction linking the side length of a perfect square with an area of 16 units and the root of 16, which are both four. We see from her discourse that she was associating the number four for determining *all* perfect squares rather than observing that the square root is only four when the number is 16. Although she recognized that her method was related to perimeter (line 7), she continued with the strategy of dividing by four to find the other square roots. This method of estimation works relatively well for several of the questions (8–11), but failed her when trying to find the square root of 78. At this point, her method was not at issue but rather, according to Kara, the magnitude of the number under investigation (lines 12–13). The interesting point in this example is that the discursive routines that led her to incorrect mathematization are not simultaneously interacting with endorsed narratives.

| | | |
|---|---|---|
| 5 | And right now I just have to find the square root, and I know how to find the square root quick because of the calculator I'm using. So, I just have to type it in. If I can find the button. So [inaudible] the square root of thirty six is…six! | Discursive routines |
| 6 | Now, number four is estimate the value of each square root. Explain how you found one estimate. So, twenty-three, […]. Well, right now I'm just gunna [SIC] think of all the things that you can multiply twenty three by […]. I think I'm gunna try to figure out what…five times four is…five point seven five. I think it's going to be…five point seven five…because that is what it is divided by four, and there's four. Wait that's perimeter! | Discursive routines |
| 7 | I always forget that it's not the perimeter! It's the inside of the square. When I tried doing this before, I figured out the perimeter before I figured it out but it didn't work very well. | Endorsed narratives |
| 8 | I'm going to estimate. That it's going to be . . . I'm gunna [SIC] try it with thirty-six. Thirty-six divided by four is nine, the actual answer was three. So, if thirty-six is…if thirty-six, the perimeter for thirty-six is nine, but the square root is six, then maybe for twenty three it'll be three less too. | Discursive routines |
| 9 | So, if I do…twenty-three divided by four again and add five point seven, maybe it'll be…I'm gunna [SIC] go with the number four. Wow the answer was four point eighty, so I was close! | Discursive routines |
| 10 | It's definitely a good um, strategy for me to use if I just try and…if I just answer it that way then…I think I should try that for all my other questions too, and then I don't have to try and come up with some type of…I don't have to just guess a random number. | Discursive routines |
| 11 | So thirteen divided by four is three point two five, […]. I'm gunna [SIC] try three. The square root of three is my estimate. And the square root of thirteen is three point six one! See, my method definitely works, 'cause it might be over, but it's still close. | Discursive routines |
| 12 | Seventy-eight divided by four is 19.50, and I'm gunna [SIC] guess that it's gunna be a multiple of four and I'm not sure why but I'm going to subtract four from it and my answer's gunna be 15.50. So, my estimate is 15.50. And, the square root of 78 is eight point eighty three. Definitely didn't work out for me this time, but it's a good strategy. Probably because 78 is a larger number. | Discursive routines |
| 13 | I'm going to explain how I got the answer for thirteen. I got my estimate by dividing the digit, no, the number …by dividing the number by…dividing 13 by four, number of sides, and then subtracting one because of …because it's the area and not the perimeter. | Discursive routines |

In contrast to the preceding example, in the next set of transcriptions from another mathcam video, Kara described how she made sense of integers using the visual techniques in the classroom. She explained how Duane uses counters to demonstrate positive and negative integers and how this was proved to be very useful in assisting her understanding (line 14).

In this example related to integers, discursive routines are interacting with endorsed narratives (lines 14–17). This interaction has two important outcomes. First, Kara is able to move forward in her learning of integers. Second, she expands her understanding using the combined discursive routines and endorsed narratives to hypothesize about other relationships between integers. She calls this a “strategy” (line 15), and then proceeds to test and revisit her strategy to confirm her understanding (line 16). As she continued reading the homework sheet, she saw that the homework sheet ultimately outlined the “strategy” she had just developed (17). Her efforts are in contrast to those above where her strategy falls apart and there are no endorsed narratives engaged to assist her misconceptions or further her learning.

.

| | | |
|---|---|---|
| 14 | So, today in math class, I really liked how Mr. Heidi explained integers—integers by using counters. He used white squares and red squares. And the red squares are positive and the white squares were negative, and what he did is he added and um, subtract them using integer numbers and it was really—it made it easier to understand when you could see that they canceled each other out. Now, I’m on question three, and I’ve—I kind of do the same thing with the counters, except I do it in my head, which makes it- because I’m really good at that kind of mental math, it just kind of works out. | Words, Discursive routines, Visual, Endorsed narratives |
| 15 | So four positives, three negatives, it’s three pairs, which makes it positive one. […] So now I have a new strategy—now, when there is a higher positive number than the negative number that’s getting added, from the negative number that’s getting added, I can just subtract the positive number as if it was just both positive numbers. So ten subtract six, which is four. And I know the answers gunna be four, ‘cause there’s four positives left. So I can just do that as a strategy now, so I don’t always have to… so I don’t always have to write it out. | Discursive routines, Endorsed narratives |
| 16 | I think the same thing might be for if there’s a higher negative than positive, except it’s the opposite- instead of having the sum of the equation a positive number, the sum of the equation would be a negative number. So, seven, my prediction that seven minus two is five…so I believe the answer’s gunna be negative five. Now, I’m just gunna prove my theory by doing one, two, three, four, five, six negatives and two positives. I’m circles the two positives, and that leaves one, two, three, four, five. That leaves five negatives left. That means that my hypothesis was correct. | Discursive routines, Endorsed narratives |
| 17 | This is a second part to question number four. It says: when you add a positive integer and a negative integer, the sum is positive…when the numerical larger integer is. Oh! Positive, when the numerical larger integer is positive, negative when the numerical larger integer is negative... just like my theory—my strategy that I was doing when I was figuring out! And, the sum is going to be zero when the integers are the same number. | Discursive routines, Endorsed narratives |

The preceding example from Kara is important. It illustrates what was seen throughout the students mathcam submissions; namely, that mathematical understanding as verbalized by the students was characterized by an interaction between discursive routines and endorsed narratives. Mathematical *mis*understanding was linked to inappropriately transfer knowledge from one context to another (i.e., Kara’s use of 4 as the divisor and potential root of many numbers) and consistently lacked an interface with the endorsed narratives.

Our results do not suggest that students improved their understanding as a result of verbalization (i.e., engaging in mathcams) (cf. Mercer, et al., 1999; Sfard & Kieran, 2001). There was minimal evidence of students engaging in self-correction based upon their verbalization (n = 6). However, there were more instances (n=12) where students verbalized incorrect calculations but proceeded with their work unaware of their errors.

As outlined by Nesher et al. (2003), a student's ability to access mathematical knowledge may be linked to their initial ability to make sense of mathematical texts. Our research adds to this finding to suggest that the inability to make sense of mathematical texts may be linked to the extent to which students are able to relate discursive practices to endorsed narratives. Our findings do not suggest the same sort of requisite interactions for mathematical visual mediators and words. Rather, the latter two were seen as having supporting roles in students' ability to complete homework independently following instruction.

## Conclusions

Real-time data collection in naturalistic settings is a strength of this research. However, a limitation of this design is the inability to track more than six students at one time due to technological constraints (i.e., only six laptops available for the project). The results presented in this paper represent a small sample drawn from the larger research project that is currently underway. We make no claims that the conclusions we have presented can be generalized or true of the remaining data to be analyzed.

Our results suggest that a students' inability complete homework accurately so that the task of completing homework is not reinforcing misconceptions may be related to the interaction between discursive routines and endorsed narratives. Our results show that misconceptions were largely discursive routines that were not paired with endorsed narratives and thus the mathematization was often incorrect.

More specific to the example we highlighted from Kara's mathcams, we see that also important in the learning of mathematics is the ability to transfer knowledge (or not), as a specific goal of instruction. Although understanding relationships in mathematics are widely viewed as significant in the learning of mathematics (National Council of Mathematics Teachers, 2000), it is also of critical importance to examine when certain relationships do not hold or fail to adhere to endorsed narratives of mathematics.

# META REPRESENTATIONAL KNOWLEDGE, TRANSFER, AND MULTIPLE EMBODIMENTS IN LINEAR ALGEBRA

Lance Burger
California State University, Fresno
lburger@csufresno.edu

*Previous research suggests spontaneous transfer between non-isomorphic problem settings to be rare in the absence of hints concerning the relationships between those settings (Holyoak & Koh, 1987). Two factorial experiments reinforce previous findings that transfer does not significantly occur between dissimilar settings, even when problems share abstract problem solving schemas and representations. A third experiment supports the Indirect Representational Transfer Hypothesis: meta-representational reflection on the meaning of a common abstract representation in relation to diverse mathematical settings induces schema transfer. Qualitative interviews uncover evidence of the role of meta-representational thought as part of a larger developmental process of actor-oriented transfer.*

## Introduction

A common theme in educational research on linear algebra concerns cognitive inflexibility associated with the appropriation of different linear algebra problem settings to similar matrix representations and methods, a consequence of the *multiple embodiments* of linear algebra concepts (Harel, 1989; Hillel & Mueller, 2006; DeVries & Arnon, 2004; Hillel & Sierpinska, 1994; Dias & Artique, 1995; Dorier, 2000). The study of multiple embodiments in linear algebra is important since students require an ability to establish meaningful links between representational forms in order to "understand the necessity for representing these situations by a general concept," a competence known as *representational fluency* (Harel, 1987, p.30-31). A common conclusion drawn from previous studies points to the general inadequacy for students to develop theoretical setting change competencies on their own, requiring didactic intervention on a meta-mathematical level. Informed by methods from experimental psychology, this study reconceives cognitive inflexibility and the role of meta-mathematical information as a study of the transfer of knowledge from familiar to unfamiliar problems settings sharing common abstract problem solving schemas.

## Theoretical Framework

*Meta Mathematical Knowledge as 'Sierpinska's Theoretical Thinking'*

Dorier (1995) defines meta-mathematical knowledge as:

> Information of that which constitutes mathematical knowledge concerning methods, structures, and (re)organization (of lower level competencies). Methods are defined as the procedures applicable to a set of similar problems within a given field: the methods designate that which is common to problem solving and not the technique itself (p.151).

Sierpinska (2000), defined the terms *practical* verses *theoretical* thinking, as similar to Vygotsky's notion of *everyday concepts* verses *scientific concepts*. Practical thinking is characterized by the propensity for students to view a subject, such as linear algebra, as an aggregate of "prototypical examples" interconnected and understood primarily through "goal-oriented, physical action(s)" (Sierpinska, 2000, p.212). Representations important at the practical level are the necessary symbols needed to perform computations; whereas, theoretical thinking produces formal systems in which "semiotic representation systems become themselves an object of reflection and analysis." In view of these definitions, the term *meta representational knowledge* is defined as meta-mathematical knowledge directed toward theoretical thinking upon the *meaning* of abstract representations in relation to mathematical contexts, settings, or schemas they are applicable to.

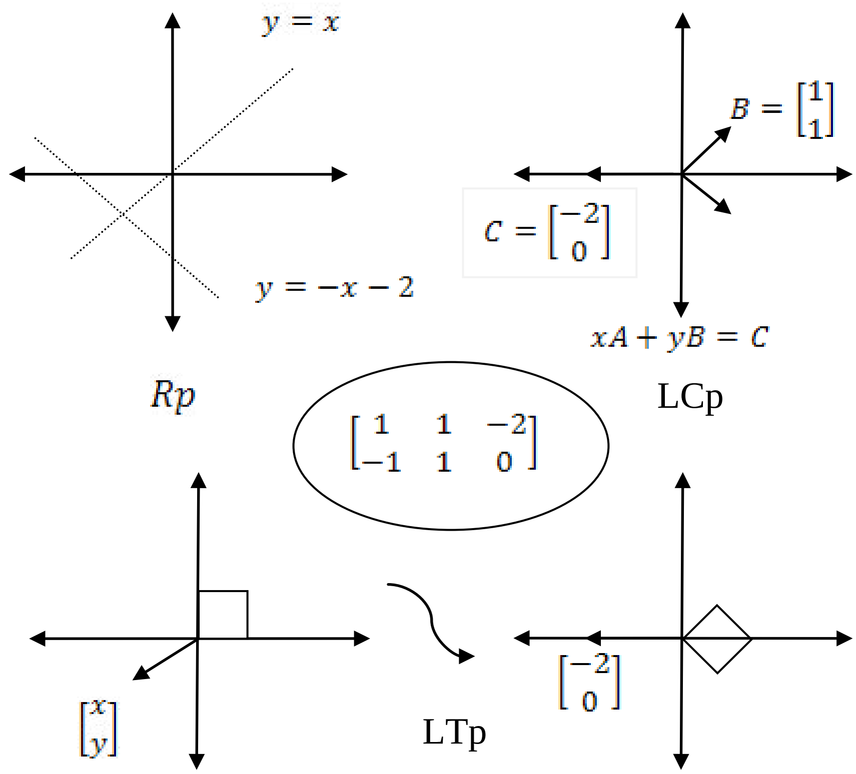

*Figure 1*. Row-picture (Rp), linear combination-picture (LCp), and linear transformation-picture (LTp) settings associated with central augmented matrix.

*Rp, LTp, and LCp Settings*

*Conceptually non-isomorphic settings* are defined as mathematical settings which are not mere re-labelings of each other, but consist of schemas containing different definitions, mathematical objects, concept-images, and structural relationships. The linear algebra settings of interest for this study include the Cartesian row setting (Rp), the linear combination setting (LCp), and the linear transformation setting (LTp). As an example, in figure 1 the matrix $\begin{bmatrix} 1 & 1 & -2 \\ -1 & 1 & 0 \end{bmatrix}$ forms a representation having the following associated meanings: (i) in the Rp setting the matrix represents the system which solves for the intersection of two lines; (ii) in the LCp setting the matrix solves for the linear combination of vectors $A = \begin{bmatrix} 1 \\ -1 \end{bmatrix}$ and $B = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$ which add to give the vector $C = \begin{bmatrix} -2 \\ 0 \end{bmatrix}$; and (iii) in the LTp setting the matrix solves for the vector $\begin{bmatrix} x \\ y \end{bmatrix}$

which, upon clockwise rotation of 45 degrees, would result in the vector $\begin{bmatrix} -2 \\ 0 \end{bmatrix}$. Prior to this study, a pilot experiment with 87 undergraduate linear algebra students was conducted which analyzed performance on an exam question involving all three of the above settings in figure 1. Based on the results of that experiment, and the preponderance of the Rp viewpoint in prerequisite coursework such as pre-calculus and calculus, the Rp setting is defined as a ‘familiar’ setting, while the LCp and LTp settings are defined as ‘unfamiliar.’

*Traditional and Actor-Oriented Transfer Perspectives*

The notion of traditional transfer derives from Thorndike’s *Theory of Identical Elements,* which states that transfer is more likely to occur when tasks share similar elements (Thorndike & Woodworth, 1901). When tasks have similar elemental structures, they are said to be *isomorphic*. Research in traditional transfer has often been criticized for its predominant emphasis on what MacKay terms, the *expert point of view,* as deciding criteria for task similarity or determination for whether or not transfer occurs (Marton, 2006, p.499; Lobato, 2006). Over the past several decades, a debate has ensued concerning the theoretical foundations of transfer theory. Rather than judging transfer according to normative, i.e., expert functionalist views, according to Lobato (2003), “actor-oriented transfer is defined as the personal construction of relations of similarity between the activities.” Both traditional and actor-oriented transfer perspectives comprise main elements of the theoretical framework for this mixed-methods study against the backdrop of an overall Piagetian developmental epistemology

## Methodology

Employing a *mixed methods* approach (Johnson, R. B., & Onwuegbuzie, 2004), three experiments and three interview case studies aimed to address the following questions:

Research Question 1 (Quantitative*)*

> Is there evidence, from the traditional transfer perspective, that transfer is facilitated between linear algebra problems from non-isomorphic settings which share similar (matrix) representations and solution procedures? (Experiments 1 and 2)

Research Question 2 (Qualitative)

> In what ways, from the theoretical perspective of actor-oriented transfer, do novice linear algebra students commonly have difficulty with conceptually non-isomorphic problem settings, even when sharing similar problem representations and solution procedures as familiar problem settings? (Interviews)

Research Question 3 (Mixed: Quantitative + Qualitative)

> Is there evidence that meta-representational intervention may facilitate traditional and/or actor-oriented transfer across conceptually non-isomorphic problem settings involving novel target problems sharing similar problem representations and solution procedures as more familiar problems? (Interviews and Experiment 3)

All of the subjects in this study were university sophomores and juniors, mostly engineering and science majors, in a university course. 260 participants took part in Experiments 1 and 2 (130 each), while 3 subjects participated in the interviews. 66 subjects participated in experiment 3. Subjects were randomly assigned to condition groups for the factorial experiments.

*Experiments 1 and 2*

To address research question 1, a multi-dimensional procedural problem-solving model, inspired by Chen & Mo (2004), was created for implementing factorial experiments employing a source problem – target problem design (see MSP model in figure 2). Problems used for the experiments all shared common goal structures and were matrix representable. Experiment 1 juxtaposed the familiar Rp setting with the Cp setting in the SETTING dimension of the MSP model, as well as manipulated different solution types to the matrix systems formed via the SOLUTION TYPE dimension. Experiment 2 was designed similarly to Experiment 1, except the LTp setting was used instead of the Cp setting in the manipulation of the SETTING factor. For both Experiments 1 and 2, preliminary pilot studies found significance and non-interaction for the BASIS and ROW-OPS dimensions, hence to avoid confounding variables, these dimensions of the MSP model were held fixed.

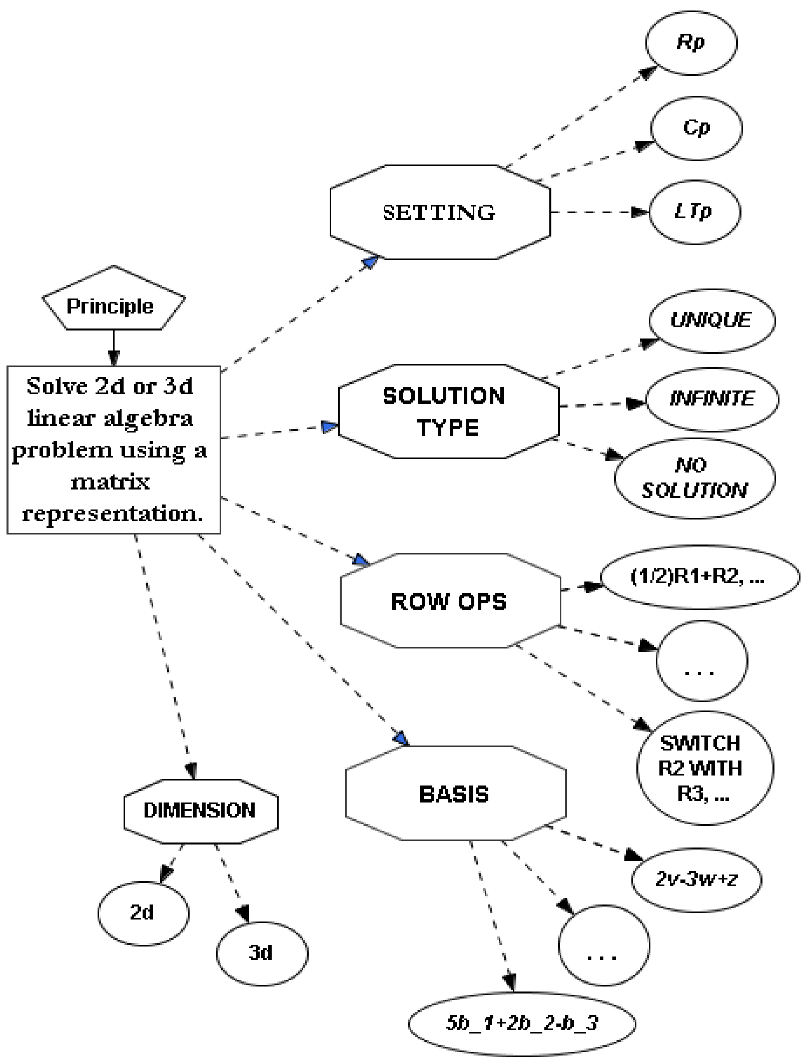

*Figure 2.* Multiple Setting Problem Model (MSP model).

*Interviews*

Using problems experimentally verified as belonging to novel non-isomorphic linear algebra settings (Experiments 1 and 2), it was the purpose of the interview portion of this study to investigate transfer difficulties from a non-expert, actor-oriented perspective, characterized by the subjects' "personal structuring" of phenomena, as well as "transfer distributed across social planes," hence; the interview format was largely semi-structured, with its adherence to the order and completion of the interview problems, and minimal interviewer interaction, unless subjects appeared stalled in problem solving (Lobato, 2003). The interview design consisted of two consecutive problems from the *Cp* setting, and one problem involving the *LTp* setting. As in the previous experiments, all of the interview problems could be solved through the successful use of the general goal structure:

1. Representation of the problem with an appropriate matrix.
2. Row reduction algorithm employed as solution procedure to solve matrix.
3. Interpretation of matrix system solution in the context of a novel problem setting.

*Experiment 3*

*Indirect representational transfer hypothesis.*

In order to coordinate the solution resulting from a process of row reduction on a matrix representative of a given problem embedded in a particular linear algebra setting, it is necessary and sufficient to understand the meaning of the initial matrix representation in relation to the setting.

Based on the results of Experiments 1 and 2 and the interviews, the *Indirect Representational Transfer Hypothesis* was conjectured, and a meta representational intervention was constructed for a treatment/non-treatment design. Treatment participants were given the two-fold interpretation of matrix multiplication as a system of row equations belonging to the row-picture (Rp) setting, or a linear combination of the columns of the matrix, belonging to the linear combination-picture (LCp) setting. Non-treatment participants were only given the target problem. Since the Rp setting was earlier categorized as a familiar setting for most undergraduate linear algebra students, Experiment 3 did not have a source problem. Target problem success was interpreted by the researcher as an indication of successful transfer from Rp to LCp settings.

## Results

*Experiments 1 and 2*

The results of Experiments 1 and 2 are summarized as follows:

1. Dissimilar SETTING conditions from the familiar Rp setting to the less familiar and conceptually non-isomorphic LCp and LTp settings created reliably significant obstacles in applying source solutions.

2. Dissimilar conditions in the SOLUTION TYPE dimension of the MSP model presented reliably significant difficulties in transferring source problem solutions.

*Interviews*

Upon initial coding analysis of the interview data, two stages of problem solving became evident in the form of (1) actor-oriented *representational transfer*, and (2) actor-oriented *solution-interpretational* transfer. From the perspective of actor-oriented transfer, the following six results were found:

1. Lack of understanding of the representational meaning of a matrix in relation to the problem setting, equation scalars, and equation variables (*scalar-variable conflict*), created obstacles in the transfer of correct matrix representations and solution interpretations.
2. Incomplete semantic-access to setting-specific information defining both the LTp and LCp settings, posed as an obstacle to successful representational and solution-setting transfer across conceptually non-isomorphic problem settings.
3. The beneficial effects of meta-cognitive intervention appear to consist in the formation of co-ordinations between non-isomorphic settings, matrix representations, and corresponding matrix solution interpretations.

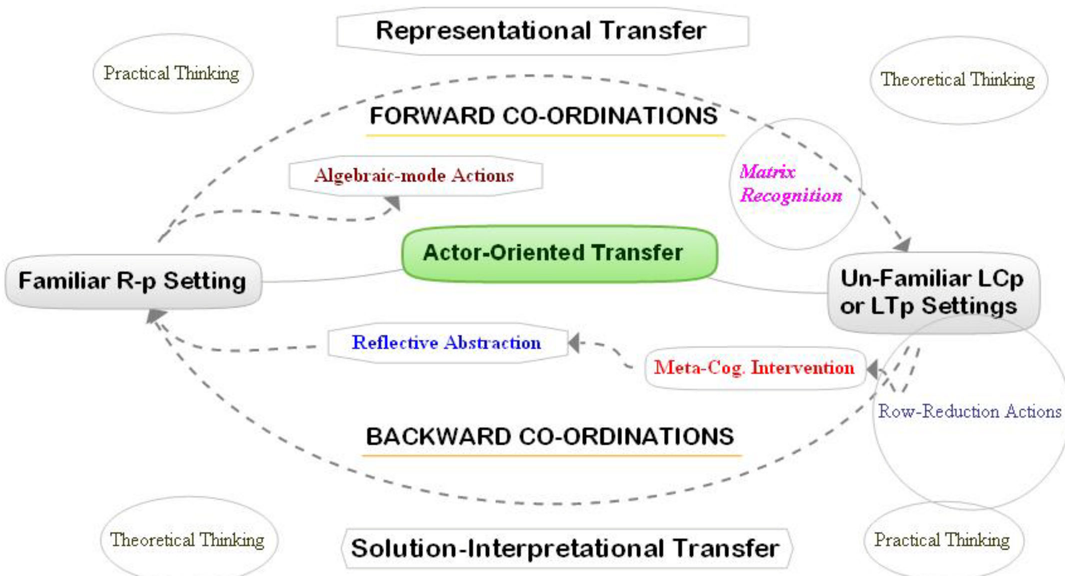

*Figure 3.* Result 4 illustration.

4. Algebraic mode computations characteristic of practical thought, in combination with meta representationally induced reflection characteristic of theoretical thinking, characterized a general pattern of *actor-oriented transfer* seen in the formation of co-ordinations between non-isomorphic settings, their representations, and corresponding solution interpretations. Furthermore: (a) Forward co-ordinations facilitating *representational transfer* were constructed from algebraic-mode transformations from definitions to familiar Rp-like systems of equations. (b) Backward co-ordinations facilitating setting-solution transfer involved the reversibility of reflectively interpreting the solution to a system of equations back through the representational co-ordinations connecting the matrix representation to the problem setting (see figure 3).

5. Upon successive exposure to problems from conceptually non-isomorphic settings sharing procedurality and matrix representations, the evidence indicated a reduction of the multiple constructive processes characteristic of previous actor-oriented transfer, leading to the conjecture that actor-oriented transfer become progressively streamlined in learning, encapsulating towards the spontaneous transfer of an abstract problem solving schema from familiar to conceptually non-isomorphic settings.

*Experiment 3*

The results of Experiment 3 indicated that the meta representational treatment was effective and reliable in promoting *target problem* success and traditional transfer from the assumed familiar knowledge in the Rp setting.

## Conclusions

The quantitative methods of this study produced three significant results in the area of traditional transfer experimentation. (i) Experiments 1 and 2 duplicated previous research by finding spontaneous transfer between *conceptually non-isomorphic* linear algebra problem settings to be rare in the absence of hints concerning the relationships between those settings. (ii) Experiments 1 and 2 extended research in the area of non-isomorphic transfer experimentation by finding that the combination of representational similarity and solution-procedural similarity between conceptually non-isomorphic linear algebra settings did not enhance transfer. And finally, (iii) Experiment 3 extended previous work by demonstrating transfer was indirectly facilitated with information of the meaning of a common representation (matrix) in the context of familiar and unfamiliar settings, not requiring meta information as to the relationships between the non-isomorphic Rp and LCp settings themselves (see figure 4).

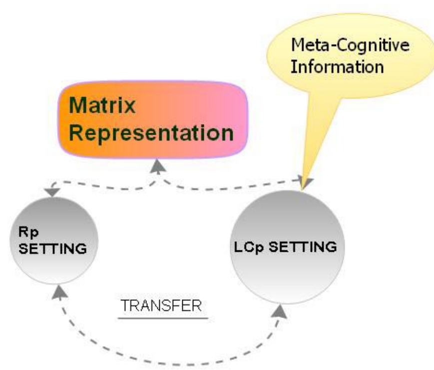

*Figure 4.* Indirect representational transfer.

From Result 5, as subjects repeatedly solved problems from conceptually non-isomorphic settings, the evidence showed a subtle decrease in the degree of personal constructions necessary in order to facilitate actor-oriented transfer. The author characterized this phenomenon as the occurrence of transfer, in the traditional sense, of prior problem solving knowledge from *within* the multiple constructive processes of actor-oriented transfer. From a Piagetian interpretation, the formation of forward and backward co-ordinations within the general process of actor-oriented transfer constitutes evidence of *reversibility* and potential *encapsulation,* marking the progress between *inter-operational* and *trans-operational* constructive phases, or in other terms, practical verses theoretical thinking (Piaget, 1983; Sierpinska, 2000).

# THE EFFECTS OF THE FUNCTION MACHINE ON STUDENTS' UNDERSTANDING LEVELS AND THEIR IMAGE AND DEFINITION FOR THE CONCEPT OF FUNCTION

Tangül (Uygur) Kabael
Anadolu University
tuygur@anadolu.edu.tr

*This study is on the effects of the function machine as a cognitive root on students' understandings of function concept. Data of the study was obtained from open-ended tests and clinical interviews. Results were analyzed according to the conception levels of the concept of function of APOS theory and concept image- concept definition framework of Tall and Vinner. It is concluded that function machine is a helpful cognitive root to raise the students' conceptual levels and to develop their concept images and concept definitions for the function concept.*

## Introduction

Mathematics education literature includes a lot of studies on function concept. Most of them agree with using multiple representation (table, graph, formula, procedure, verbal formulation, etc) environment in the teaching process of function concept (Janvier, 1987; Ferrini-Mundy and Graham, 1990; Confrey and Smith, 1991; Yerushalmy, 1997).

## Aim of the Study

In this study, our attention is to investigate the effects of the function machine on students' understanding of function concept.
We aimed to answer the following research questions:

- What is the effect of the function machine on students' understanding levels of the function concept?
- What is the effect of the function machine on the images and definitions that the advanced analysis course students have for the concept of function?

## Theoretical Framework

Because we aimed to investigate the effects of function machine on students' understandings of function concept, we evaluated their understanding levels according to APOS theoratical framework. Dubinsky and his colleagues' theory, APOS is a specific theoretical framework for research and curriculum development in collegiate mathematics education. The purpose of the theoretical analysis is to describe the specific mental constructions that a learner might make in order to develop her or his understanding of the concept. These mental constructions are called actions, processes, objects, and schemas. Dubinsky and his collagues (Breidenbach, Dubinsky, Hawks & Nichols, 1992; Dubinsky & Harel, 1992; Dubinsky, 1991) studied on conceptions of function concept. A subject who is at the level of an action conception of function is able to calculate the value of the function for a function formula and a point. To interpret a situation as a function unless a formula for computing values is given, inverses of functions, and the notion that the derivative of a function is a function are difficulties for a subject whose understanding of function concept is at the action level. When the action is repeated and reflected upon, it is interiorized to a process. The subject, who has the process conception of function thinks of a function as receiving one or more inputs that are independent variables, performing one or more

operations on the inputs and returning the results as outputs that are dependent variables. When a subject becomes aware of the process as a totally and is able to transform it by some actions or processes, it is said that the process has been encapsulated as an object. When a subject perceives manipulations of functions such as adding or multiplying, she or he encapsulates the process conception of function to an object. We should note that according to the Dubinsky and Harel (1992),
1. The three main restrictions students possess about what a function are:
(a)The *manipulation restriction* (you must be able to perform explict manipulations or you do not have a function)
(b) The *quantity restriction* (inputs and outputs must be numbers)
(c)The *continuity restriction (a graph representing a function must be continuous)*
*2.* Severity of the restriction. Some students feel, for example, that before they are willing to refer to a situation as a function, they personally have to know how to manipulate an explicit expression. (Dubinsky and Harel, 1992; pp. 86, 87)

Because other aim in this study is to investigate the effects of function machine as a cognitive root on students' concept images and concept definitions for the function concept, Tall and Vinner's framework of concept image-concept definition is also important for us. Tall and Vinner (1981) call the total cognitive structure that includes all mental pictures, associated properties and processes by concept image. According to Tall and Vinner, whether the concept definition is given to the student or constructed by himself, he may vary it from time to time, and in this way, a personal concept definition can differ from a formal concept definition. According to Vinner (1991) something which is evoked by the concept name in our memory is usually not the concept definition. Vinner (1991) takes the concept image and concept definition as two different "cells" in the cognitive structure. Vinner states the concept image cell is empty as long as some meaning is not associated with the concept name, and when the concept definition is memorized in a meaningless way, concept image cell is empty in many situations.

According to Vinner, after the teacher has given the definition of the concept to the student, who has a concept image, the concept image may be changed to include also the concept definition (satisfactory reconstruction or accommodation), the concept image may remain as it is and the concept definition will be forgotten or distorted after a short time (in this case the concept definition has not been assimilated), or both cells will remain as they are. Vinner states when the concept definition is first given, a similar process might occur. The concept image cell is empty at the beginning and it is gradually filled by examples and explanations. But, after the concept image cell has been filled, it does not always reflect all the aspects of the concept definition. According to Vinner, interplay between concept image and concept definition as seen in the Figure 1 refers to the long term processes of the concept formation.

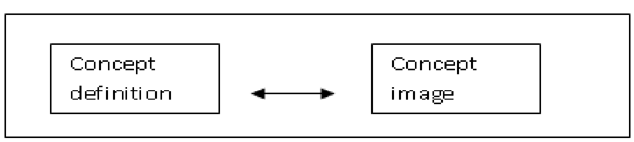

*Figure 1.* Interplay between concept image and concept definition.

Vinner adds that in addition to the process of the concept formation, there are also the processes of problem solving or task performance. When a cognitive task is posed to a student, different

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

relationships between the cells and the cognitive task can be occur according to the student's concept image and concept definition cells.

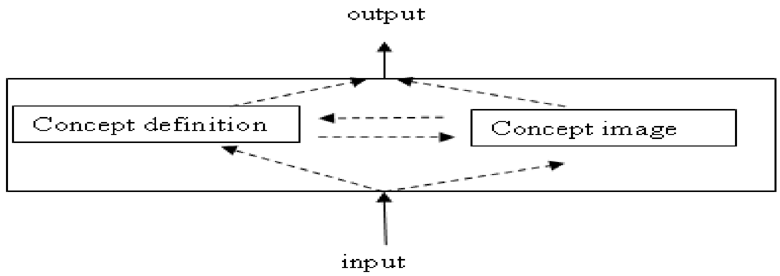

*Figure 2*. Relationships between the cells.

**Cognitive Root**

Tall, McGowen and DeMarois (2000) defined the notion of cognitive root as follows:
A *cognitive root* is a concept that:

- is a meaningful cognitive unit of core knowledge for the student at the beginning of the learning sequence,
- allows initial development through a strategy of cognitive expansion rather than significant cognitive reconstruction,
- contains the possibility of long-term meaning in later developments,
- is robust enough to remain useful as more sophisticated understanding develops.

(Tall, McGowen and DeMarois, 2000; p. 3)
Tall, McGoven and DeMarois (2000) suggests using the function machine (input-output box) as a cognitive root while teaching the function concept.

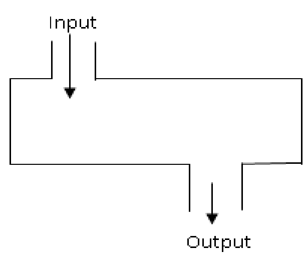

*Figure 3.* Function machine.

Tall and others stated the function machine (input-output box) as the cognitive box embodies both the process-object duality and also the multiple representations of the function concept as seen in following:

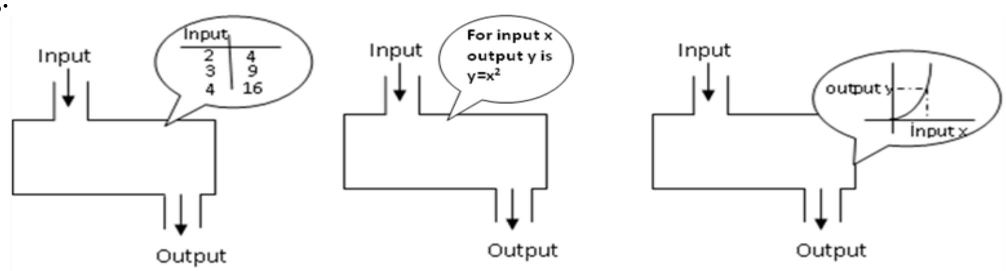

*Figure 4*. The function machine and representations of function.

Tall and others stated that the function box which is an embodied version of the more general function concept allows simple interpretations of profound ideas, for example two function boxes are “the same” if they have the same output for each input in the domain. They interpreted this perception of two function boxes being the same as occurring at the *process* level in the sense of Dubinsky.

## Methodology

This study was conducted to 23 students of one of the two groups of the advanced analysis course in the mathematics education program of a university in Turkey. Study is a part of a more comprehensive study in which understanding two variable function concept was aimed to investigate in the APOS theoretical framework (Asiala et al.,1996 ; Dubinsky, E. & Harel, G. , 1992). A lot of tests and clinic interviews were conducted in the advanced analysis course through an academic semester in the comprehensive study, whose method is teaching experiment (Cobb and Steffe, 1983). At the beginning, a test on single variable function concept was prepared and conducted to 23 students. After this test, single variable function concept was summarized by using function machine as a cognitive root. After the summary, another test on single variable functions was prepared in a similar manner to previous test. Then process of instruction of two variable function concept and preparation and conduction of tasks about this concept was started. After this process, clinic interviews were conducted with six of subject. These six subjects were chosen according to purposive sampling **(**Fraenkel and Wallen, 1996 ). Main criterion was to reach process conception for both single variable and two variable function concepts. Other criterion was accessibility. Because we aimed to report the effects of function machine as a cognitive root in this study, we will give the findings of first two tests and relevant tasks of interviews.

## Findings

According to the results of the first test, students had several difficulties and misconceptions about functions. Some graphs are given in the first question and it is asked if they are graph of a function whose independent variable is x. It is seen that most subjects did not have the notions of independent and dependent variables of a function. Several misunderstandings were seen in data. Most subjects (17 out of 23) have written an algebraic expression, which is familiar to them beside the graph. Generally (except three subjects), subjects focused on the notion of independent variable by overriding the concept definition.

In the aspect of algebraic (formula) representations of functions, students had similar misconceptions to the misconceptions students had in graph cases. Again, it is seen that the most effective reason of these misconceptions was that students did not have notion of independent variable of a function. Most students (16 out of 23) could perceive the functions only in table situations. That is, they could regard input-output and transference notions only in table situations. All students could find the input corresponding to the given output for the function, whose algebraic representation was given. Moreover, almost all students could complete the input-output table by using the given graph. The students who had faults in this task could not perceive the output corresponding the input in which the function was discontinuous. Almost all students could draw the graph of partial functions, while most students drew a whole circle instead of semi-circle by regardless of range of function. Contrary to the first test, most students (13 out of 23) could perceive the functions both graph and algebraic situations. Only four subjects had still focused on the independent variable notion instead of the function process.

For the definition of function, various types of definitions for the function concept were given in the pre-test. Most categories of the definitions are similar to the categories that Vinner and Dreyfus (1989) had. Subjects chose the class of item, which was defined, variously like equation, expression, or rule. Some of them also gave the uniqueness to the right condition of transfer. Three subjects defined the function correctly as a relation, while four subjects defined as a relation, but without uniqueness to the right condition. One subject defined as a correspondence with uniqueness to the right condition, while another subject defined as a correspondence without uniqueness to the right condition. When the function definitions in the pre-test and in the post-test were compared, it was seen that development was surprising. 18 subjects gave correct definition of function concept. Most of them defined the function concept as a special relation, and remaining defined as a correspondence correctly. While one of other subjects defined the function concept as a rule with uniqueness to the right condition, two of them defined as a machine. Only one subject defined as an expression.

Another task in which students had difficulties was that required the graph of an upper semi-circle in the sixth question of the first test. Similarly, the algebraic expression of lower semi-circle was given in the second test, and its graph was required. 17 out of 23 subjects gave correct graph in the second test. Only five subjects gave the graph of whole circle in the second test, while 13 out of 23 subjects gave the graph of whole circle in the first test. Remaining one subject gave completely wrong graph in the first test.

One of the relevant tasks to the aim of this study in the interview questionnaire was to find a function process on a set of functions. At the beginning of the interviews, the meaning of function was again questioned with a question like "what is a function?” or “according to you what does function mean?”. After following some other tasks, subject prompt to find a function process on a sets of functions with the questions as seen in following:

- You defined the function concept at the beginning of our interview. Is there any restriction on the domain of a function?
- Can the domain of a function be any set, which does not equal to the empty set?
- Do you know a function whose elements are also function?

If the subject could not see function as an element of a function, that is she/he could not see function as an object, she/he prompted as following:

- Can you imagine a function machine such that its inputs are functions?
- What can be the outputs of such a function machine?
- Do you know such a function machine on functions?

According to the responds of subjects to this task, four of six subjects could see function as an element of domain, and they gave the operations on a set of functions like composition, derivative, integral. Also one subject could see the taking inverse of a function as a function operation on the set of one to one and onto functions, but then it was seen that she could not have seen a function as an object. Other subject could not give any interpretation about this task.

## Results

According to the results of the first test, six of 23 students’ understanding of function concept was action level at the beginning of advanced analysis course. One of the remaining subjects’ conception level was transition from action to process. Except one subject, who had process conception, remaining 15 subjects had relatively weak process conceptions, which include at least one of the restrictions of severity, manipulation, and quantity. We should note that the conception levels were determined after qualitative analyze of data which were obtained from responds for open-ended tasks.

After brief instruction by using function machine as a cognitive root, two subjects' conception level rose from action to process, and four subjects' conception level rose from action to transference from action to process. Ten subject's conception levels were process even if some of them had restrictions, while their levels were relatively weak process conception before the brief instruction. Two subjects' conception levels were relatively weak process both before and after the brief instruction, but at least they abandoned the restrictions they had. Remaining subjects raised their conception levels from relatively weak process to weak process, because at least they developed to perceive functions in the table situations.

After the interviews which were conducted by six subjects whose conceptions levels were seen as at least process after brief instruction, it was concluded that conception levels of four of them were object level.

In the aspect of concept image and concept definitions of subjects for the function concept, most students' developments were well. Subjects' concept images, which included various misconceptions like familiarity, variable complexity at the beginning were disappeared after brief instruction. Moreover, most of them gained the concept definition and began to consult their concept definition and to relate their concept images and concept definitions, while they consulted only their concept images at the beginning.

## Conclusion

We concluded that function machine is very effective as a cognitive root on understanding the function concept. By instruction this cognitive root, students gain input-output and transference notions. Emphasizing with various examples that input of the machine, which is independent variable of function is an element of any set, which is not empty, this input transforms an output, which is dependent variable of function with the operation of the machine is gained the students the concept definition. Moreover, students develop the notions of domain and range by such an instruction. In the aspect of understanding levels of the students, it is helpful to rise the students' conceptual levels. Especially, by increasing in variety the inputs, students can begin to see a function as an object. For instance, students can make some operations on the set of functions, but generally they do not see neither these operations as functions nor the functions as an elements of a set. To give such operations on the sets of functions like arithmetical operations or composition as an example of function machine is gained the students seeing a function as an object. Moreover, such examples are helpful to be disappeared the restrictions like quantitative or manipulation. Such function machine examples can be given instruction of not only the single variable function concept but also two variable function concept.

# ACCOMMODATING INFINITY: A LEAP OF IMAGINATION

Ami Mamolo
York University
amamolo@yorku.ca

*This paper is the first installment of a study which seeks to identify the necessary and sufficient features of accommodating the idea of actual infinity. University mathematics majors' and graduates' engagement with the Ping-Pong Ball Conundrum is used as a means to this end. This paper focuses on one of the necessary features: the leap of imagination required to conceive of actual infinity, as well as its associated challenges.*

## Introduction

The concept of infinity has a distinctive quality which rouses the imagination, provoking controversy, and challenging fundamental ideas intuited as truth. In meeting these challenges and controversy an individual is invited to think in often new and complex ways—to engage in "advanced mathematical thinking."

The term 'advanced mathematical thinking' carries with it many descriptions. Although there is no agreement on the definition, many of the characteristics describing advanced mathematical thinking are exemplified in the concept of infinity.

One working description suggests advanced mathematical thinking (AMT) involves abstract, deductive thought (Tall 1991, 1992), and includes "proving in a logical manner based on definitions" (Tall, 1991, p. 20). Alternatively, ideas that exercise advanced mathematical thinking may be considered as ones that are not "entirely accessible to the five senses" (Edwards, Dubinsky, & McDonald, 2005, p. 18), and lack "an intuitive bases founded on experience" (Tall, 1992, p. 495). The abstract and intangible nature of actual infinity epitomises both of these descriptions.

This paper presents research from part of a broader investigation which aims to identify the necessary and sufficient features involved in accommodating the idea of actual infinity. It focuses on the 'leap of imagination' required to conceive of mathematical infinity, as well as on the challenges university mathematics students and graduates faced in making such a leap.

## Background

The concept of infinity carries with it a "surprisingly rich intuitive base that many students seem naturally to be endowed with" (Mamona-Downs, 2002, p. 49). Research into the nature of learners' intuitions of infinity has shown "that infinity appears intuitively as being equivalent with inexhaustible" (Fischbein, 2001, p. 324). Specifically, learners are naturally inclined to conceive of a potential or 'dynamic' infinity – a process for which every step is finite, but which continues endlessly. Intuitions of an 'endless infinite' have been observed in students of all levels, from middle school to university (e.g. Tirosh, 1991). In resonance with the general characteristics of intuitions, the idea of an endless infinite tends to be resilient: it is seen as self-evident, intrinsically certain, coercive, and resolute (Fischbein, 1987).

Current research suggests students' understanding of mathematical infinity tends to develop by reflecting on knowledge of related finite concepts and extending these familiar properties to the infinite case (Fischbein, 2001; Fischbein et al., 1979). As Fischbein (2001) observed, when learners attempt to establish an understanding of abstract concepts, their tacit mental

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

representations in the reasoning process replace the abstract concepts by more accessible and familiar ones. For example, when analysing infinite sets, students may apply familiar methods for comparing sets that are acceptable in the case of finite sets, such as the inclusion (or part-whole) method, but which result in contradictions in the infinite case (e.g. Fischbein et al., 1979). With respect to infinite sets, only one method of comparison yields consistent solutions: one-to-one correspondence. Through the idea of 'coupling' elements, two (infinite) sets that can be put into one-to-one correspondence are accepted by the normative standard as having the same 'size', or cardinality.

Students' well-documented struggle to understand and appreciate aspects of infinite cardinality has motivated efforts to improve and refine pedagogical strategies. For instance, in set activities administered by Tsamir and Tirosh (1999), geometric figures were used to emphasize a correspondence between numerical sets, as well as to draw students' attention to the inconsistencies of comparing infinite sets with different methods. One of the goals of this study was to elicit cognitive conflict in the participants, thus a task which elicited an inclusion method of comparison was followed by one which elicited a one-to-one correspondence method. Tsamir and Tirosh concluded that this series of activities, which can elicit cognitive conflict "has the potential for raising students' awareness of incompatibilities in their own solutions to the same mathematical problem" (1999, p. 216). However, Tsamir (2003) warns that participants must come to appreciate one-to-one correspondence as the *only* appropriate method of infinite set comparison, and such was not the case in Tsamir and Tirosh (1999).

This study extends on prior research by examining conceptions of university mathematics students and graduates as they engaged with the well-known paradox 'The Ping-Pong Ball Conundrum'. Despite participants' sophisticated mathematical background and their experience and skill with abstract mathematics and mathematical thinking, participants faced challenges distancing themselves from realistic concerns and engaging with the mathematics presented in this novel problem-solving situation. These challenges are explored in this paper with the intent to shed light on the necessary and sufficient aspects required for a normative understanding of actual infinity, as well as on pedagogical strategies to guide learners toward such an understanding.

## Theoretical Framework

The concept of infinity relies on abstract, formal definitions of concepts for which intuition and the senses have no foundation. As such, one of the theoretical perspectives which guided this study is Hazzan's (1999) 'reducing levels of abstraction'. In Hazzan's (1999) perspective, when learners are confronted with a novel problem solving situation, they will attempt to make sense of unfamiliar or abstract concepts by reducing their level of abstraction. Hazzan describes different ways a learner may attempt to reduce abstraction. One such way she observed was in working with familiar entities when learners were faced with problems for which an understanding of the mathematical entities involved were not yet constructed. As an example, Hazzan noted that when learning abstract algebra, students would "often treat groups as if they were made only of numbers and of operations defined on numbers" (1999, p. 77). By basing arguments on familiar mathematical entities, such as numbers, in order to cope with unfamiliar concepts, such as groups, students lower the level of abstraction of those concepts.

In addition to relying on familiar entities to reduce the level of abstraction of novel ones, Hazzan interprets "students' personalization of formal expressions and logical arguments by using first-person language" as an attempt to reduce the level of abstraction of that expression.

For instance, language such as “I can find” or “I want to find” (Hazzan, 1999, p. 80), indicate, in Hazzan’s perspective, ways that a student may cope with unfamiliar terminology and concepts.

Hazzan (1999) relates her framework of reducing levels of abstraction to the APOS (Action, Process, Object, Schema) Theory of Dubinsky and McDonald (2001) through the observation that process conceptions of a mathematical entity may be considered on a lower level of abstraction than their corresponding conceptions as objects. She also argues that a learner’s attempt to reduce the level of abstraction of a mathematical entity through, for instance, the use of first-person language, indicate that the learner holds a process (rather than object) conception of that entity. Process and object conceptions are in the centre of the second framework considered in this study, that of the APOS Theory (Dubinsky & McDonald, 2001).

Dubinsky, Weller, McDonald, and Brown (2005a, 2005b) proposed an APOS analysis of infinity. They suggested that interiorising infinity to a process corresponds to an understanding of *potential* infinity, or the inexhaustible. As such, a process conception of infinity is imagined as performing an endless action, though without imagining the implementation of each step. Encapsulating this endless process to a completed object, in turn, corresponds to a conception of *actual* infinity, a quantity which describes the ‘size’, or cardinality, of a completed infinite set. As in the more general case, encapsulation of infinity is considered to have occurred once a learner is able to think of infinite quantities “as objects to which actions and processes (e.g., arithmetic operations, comparison of sets) could be applied” (Dubinsky et al., 2005a, p. 346). Dubinsky et al. also observed that “in the case of an infinite process, the object that results from encapsulation transcends the process, in the sense that it is not associated with nor is it produced by any step of the process” (2005a, p. 354).

## Methodology

### *Participants*

Data for this study were collected from five participants with advanced mathematical backgrounds. Each of the participants had prior experience with Cantor’s theory of transfinite numbers through formal instruction during upper level undergraduate mathematics courses. In particular, they were familiar with comparing infinite sets via one-to-one correspondence, such as corresponding the sets of natural numbers and rational numbers, and also with Cantor’s diagonal argument establishing the set of real numbers as having larger cardinality than the set of natural numbers. Participants also had substantial experience with infinity in calculus. The participants in this study included students enrolled in undergraduate degrees in mathematics, as well as participants who had completed at least a master’s degree in mathematics or mathematics education.

- Marc was a mathematics major in a south eastern state university in the USA. He was very bright and eager to engage with the paradoxes. In addition to his background with cardinal infinity, he had informally explored aspects of infinity in other contexts. Marc anticipated pursuing a graduate degree in mathematics.
- Maria was a classmate of Marc’s in the mathematics program. Her familiarity with Cantor’s theory included an awareness of the Continuum Hypothesis, as well as some properties of transfinite ordinal numbers.
- Joey was in his fourth year of an undergraduate degree in mathematics and physics at a university in eastern Canada. Joey had taken upper year courses in set theory and analysis, both of which touched on Cantor’s theory.

- Vince was a doctoral candidate in mathematics at a university in eastern Canada. Since his participation in this study, he had completed his degree, and began a professional research career in cryptography.
- Jenny was a doctoral candidate in mathematics education at a university in eastern Canada. Her area of research was didactiques des mathematics, and her scholarly background included an undergraduate degree in mathematics and physics.

*Data Collection*

Data from the five participants were collected through email correspondence, which was intended to offer participants the opportunity to put their thoughts in writing in order to contribute more precise and balanced responses than possible in a formal interview. The Ping-Pong Ball Conundrum (described below) was presented to participants, and they were asked to determine how many ping-pong balls remained in the barrel at the end of the 60-second experiment, and to explain their reasoning. The Ping-Pong Ball Conundrum was chosen because of its level of complexity, and because of the necessity to address a bound infinite set in the paradox resolution.

*The Ping-Pong Ball Conundrum*

> An infinite set of numbered ping-pong balls and a large barrel are instruments in the following experiment, which lasts 60 seconds. In 30 seconds, the task is to place the first 10 balls into the barrel and remove the ball numbered 1. In half of the remaining time, the next 10 balls are placed in the barrel and ball number 2 is removed. Again, in half the remaining time, balls numbered 21 to 30 are placed in the barrel, and ball number 3 is removed, and so on. At the end of the 60 seconds, how many ping-pong balls remain in the barrel?

The normative resolution to this paradox involves coordinating three infinite sets: the in-going ping-pong balls, the out-going ping-pong balls, and the intervals of time. Although there are more in-going than out-going ping-pong balls at each time interval, at the end of the experiment the barrel will be empty. A fundamental aspect in the resolution of this paradox is the one-to-one correspondence between any two of the three infinite sets in question. Given these equivalences, at the end of the experiment, the same amount of ping-pong balls went into the barrel as came out. Moreover, since the balls were removed in order, there is a specific time for which each of the in-going balls was removed. Thus the barrel is empty at the end of the 60 seconds.

## Results and Analysis

Surprisingly, despite the sophisticated mathematical knowledge of participants, only one participant, Marc, provided a resolution to the Ping-Pong Ball Conundrum that was consistent with the normative one. Indeed, as participants attempted to reconcile properties of actual infinity with the notions that were elicited by the Ping-Pong Ball Conundrum many were unwilling to take a leap of imagination beyond practical or realistic considerations and toward the 'realm of mathematics'.

The inability to leap toward the imaginative surfaced in participants' reluctance to distance themselves from concerns such as physical possibilities and constraints. For instance, Vince, a doctoral student in mathematics, objected to the feasibility of the experiment, and refuted the possibility of completing the experiment. He remarked that the "first thing that comes to mind is that the problem is not really that well-defined as the time left, 1/2n, never reaches zero." Vince went on to consider the processes of inserting and removing balls, and concluded that:

> You'll have lots of balls in the barrel when you reach 0 [end of the experiment], which you won't. And this is clearly a ridiculous answer if you consider the whole thing to be something that could take place. So my final answer is 136.

Vince's desire to consider the experiment as "something that could take place" suggests a reluctance to engage with the thought experiment in the Ping-Pong Ball Conundrum, which is by no means an experiment that could actually take place. Vince's resistance to let go of practical experience is also recognised in his comment that "lots of balls in the barrel" is "clearly a ridiculous answer", which suggest he was unable or unwilling to conceive of a barrel that could contain infinitely many balls. Also, Vince's notion of an endless experiment corresponds to a conception of potential infinity and is suggestive of a process conception, in terms of the APOS Theory. A conception of potential infinity, together with resilient practical concerns, seemed to prevent Vince from considering the infinite sets of balls or time intervals as completed objects.

Imagining the experiment being carried out also influenced Joey, an undergraduate student in mathematics. Joey's response began by describing the physical items in the paradox – such as the barrel and the balls – and speculating on the outcome if he were to actually perform the experiment. Joey wrote:

> Well, at first I'm thinking about a massive collection of white ping-pong balls. And an actual wooden barrel. Clearly thinking about actually performing the experiment and then realising there is no way I can actually move that fast in real life so I realise the final ping-pong ball count would be finite. However thought experiment… so... mathematically…

Joey's instinct was to consider the experiment in a 'realistic' way, and like Vince, he initially approached the paradox as though it were an experiment that he could perform. Once Joey realised that the physical constraints of reality restricted his solution to a finite "count", he distinguished between what was possible practically versus mathematically. This distinction suggests Joey was, to a degree, aware of a conflict between practical experiences and the realm of infinity. Nevertheless, Joey's realistic approach of "thinking about actually performing the experiment" seemed to influence his deliberations even as he addressed the thought experiment "mathematically." For instance, he continued to describe the experiment as though it were being carried out:

> Since I keep halving the time I add and remove ping-pong balls, I will never reach 60 seconds. So the experiment should never end, really. Meaning I have an infinite number of ping-pong balls, and yet there are more in the barrel. Since infinity is not an actual number, you can't say I have infinity here, but 9 times infinity there.

Joey maintained a personal connection to the experiment, and described his own involvement in terms of the actions he would take and the outcomes he would face. The use of personal language to cope with an abstract concept is, in Hazzan's (1999) perspective, an attempt to reduce the level of abstraction of that concept, and as such is indication of a process conception of infinity. Further, Joey's description of infinity as "more like a destination, an indication of an unlimited amount", and his remark that the "experiment should never end", are consistent with a process conception of infinity.

A use of personal language was also identified in Jenny's response, as she too resisted letting go of 'practical' concerns. Jenny, a doctoral candidate in mathematics education, also commented on physical limitations in the experiment. She found the issues of speed and time problematic, suggesting, "there is not enough time to work so fast." She also noted that "the fastest speed is light speed" and that if she could work at the speed of light then time would slow down and there would be "infinity time, so there will never be a last ball." She described herself as being stuck in an endless experiment, left to insert and remove ping-pong balls for eternity, lamenting "but I don't want to do that with my life."

The cognitive leap from the 'realistic' to the realm of mathematical infinity was a source of difficulty for Vince, Joey, and Jenny. Their resistance to engage with the realm of imagination and mathematics noticeably impacted each of their resolutions, and in the case of Vince prevented him from resolving the paradox beyond giving an arbitrary number as his solution. Another student attempted to bridge her realistic concerns with the surreal thought experiment by introducing assumptions. This student, Maria, attempted to reconcile reality and infinity by assuming the impossible was possible. For instance, Maria, an undergraduate student in mathematics, reasoned there would be an infinite number of ping-pong balls remaining in the barrel at the end of the experiment "assuming the barrel has an infinite volume and can house an infinite number of ping-pong balls." Maria imagined an infinite iterative process, noting that "per iteration, the barrel gains an additional 9 ping pong balls than it had previously… so to determine the number of ping pong balls in the barrel at the end of the experiment, we can simply determine the number of iterations and then multiply this by 9." Maria seemed to treat infinity as a very large number, and as such, needed to assume that the physical constructs could accommodate this 'infinite size'. Interestingly, Maria did not assume the existence of infinitely many ping-pong balls, only that they could be housed in the barrel. Recalling the normative solution, Maria's assumption is superfluous as the barrel at no moment contains infinitely many ping-pong balls.

In accordance with Mamolo and Zazkis (2008), participants who resisted distancing themselves from reality by clinging to practical concerns or by introducing capricious assumptions tended to approach the paradox in intuitive, process-oriented ways, such as focusing on infinite iterations. As Fischbein (1987) observed, properties of actual infinity contradict the finiteness of mental schemas and intuitions. In contrast, the ability to take a leap of imagination away from the realistic or the intuitive corresponds to an ability to engage effectively in advanced mathematical thinking—thinking which lacks "intuitive bases founded on experience" (Tall, 1992, p. 495). Clarifying the limitations that finite experience has on an understanding of infinity seems to be a fundamental aspect of accommodating properties of actual infinity—properties which by all means lack intuitive bases founded on practical experience.

Distinguishing between an intuitive and a formal understanding of infinity was an essential aspect in Marc's reasoning as he addressed the Ping-Pong Ball Conundrum. Marc, an undergraduate mathematics student was the only participants who came up with a solution that was consistent with the normative resolution to the paradox. Marc's approach was proof by contradiction. He wrote:

> We can assume that some ball does remain after the minute is up, and without loss of generality, let's say it's the nth ball. But we know that this ball is taken out during one of the steps 10n-9, 10n-8, .... ,10n-1, 10n, and all of these steps occur within one minute due to the fact that the series: (Sum from k=1 to k=infinity of (1/2^k)) converges to 1. But then the aforementioned ball is NOT in the barrel at the end of the minute, which contradicts our original assumption that it was. Therefore, there are no balls left in the barrel at the end of the minute.

Notable in Marc's response is his use of language. Marc seems to refer to a general, and perhaps impersonal, body of knowledge. For instance, Marc refers to "our original assumption", commenting on what "we know" in his solution. His depersonalized use of language is in sharp contrast to other participants who referred to what they as individuals could achieve (i.e. 'I add', 'I find', 'I want').

In connection to his removed stance from the experiment, Marc was also the only participant to clarify a separation between his realistic intuitions and his mathematical thinking. Marc's awareness of the limitations of intuition and realistic experience seemed to contribute significantly to his understanding of actual infinity. After discussing his solution, Marc reflected that "the intuition we've learned from the physical world fails us when it comes to the infinite." His willingness to distinguish between intuitive and formal understandings can be linked to his ability to take the leap of imagination necessary for accommodating actual infinity. Indeed, holding on to realistic, finite experiences and intuitions seemed to hinder the encapsulation of a process for which there is no final step, but for which a completed totality does exist.

## Conclusion

Conceiving of actual infinity exemplifies mathematical thinking that "extrapolates beyond the practical experience of the individual" (Tall, 1980, p. 1). As such, problems addressing infinity require a leap of imagination away from practical experience. In resonance with observations made in Mamolo and Zazkis (2008), participants resisted extrapolating beyond their practical or realistic experiences when addressing the ping-pong experiment. Letting go of realistic considerations was problematic for participants despite their considerable experience with advanced and abstract mathematics – mathematics that is inaccessible to the five senses (Edwards et al., 2005) and that lacks an intuitive basis (Tall, 1992). The inability to take the cognitive leap into the realm of mathematical infinity manifested in participants' responses in striking similarity to the reactions of participants in Mamolo and Zazkis (2008), despite much more sophisticated experience with 'advanced mathematical thinking'. There were those participants who were unable to 'leap', others who recognised the need to 'leap' but resisted, and some who could 'leap' to work within the realm of mathematics and clarify a separation between 'real' possibilities and mathematical truth.

This study draws attention to a pedagogical necessity to guide learners away from 'realistic' or intuitive approaches when addressing abstract mathematics, particularly with respect to concepts such as infinity. Continued research on effective pedagogical strategies to achieve this end, as well as on further necessary and sufficient features of accommodating the idea of actual infinity is underway.

# STUDENTS' IDEAS ON FUNCTIONS OF TWO VARIABLES: DOMAIN, RANGE, AND REPRESENTATIONS

Rafael Martínez-Planell
Universidad de Puerto Rico – Mayagüez
rafael@math.uprm.edu

Maria Trigueros Gaisman[1]
Instituto Tecnológico Autónomo de México
trigue@itam.mx

*The study of student understanding of multivariable functions is of fundamental importance given their role in mathematics and its applications. The present study analyses students' understanding of these functions, focusing on recognition of domain and range of functions given in different representational registers, as well as on uniqueness of function value. APOS and semiotic representation theory are used as theoretical framework. The present study includes results of the analysis of interviews to 13 students. The analysis focuses on student' constructions after a multivariate calculus course, and on the difficulties they face when addressing tasks related with this concept.*

## Introduction and Purpose of the Study

The notion of a multivariable function is of fundamental importance in advanced mathematics and its applications. Even though its understanding is essential for mathematics, science and engineering, little is known about students' ideas and difficulties. There are very few research based studies that probe student understanding of the particularities of a multivariable function. This lack of research findings limits our understanding of how students learn the main ideas of the multivariable calculus.

The present study is a continuation of a previous study (Trigueros & Martínez-Planell, 2007) which reported on student understanding of graphs of functions of two variables. The focus of the present study rests on the following research questions: What are students' conceptions of domain and range of functions of two variables when they finish a Multivariate Calculus course? How are these conceptions related to their abstract, general notion of function?

## Theoretical Framework

Two conceptual frameworks inform the theoretical basis used in this study. Firstly APOS theory is used to model the development of the concept of two variable functions and, secondly, semiotic representation theory, provides the conceptual tools to analyze flexibility in the use of different representations and its role in the cognitive evolution of the mathematical ideas under consideration.

As APOS Theory is a well known theory, only its application for the purpose of this study is described. For more detail the reader may consult Asiala et al. (1996), and Dubinsky (1991, 1994).

The application of APOS theory to describe particular constructions by students requires researchers to develop a genetic decomposition—a description of specific mental constructions one may make in understanding mathematical concepts and their relationships. A portion of a preliminary genetic decomposition for the function of two variables concept given in Trigueros and Martínez-Planell (2007), is summarized below since it will be referred to throughout this paper:

The Cartesian plane, real numbers, and the intuitive notion of space schemata must be coordinated in order to construct the Cartesian space of dimension three, $R^3$, through the action

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

of assigning a real number to a point in $R^2$, and the actions of representing the resulting object both as a 3-tuple and as a point in space and making conversions between them. These actions are interiorized into a process that considers all the possible 3-tuples and subsets of 3-tuples, and their representation in space, to construct a process that when coordinated with the respective verbal, analytic and geometric representations can be thematized as three dimensional space, $R^3$.

This space schema is coordinated with the schemata for function and set through the action of assigning one and only one specific height to each point in a given subset of $R^2$, either analytically or graphically. This action is interiorized into the process of assigning a height to each point on a subset of $R^2$ to construct a two variable function, and the process of conversion needed to relate its different representations. When the process of generalization of these actions to consider any possible function of two variables, as a specific relation between subsets of $R^2$ and R is encapsulated, it can be considered that the notion of two-variable functions has been constructed as an object.

Duval (1999, 2006), argued that thinking processes in mathematics require not only the use of representation systems, but also their cognitive coordination. In Duval's analysis, understanding and learning mathematics require the comparison of similar and different representations. According to this author, there are two different types of transformations of semiotic representations: treatments, which are transformations of representations that happen within the same representation register, and conversions which consist of changes of representation register without changing the object being denoted. He argues that these two types of transformations are the source of many difficulties in learning mathematics, and that overcoming these difficulties needs to take them both into account: to compare similar representations and treatments within the same register in order to discriminate relevant values of the mathematical object so that students notice the features that are mathematically relevant and cognitively significant, and to convert a representation from one register to another to dissociate the represented object and the content of the particular representation introduced so that the register does not remain compartmentalized.

## Method

An instrument was designed to conduct semi-structured interviews with students and test their understanding of the different components of a proposed genetic decomposition (Trigueros & Martínez-Planell, 2007). Nine students were interviewed. The students were chosen from a group of undergraduate students at a private university who had taken the equivalent of an introductory multivariable calculus course the previous semester. The instructor of the mathematics course they were currently taking chose what he judged three good, three average, and three weak students to be interviewed. On the basis of the results obtained, and in preparation for the present study, the researchers decided to conduct more interviews focusing on items in which it seemed more data would be useful. The instrument was once again revised to do this and five new interviews were conducted. These students were chosen from a group of undergraduate students at a public university who had just finished taking the equivalent of an introductory multivariable calculus course that same semester. The instructor of the multivariable course they took chose what he judged two slightly above average, and three average students to be interviewed. All interviews lasted for 45-60 minutes, were audio-recorded, and all the students' work on paper was kept as part of the data. The results obtained in 13 of these interviews were independently analyzed by two researchers, and the conclusions negotiated.

## Results

Results of the analysis of students' responses during the interview showed that none of these students was able to demonstrate all the constructions described in the genetic decomposition. Their description of what they consider a function seems to be more closely related to that of relation and associated mainly with its analytical representation. Students differed in the difficulties they faced during the interview but most of them struggled with the description of the domain of these functions in all the representations included in the tasks and in the conversion between representation registers.

Eight of 13 students had difficulty with the arbitrary nature of the relational correspondence. For example, when Emily was asked if the rule: "Input: weight in kilograms and height in centimeters. Output: name of person with that weight and height" defined a function, she responded:

Emily: *ok … [nervous laugh] for me, the fact that you have the weight, a weight and a height in centimeters [nervous laugher], the name is not there anywhere, … I don't know how one gets to …*

The same type of response is observed in Rodrigo:

Rodrigo: *…because it can't be that with only the weight and the height we can obtain the name of the person.*

When asked to define a function of two variables Gaddis responded:

Gaddis: *…, for me a function of two variables is a function of the form* $f(x,y)$ *is equal to x … a term in x, a term in y, and a constant or any number, then the domain would be, the two variables, that would be independent … and the range would be the result of those two variables evaluated in the function.*

In the genetic decomposition we assumed that the construction of the notion of function of two variables requires the coordination of a schema for $R^2$ with that of function through the action of assignation of one and only one value to each element in the domain of the function. Some students did not show to have made this coordination. Among them, there were 4 students who did not consider that a function is determined by the uniqueness of that assignation. Rodrigo is one such student:

Interviewer: *and if I were to give you a list with all students at this university with their weight and their height*
Rodrigo: *ok, here you could, but you'd get several results*
Interviewer: *and that, would be a function?*
Rodrigo: *yes, hmm, yes, yes*

Another student, Gaddis, commented to this same question:

Interviewer: *…is that a function?*
Gaddis: *…yes, I think so*
Interviewer: *So if a give you the weight, say 60 kg and height 2 m, what could be the output?*
Gaddis: *It would be the name of a person with that data*
Interviewer: *and, if there were more than one person with that data?*
Gaddis: *…the output would be the name of the person*

Later, while further exploring Gaddis's uniqueness of value notion, the interviewer presented the equation $x^2 + y^2 = 1$ to him, and asked:

*Interviewer: … y, is it a function of x?*
*Gaddis: … it could be, if we solve for the y*
Interviewer: *ok, I solve for the y and get* $\pm\sqrt{1 \;\; x^2}$ *, the y, is it a function of x?*

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

Gaddis: *y, there it depends on x in that case*
Interviewer: *then, is it a function of x?*
Gaddis: *I think it is.*

Most of the students had difficulties when describing the domain of a two variable function. It was found that 3 students do not have a clear idea that the elements in the domain of this type of function are always ordered pairs. Even though they accept they need ordered pairs in order to find the value of a particular function, when they are asked how many elements are there in the domain of a function given in a table representation, they count the elements of each pair as different elements in the domain. For example:

Fernando: *… the elements, would be eight [he was using a 4 by 4 table]*
Interviewer: *give me an example of an element in the domain of*
Fernando: *0 comma 2*

Even though he uses "0 comma 2" as example of an element in the domain, he still counts the domain as a set of numbers. In terms of the genetic decomposition it seems these students have not interiorized the action of assigning one and only one specific height to each point in a given subset of $R^2$; rather than applying the action to elements of $R^2$, they seem to be acting on sets of two real numbers. In the case of María, she correctly listed the elements in the domain, but when asked to count them, she stated:

Maria: *ok, then, do I count them as pairs or separate?*

Another problem some students had in finding the domain of functions was that they were not able to restrict the domain to specific subsets. For example, when analyzing the function defined by $f(x,y)=1+x^2+y^2$, where the domain is restricted to the pairs $(x,y)$ that satisfy: $-1\le x\le 1$ and $-1\le y\le 1$, Paola could not understand the meaning of that restriction. With some help, she eventually succeeded in drawing the domain. However, later on, when trying to find the range she said:

Paola: *the thing is that I'm not sure what it means that it is restricted to the pair of numbers that satisfy this*

Of the 8 students having difficulty representing the domain of the above function, 5 tried to draw the graph of *f* first, without considering any restriction. Emily and Gracielle are examples of this difficulty:

Emily: *I'm trying to do the graph, to know more or less what would be the domain …*
Gracielle: *… [mumbles] …It says x goes from -1 to 1, and y goes from -1 to 1, a circle*
Interviewer: *and why is it a circle?*
Gracielle: *because the graph is a paraboloid …*

It was also found that students' ability to find the domain of a given function was related to the representation register used to present the information. The following was one of the questions of the interview: The following is the complete graph of a function *f:*

a. Find the domain of *f.*
b. Evaluate $f(0,0)$, $f(2,0)$, $f(2,2)$, $f(0,2)$.
c. Find the range of *f.*

In parts (a) and (c), the domain and range were found correctly by 10 students, and incorrectly by 3. As was already mentioned, some students tried to graph functions in order to find their domain, even when a restriction defining it was given, so it seems that students did not have much difficulty obtaining domain and range information from a graphical representation of a two-variable function. However, as was reported previously (Trigueros & Martínez-Planell, 2007), students do have great difficulty obtaining the graphical representation of functions of two variables, as well as obtaining other kinds of information from such surfaces. In this case Patricia, who treated domain incorrectly as a set of numbers when presented with functions in tabular or algebraic representations, was able to correctly find the domain in this case. This is one of the several examples found which confirm what was observed by Gagatsis, Christou, and Elia (2004): the cognitive demands for translating (converting) among representations are not the same, and so each one needs to be specifically attended.

It was also observed that all students who could get neither the domain nor the range of a function when its graphical representation was given also had difficulties when asked to find them for functions given in tabular or algebraic representations.

Some students showed some confusion between the domain of the function and the intersection of the graph of the function with the *xy* plane:

Patricia: *…yes, and if this (pointing to* $x^2+y^2+1=0$ *) …is zero, if z = 0, then it is a circle with radio equal 1…*

All the above mentioned difficulties seem to be related to the coordination of students' schema for space and that for function. Although they are able to assign values to specific points in $R^2$, either analytically or graphically, they cannot consider sets of points in the plane as the domain of the function or do not clearly understand the role of the domain of the function. When they are able to consider sets of points, they have difficulty considering the result of applying a function to the whole set.

Regarding the range of the function, most students' responses showed that their difficulties were mainly related to the lack of interiorization of the actions needed to find values of the function into a process. Some students showed that their idea of range of a function was not clearly differentiated from that of graph of the function, but this was not a prevalent difficulty. Most of them were able to calculate specific values in the range or to read it from a given graph. This was also observed through a task where most students used this strategy to match the algebraic representation of six functions, with their corresponding graphs. Students showed many difficulties doing this task. We expected them to use sections in the analysis of the graphs but only one of them was able to do this. Gaddis was the only student to consistently, and without prodding, use sections to analyze graphs of two-variable functions:

Interviewer: *say, start with the second formula* $g(x,y)=\sin(x)+y$

Gaddis: *ok, we take that* $g(x,y)$ *is the function in z, if we put that the y is 0 , we have that* $z=\sin x$*, which is the normal function, and if we put that the x is 0, the sine of 0 is 0 and we have that the, that* $z=y$

Interviewer: *and you, could you identify, with what you've done, the graph of that function?*

Gaddis: *wouldn't it be the graph on the upper right hand corner?*

Interviewer: *that's the one … and let's say that* $h(x,y)=\sin(xy)$

Gaddis: *every time that x or y is 0, it will be 0, z is substituted equal to … one would have to assign values to the x and the y and see the behavior of … to me it would be the, the second on the left hand column [correct]*

He was asked more questions that showed that he understood what he was doing and used sections in his graph analysis.

These results are also evidence that independently of the grades obtained by students during their course, they were not able to construct a process conception of function. They did not demonstrate having generalized the action of taking a point in the domain of the function and assigning it a height, or to have constructed the process of conversion needed to develop effective strategies to relate different representations of functions.

We found that students' definitions of two variable functions can be classified in essentially three groups. The first one contains definitions of the function machine sort: two inputs$\rightarrow$ one output, or input$\rightarrow$ output (5 students); the second one uses variable dependence, algebraic expression, or formula (4 students); and the third type of definition is given in terms of geometric images (4 students).

Fernando's definition, for example, was given in terms of an input$\rightarrow$ output conception, which can be related to a process understanding of function:

Fernando: *so that for each, …, so that for my domain, for each element of my domain, I can only have one point in the range and no more points for each point in the domain*

Interviewer: *and what is it that makes the function be of two variables?*

Fernando: *of two variables? That I have two different … because my function, because my output depends on two inputs, precisely, and we have two variables*

Gaddis uses a formula; this can be related to an action conception of function:

Gaddis: *…, for me a function of two variables is a function of the form* $f(x,y)$ *is equal to x … a term in x, a term in y, and a constant or any number, then the domain would be, the two variables, that would be independent … and the range would be the result of those two variables evaluated in the function.*

Pablo, whose definition was very clear, seemed to be guided by a geometrical model:

Pablo: *…, a function of two variables means, is, that starting from a certain region in a plane one can, that is, of variables x y, a height function can be constructed and for each point in that x y region there exist only one defined height*

When considering only the definition for two variable functions given by students, it may seem that some of them have a process conception of these functions, however, when relating their definition with their responses to the other tasks it is shown that this is not the case: they have not interiorized their actions and they are not always able to do treatments and conversions on different representations.

## Discussion

All the interviewed students had successfully finished a course on multivariate calculus in their university, but in spite of this, showed a very shallow understanding of the concept of two variable functions. They were not able to coordinate the schema that were considered to be important in the construction of this concept.

If we review the historical development of the function concept as summarized in Kleiner (1989) and Sfard (1992), we find the development of the concept can be divided in three stages: The first formal definition of function was given by Johann Bernoulli in 1718: "one calls here Function of a variable a quantity composed in any manner whatever of this variable and constants." This definition is similar to that given by Euler in 1748: "a function of a variable quantity is an analytical expression composed in any manner from the variable quantity and numbers or constant quantities." Latter developments required that the definition of function could include cases where functions were not expressed by equations. Further developments spurred by the need for rigor, together with the great growth experienced in all fields of mathematics in the late 19$^{th}$ and early 20$^{th}$ centuries, led to the prevalent view of function as a mapping between arbitrary sets and Bourbaki's definition of a function as a set of ordered pairs.

Results show that students' idea of a function seems to be pre-Bourbaki, but this does not deter many of them from succeeding in an undergraduate multivariable calculus course. Objectives of teachers of these courses include helping students develop a deep understanding of the concept of function. In particular we consider teachers would like to help students construct an object conception of two-variable function, as a set of ordered pairs.

We can conclude that results of this study show that students' conception of domain of a two variable function is not clearly differentiated from that of real valued functions. Their difficulties finding or describing the domain of functions can be related to a lack of coordination between the schema of $R^2$ and that of function, and with conversions between representations. These difficulties underline the difficulty involved in the generalization that takes place in the transition between functions of a real variable and multivariable functions. It seems that the assumption that this generalization is straightforward for most of the students is not valid. Results on domain and range of functions show that these students were not able to interiorize the notion of two variable functions into a process even though they had already finished a calculus course on multivariable functions.

The relationship between students' notions of domain and range of a two variable function and their construction of the general concept of function is less clear from the data of this study. We found students who showed good understanding of domain and range of functions of two variables but whose general definition of function did not enable them to consider functions defined on arbitrary sets, and uniqueness of image. Other students' definition of two variable functions showed some aspects that could be related to interiorization of this concept, but demonstrated a poor understanding of domain and range of specific functions in different representations. We consider that more research is needed to gain a deeper understanding of this relationship.

The results of this study show that the description of how a student may construct the notion of a function of two variables has many subtleties that need to be addressed in instruction if students are to achieve at least a process conception of the modern function concept. One difficulty that had been reported has to do with the structure of students' schema for three-dimensional space, which includes building a subschema of subsets of $R^3$ to be able to analyze graphically functions of two variables (Trigueros & Martínez-Planell, 2007). The construction of the function concept as a process requires that students interiorize actions on sets. They also need to differentiate between functions of one and two variables and be able to consider subsets (in particular, restricted domains) of $R^2$ (and ordered pairs) as domains of functions. Further, the action of assigning a unique value to each point on a subset of $R^2$ needs to be interiorized into a process that includes the treatments and conversions needed to identify important elements in each representation and to relate different function representations. As seen repeatedly in the analysis of results, students frequently struggle when doing actions on representation registers and when converting between them. To address this, and agreeing with Duval's position on cognitive development (2006) and Gagatsis, et al (2004), we consider that much work was to be done with functions in different representations. Representations constitute different entities and, as such, require explicit instruction; actions to perform treatments and conversions and opportunities to interiorize them as processes must be part of the instructional process.

*This study examines three calculus students' cognitive processes as they sketched antiderivative graphs when presented with derivative graphs. As we explored the students' analytic or visual strategies leading to different and sometimes divergent interpretations of derivative graphs, we provide insight into how students' understandings can be enriched by establishing reversible relationships between graphs of functions and their derivative or antiderivative graphs. Our results suggest that their work and thinking illustrate the importance of flexibility and reversibility of thinking in the complete understanding of differentiation and integration in calculus.*

## Background

The visual and analytic elements of mathematical thinking have been the subject of discussion and debate for decades (e.g., Zazkis, Dubinsky, & Dautermann, 1996). This study explores three calculus students' analytic or visual strategies as they sketched antiderivative graphs when presented with derivative graphs. Our descriptions of the students' thinking processes demonstrate that establishing reversible relations can greatly enhance their understanding of derivative and antiderivative graphs.

Visualization and visual thinking have been focal points of studies reforming the way calculus is taught. Zimmermann (1991) considers the understanding of differentiation from a graphical point of view as a fundamental aspect of visual thinking in calculus and suggests that students be able to sketch the graph of the derivative, the second derivative or an antiderivative of a function, given a graph of a function. Berry and Nyman (2003) conclude that students' abilities to draw graphs of functions from graphs of derivatives will enhance their conceptual understanding of the derivative and its connections to the concept of the integral.

Research literature (e.g., Presmeg, 2006) supports the assertion that understanding of mathematics is strongly related to the ability to use visual and analytic thinking. Similarly, Hughes-Hallett (2002) advocates a balance between graphical, numerical, analytical, and verbal expressions. Despite the considerable effort that has been spent exploring the relationship between visual and analytic thinking, the role of reversibility – switching from a direct to a reverse train of thought (Krutetskii, 1976) – in the understanding of the relationship between differentiation and integration, the inverse processes of calculus, has not been adequately described. Norman and Prichard (1994), whose work suggests that reversibility is closely related to the understanding of calculus, contend that when rules of integration are introduced, students who do not use reversibility to reason and understand differentiation and integration tend to view these processes as rather unrelated processes, each of which has its own rules to be memorized.

In this study, our goal was to gain understandings of three calculus students' thinking processes. We observed that these students' visual or analytic strategies led to different and sometimes divergent understandings of derivative graphs. In this paper, as the students attempted to relate the derivative graph to its antiderivative graphs, we illustrate how their understandings can be enriched by changing thinking processes and establishing reversible relations between

graphs of functions and their derivative or antiderivative graphs. It was the thinking processes in these attempts that we analyzed based on their responses and sketches while solving the tasks during interviews. We describe our research findings about their cognitive processes and discuss pedagogical implications of these results.

## Theoretical Framework

The research of Krutetskii (1976) and Presmeg (2006) is influential in our analyses of students' cognitive processes in calculus and enables us to describe students' thinking processes and difficulties associated with the use of visualization. Krutetskii (1976) identifies analytic, visual, and harmonic thinkers according to their preferences for visual or analytic thinking. A student who has a predominance toward the analytic relies strongly on analytic thinking and relies little on visual thinking. Conversely, a student who has a predominance toward the visual relies strongly on visual thinking and relies less on analytic thinking. Harmonic students rely equally on analytic and visual thinking. Krutetskii found that analytic students' strong tendency to rely on analytic means results in a certain one-sidedness in their mathematical development. Visual students do need to interpret visually an expression of an abstract mathematical relationship or to operate with visual schemes and images even when a problem is easily solved by reasoning and the use of visualization is unnecessary or difficult. According to Krutetskii, to certain extent, it is a hindrance for visual students to be riveted to visual patterns. In his studies with gifted students, Krutetskii identified several mathematical abilities related to successful problem solving, including reversibility and flexibility. Reversibility refers to the ability of establishing two-way reversible relations as opposed to one-way relations which function only in one direction. According to Krutetskii, "In a reverse train of thought, the thought does not always have to travel over precisely the same route, but simply moves in reverse order" (p. 287). In the case of flexibility of cognitive processes, to find different or elegant solutions, the successful problem solvers switched from one cognitive process to another without any difficulty.

We take the position that visual imagery resides in a person's mind, and we have used the terms "image" and "imagery" interchangeably to mean a mental construct depicting visual and spatial information (Presmeg, 1986). Our work also is framed by Presmeg's (2006) study in which five kinds of visual imagery, associated with visual thinking, are identified: concrete imagery, memory images of formulae, pattern imagery, kinesthetic imagery, and dynamic imagery. During her interviews with visual students, rich and fully detailed concrete imagery was the most prevalent, and dynamic imagery, effective in depicting transformations and movements, was rarely used. In the literature, several difficulties verifying the limitations of imagery have been documented (e.g., Haciomeroglu & Aspinwall, 2007; Aspinwall, Shaw, & Presmeg, 1997). Presmeg observed that visual dynamic imagery was effective and visual students who were able to combine visual imagery and analytic means avoided the drawbacks associated with the use of imagery. Owen and Clements (1998) confirmed Presmeg's findings that dynamic visual imagery produces high levels of mathematical functioning.

## Methodology

In a semester-long study, we developed cases describing three calculus students, Amy, Bob, and Jack, who had completed an elementary calculus sequence. We conducted weekly task-based interviews, during which they were presented with derivative graphs of functions (see Figure 1) and asked to draw possible antiderivative graphs as we sought to gain understanding of their thinking processes. In this paper, the term antiderivative has been used to describe a graph of a function from which a given derivative graph can be drawn, and the terms differentiation and integration are used describe the two inverse processes of calculus. We prepared an initial set of graphical tasks to start the interviews, and the remaining tasks were developed based on analyses of these weekly interviews. Each interview lasted about 20 minutes and was video-and audio-taped. They were presented with one or two tasks during each interview and asked to think aloud while they were solving the tasks so that we could analyze their responses and strategies as well as describe and make inferences about their thinking processes. In the end, 16 graphical tasks were developed to describe the nature of the students' understandings and investigate their strategies to create meaning for derivative graphs. One graphical task that illustrates differences among these students' thinking and concomitant difficulties is discussed in this paper; other graphical tasks as well as the students' work can be found in Haciomeroglu's (2007) study.

## Data Collections and Results

We illustrate Amy's, Jack's, and Bob's thinking processes and show how analysis or visualization alone led to different interpretations of the derivative graph. In the next section, for the task in Figure 1, we discuss the case of Amy, who preferred analytic thinking, and later, in a second section, we discuss the cases of Bob and Jack for whom visualization was primary for the task. In a final section, we discuss the importance of reversibility and flexibility of thinking in the complete understanding of calculus and pedagogical implications for these results.

*Analytic Understanding*

The graphical task in Figure 1 with the following instructions was presented to Amy: *The graph of the derivative* $f'(x)$ *of a function f(x) is shown. Sketch a possible graph of f(x).*

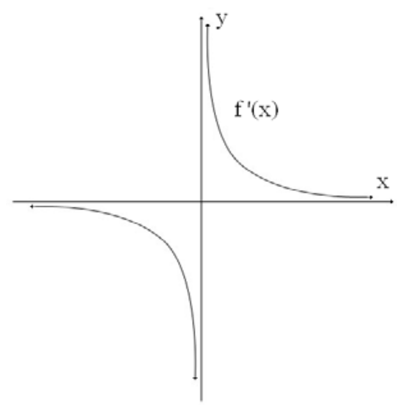

*Figure 1*. The task.

When we first presented the task, Amy made no mention of graphic interpretations of the task and instead translated from the graphic representation to the algebraic representation. That is, she estimated the equation of the derivative graph as $f'(x) = 1/x$. While integrating the equation, Amy, without using the absolute value of $x$, wrote $f(x) = \ln x$ as its integral and drew the graph in Figure 2. Amy knew that her graph could be shifted vertically; that is, shifting a graph of a function vertically does not change its derivative graph. Due to her methods of integration, Amy thought that her graph in Figure 2, the natural logarithm, was undefined on the interval $(-\infty, 0)$ and excluded this interval from the domain.

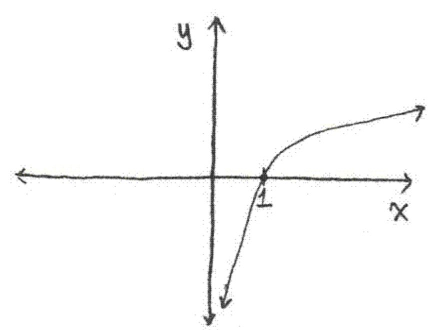

*Figure 2.* Amy's sketch.

At the end of the study, after discussing sixteen graphical tasks with Amy, Bob, and Jack, we decided to discuss the task in Figure 1 with Amy again to determine whether she would use the same strategies that led to her misunderstanding in integrating and interpreting equations in the previous interview. When presented with the task, Amy again estimated $f'(x) = 1/x$ as the equation of the derivative graph and computed its integral to draw the graph in Figure 3.

*Amy:* This graph looks a lot like the graph of *1/x*. It would be *1/2x* or *1/3x* but I just wrote it as *1/x* so the integral of *1/x* is *ln* |*x*| but I wrote it as absolute value to take into account the negative part of the graph too.

When asked if she could draw another graph from which the derivative graph in Figure 1 could be drawn, Amy said that since there were not any specific values for the derivative graph, her graph could be compressed or stretched horizontally due to different coefficients or it could be shifted up or down vertically but there were no other graphs that could produce the derivative graph in Figure 1. Consider this excerpt from the interview:

*Amy:* Another function [long pause] I don't think so.

*I:* Is this the only graph we can draw?

*Amy:* If that were *1/2x*, then we could have *1/2ln* |*x*|. This could be a little bit more gradual [draws a dotted line in Figure 3]. We could shift it up or down.

Since Amy assumed that the antiderivative graph had to be a logarithmic function, she said that her graph could not touch or cross the *y* axis because the graph in Figure 3 had an asymptote at $x = 0$. Consider the following passage:

*I:* It's approaching the *y* axis. Do you think it will touch or cross the *y* axis?

*Amy:* No, there is an asymptote at [$x =$]$0$. It'll keep going down.

*I:* The original function, *f*, can't be continuous?

*Amy:* Right. There is a discontinuity at [$x =$]$0$.

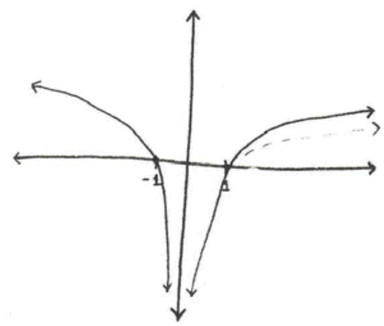

*Figure 3.* Amy's sketch.

*Analysis of Amy's Understanding*

Amy, without any apparent attempt to utilize visual means, estimated an equation of the derivative graph and integrated this equation to draw a possible antiderivative graph. Apparently, for Amy, the derivative graph represented an equation and this indicates her preference for analytic thinking for the graph in Figure 1. For the derivative task presented graphically, Amy's responses suggest that her thinking is Krutetskii's (1976) analytic type. We observed that Amy used analysis as the primary method in her work but her analytic approach without visual support hindered her thinking; that is, due to her methods of integration, initially she thought that her graph was not defined on the interval ($-\infty$, $0$). Later, she correctly integrated the equation but continued to assume that her graph had to be discontinuous. In addition, Amy's responses illustrate how her strong preference for analytic thinking and working in one-direction – from the derivative graph to its antiderivative graphs – instead of working in both directions exerts an influence on her thinking. Since Amy determined the equation as well as the graph of the antiderivative based on the equation extracted from the derivative graph, without considering whether other functions or graphs could create the same derivative graph, she said her graph did not touch the *y* axis and could not be continuous. If she had visualized the changing slopes of a possible antiderivative graph or considered the derivative of a graph with a cusp, perhaps she would have thought of other possible antiderivative graphs.

*Visual Understanding*

The graphical task in Figure 1 with the same instructions was presented to Bob and Jack. First, we consider the case of Bob. When we presented the task to Bob, he examined how the slopes changed on the derivative graph and transformed the slopes of tangent lines into the graph in Figure 4. Consider this excerpt from the interview:

*Bob:* Very little slope to big negative slope [approaches the *y* axis from the left in Figure 1] and it [slope] would be going to be a very high positive slope [approaches the *y* axis from the right in Figure 1].

Bob's descriptions of changing slopes suggest that he was employing Presmeg's (2006) dynamic imagery when he visualized the changing slopes of tangent lines to determine the shape of the antiderivative graph. Bob drew the graph in Figure 4 on the basis of his estimates for the slopes. Then, he tried to determine the continuity with the help of visual means as the following excerpts from the interview suggest:

*Bob:* This [the graph in Figure 4] can move up and down. Even though this [the graph in Figure 1] tells me the change in my parent function, in my integral, just because the derivative [in Figure 1] changes from positive to negative, doesn't mean your integral [in Figure 4] does. It just means slope goes from positive to negative.

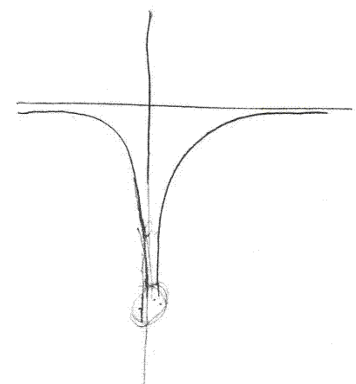

*Figure 4.* Bob's sketch.

Bob has just said that a discontinuity on a derivative graph indicated only a quick change of slopes on its antiderivative graph and not a discontinuity. Bob knew that his graph could be shifted vertically but was not sure whether it was continuous or not.

*Analysis of Bob's Understanding*

Bob described how the changing slopes (or *y* values of the derivative graph) determined the shape of the antiderivative graph without significant support from analytic thinking, and we consider this to be an example of the dynamic imagery described by Presmeg (2006). In this task, Bob's preference for visual thinking reinforces our belief that his thinking is representative of Krutetskii's (1976) visual type. For Bob, a derivative graph, representing the changing of slopes of its antiderivative graph, determined the antiderivative graph. Like Amy, Bob preferred to work in one direction – from the derivative graph to its antiderivative graphs – as he was working through the task. Without any attempt to estimate possible equations of the derivative graph or to consider derivative graphs of both continuous and discontinuous versions of his sketch, Bob determined the continuity of his graph based on his estimates for the changing slopes.

Now, we consider the case of Jack. For this task in Figure 1, Jack demonstrated a strong preference for visual thinking. That is, without any apparent attempt at translating the derivative graph into another representation, Jack visualized the changing slopes and transformed the derivative graph into the graph in Figure 5. Consider this excerpt from the interview:

*Jack:* This [the graph in Figure 1] approaches *0*. It [slope] gets to negative infinity [approaches the *y* axis from the left]. As we go to negative infinity, $f'(x)$ goes to *0* and likewise it happens to *f(x)*. We approach *y* axis from the right, it [slope] goes to positive infinity [in Figure 1]. We are going to positive infinity. It's [slope] approaching *0*.

For this task, Jack's thinking was predominantly visual, and he relied on his estimation of slopes to draw the graph in Figure 5. Jack employed dynamic images (Presmeg, 2006) while describing the changing slopes. When we asked whether his graph could be shifted vertically, Jack responded:

*Jack:* This [the graph in Figure 5] can go up or down. This can't go right or left. They can go up or down independently of each another. There is no value given for any specific point in *f(x)* here so you can change something there in the location along the y axis.

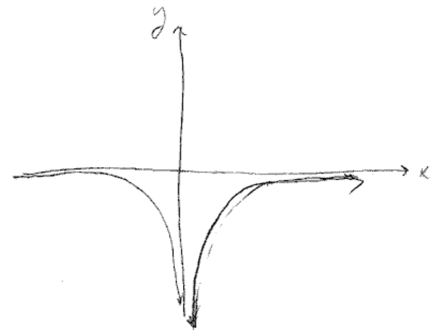

*Figure 5.* Jack's sketch

Jack's response illustrates how he could easily visualize different antiderivative graphs without analytic support. Jack said that the graphs on both sides of the *y* axis in Figure 5 could be shifted up or down independently or together but not horizontally. To further explore his thinking, we asked Jack whether his graph could be continuous. Consider the following passage.

*Jack:* Because $f'(x)$ [the graph in Figure 1] isn't continuous at the *y* axis, it's [the graph in Figure 5] not continuous at the *y* axis.

As seen in the excerpts, since the derivative graph in Figure 1 is not continuous at $x = 0$, Jack thought that its antiderivative graph had to be discontinuous at that point.

*Analysis of Jack's Understanding*

Although Jack, like Bob, used visualization as the primary method in their work, Jack had a different interpretation about the continuity of his graph; that is, Jack thought his graph had to be discontinuous at $x = 0$ where the derivative graph was discontinuous. Like Amy and Bob, Jack worked in only one direction – from the derivative graph to its antiderivative graphs – and did not demonstrate any attempts to reverse or change his thinking process. Instead, without apparent attempt to use analytic means, described how the slopes changed as he sketched a possible antiderivative graph. We considered this an act of Presmeg's (2006) dynamic imagery, as our inferences of his work supported our belief that Jack's thinking is representative of Krutetskii's (1976) visual type.

## Conclusions

For the calculus task presented graphically, Amy relied on analytic thinking, whereas Bob and Jack relied mainly on visual thinking. Their strong preferences for one mathematical thinking resulted in a one-sidedness in their understandings and presented different difficulties. For instance, since we presented a derivative graph, Amy, demonstrating a strong preference for analytic thinking, reversed the procedure by estimating and integrating the equation of the derivative graph and used that equation to draw a possible antiderivative graph. Due to the equation she estimated for the derivative graph, Amy thought that the antiderivative graph had to be a logarithmic function with a vertical asymptote. On the other hand, Bob's and Jack's visual approaches were quite similar in addressing the derivative graph. They employed dynamic images to transform the derivative graph into the antiderivative graph. From their responses, we inferred that in the absence of analytic support, dynamic images interfered with their cognition. Although, for them, a derivative graph represented the changing of slopes of its antiderivative graph, they interpreted the discontinuity on the derivative graph differently. For instance, at the point where the derivative graph was discontinuous, Jack claimed that the antiderivative graph had to be discontinuous while Bob said that the antiderivative graph was continuous with a drastic change of slopes.

We agree with Norman and Prichard (1994) that the Krutetskiian perspective and problem-solving processes – flexibility and reversibility – provide an insightful framework to analyze and describe students' understanding in calculus. From the students' descriptions of how they made their graphs, we conclude that their lack of flexibility in their cognitive processes or their reliance on one mathematical processing led to different and sometimes divergent interpretations of the same derivative graph. The idiosyncrasies in their work and thinking – estimating equations or visualizing slopes – illustrate the importance of flexibility and reversibility of thinking in the complete understanding of derivative and antiderivative graphs. The students did not demonstrate any apparent attempt to reverse their thought processes (or thinking in a reverse direction). Moreover, we consider their visual or analytic interpretations of the derivative graph to be an example of a one-way relationship (differentiation→ integration), described by Krutetskii (1976), not as a reversible two-way (differentiation↔ integration) relationship. Differentiation and integration, two fundamental concepts of calculus, are by their nature inverse processes, which suggest the use of reversibility of thinking when exploring the relationship between graphs of functions and their derivative or antiderivative graphs. We suggest that students' understanding of analytic and visual strategies and establishing reversible relationships between functions and their derivative or antiderivative graphs go together as students construct mathematical meaning for the concepts of differentiation and integration.

We conclude that failure to emphasize both analytic and visual aspects of these reversible processes can be an impediment to students' conceptual understanding of calculus. It is suggested that students be encouraged to associate a graph of a function with its derivative and a graph of a function with its antiderivatives as they examine graphs of various functions. For example, in this case, students can be asked to reverse their thinking to decide if any other antiderivative graph could have created the discontinuity in Figure 1. By encouraging students to utilize different mathematical thinking – for example, visual and analytic – and encouraging them to establish a two-way reversible relationship when interpreting data from derivative or antiderivative graphs, it is possible that students will overcome their difficulties and gain a wider and more robust perspective that cannot be provided without flexibility and reversibility of thinking.

*Graduate school socialization describes the process in which graduate students become members of the community of an academic discipline. This is important because the primary purpose of graduate school is to prepare individuals for a career, typically as a professor and/or researcher, in a particular academic discipline. This paper uncovers a role of social interaction in the socialization of mathematics doctoral students into the community of mathematicians by examining one slice of mathematics doctoral student social interaction, namely peer interactions, to demonstrate how processes of affective socialization take place and their significance on students' views of mathematics and mathematics research.*

## Introduction

Over half of doctoral students in the United States leave prior to finishing their degrees (Lovitts & Nelson, 2000; Nettles & Millett, 2006). And for some disciplines, such as mathematics, the rate of departure is even greater (Council of Graduate School, 2008). The departure of students from doctoral study comes at a high cost for the student and the university (Gardner, 2008; Lovitts, 2001). And although many perceive that the high attrition is needed to "weed out" those who are not capable, prior research indicates that a good deal of attrition is unnecessary and preventable (Golde, 2005; Herzig, 2002).

In addition, few women and minorities participate in doctoral study of mathematics. In 2007-2008, of the 540 new mathematics doctoral recipients, who were U.S. citizens, only 166 (31%) were female and only 79 (15%) were minorities (Phipps et al., 2009). Broadening the focus of mathematics to increase the participation of women, minorities, and others who typically do not "fit in" may enrich the discipline of mathematics by expanding the range of mathematical thought and as a result, "help the profession flexibly meet the challenges posed by the growing quantitative sophistication of economic and political structures of the 21st century" (Herzig, 2004, p.173-174). Therefore, educational researchers need to determine what individual skills and knowledge and departmental systems and support help mathematics doctoral students (and women and minority mathematics doctoral students, in particular) succeed.

Many, including faculty, attribute student attrition to personal characteristics, such as interest in the field, lack of academic ability, and lack of drive, and conclude that raising admission requirements will increase student persistence. Yet, no difference in qualifications has been found between students who persist and students who leave (Lovitts & Nelson, 2000). Instead, both personal characteristics and departmental structures, including financial support, social and academic integration into the departmental community, family responsibilities, and impending requirements, have been shown to influence students' decisions not to persist (Earl-Novell, 2006; Herzig, 2004; Lovitts & Nelson, 2000).

It appears that many of the personal characteristics and departmental structures connected to attrition are aspects of the socialization of mathematics doctoral students into the mathematics community. However, no study of has looked at doctoral mathematics student socialization or examined attrition through the mathematics doctoral student socialization lens. This paper begins this inquiry by examining the role of social interaction in the socialization of mathematics doctoral students

## Defining Graduate Student Socialization

In general, socialization is the process through which a novices “acquire the values and attitudes, the interests, skills, and knowledge, in short the culture, current in the groups of which they are, or seek to become a member” (Merton, 1957, p.287). More specifically, and for the purposes of this paper, graduate school socialization is used to describe the process in which individuals in graduate school become members of the community of an academic discipline (Gardner, 2008; Golde, 1998). This is important because the primary purpose of graduate school is to prepare individuals for a career (i.e., participation), typically as a professor and/or researcher, in a particular academic discipline (Weidman & Stein, 2003). At the same time, however, graduate students must participate in the graduate school community. Therefore, the socialization of graduate school is a “double socialization”, in which students simultaneously learn to participate in graduate student life and prepare to participate in the community of their academic discipline (Golde, 1998).

Graduate student socialization has two dimensions: cognitive and affective. The cognitive dimension is the academic portion and refers to learning the knowledge and skills of the discipline. The affective dimension refers to learning how to participate in the social aspects of the discipline. Students become cognitively socialized as they take classes, learn to participate in research, take part in professional activities (including attending and presenting at conferences and writing and publishing professional papers). The means for affectively socializing graduate students is much less clear but occurs through personal interactions (both formal and informal) with faculty and peers in their department. And, since many of these social interactions occur during the activities in which students become cognitively socialized, both aspects of socialization typically occur simultaneously (Golde, 2000; Merton, 1957; Tinto, 1993; Weidman et al., 2001). Graduate school socialization has been closely linked to both students’ intellectual development and doctoral persistence (Golde, 2000, 2005; Tinto, 1993; Turner & Thompson, 1993).

### *Mathematics Graduate Student Affective Socialization*

In most fields, doctoral study is associated with isolation, and mathematics is no exception. Researchers continually discuss the virtually nonexistent social dimension of mathematics doctoral study (Herzig, 2002, 2004; Stage & Maple, 1996). And attrited mathematics doctoral students commonly cite isolation as a central reason in their decisions not to persist (Earl-Novell, 2006; Herzig, 2002, 2004; Hollenshead et al., 1994; Stage & Maple, 1996).

> Social interaction is important for affective socialization into the graduate school community. Social membership within one’s program becomes part and parcel of academic membership, and social interaction with one’s peers and faculty becomes closely linked not only to one’s intellectual development, but also to the development of important skills required for doctoral completion (Tinto, 1993, p.232).

It would also seem likely that social interaction is the primary means for affective socialization of graduate students into the community of mathematicians. This leads to questions of how doctoral students are being prepared to participate socially in the community of mathematicians and whether improving affective socialization of doctoral students would lower attrition. This paper begins to address these questions by examining one slice of mathematics doctoral student social interactions, namely peer interactions, to demonstrate how processes of affective socialization take place and the significance of these processes on students' views of mathematics and the mathematical community.

## Background: The Doctoral Study of Mathematics

Doctoral study of mathematics has two distinct stages. During the first stage, the coursework stage, students focus almost entirely on completing coursework requirements. This stage culminates in the successful completion of qualifying exams, which demonstrate to the department that the student has become an integral member of the course-taking community and is therefore, prepared to begin doctoral research. The second stage, the completion of a doctoral dissertation, marks the period between passing comprehensive exams and receiving the doctoral degree. During this stage, students complete a dissertation research proposal, go through the complete research process, and defend their final dissertation.

## Method

The analysis draws on the data collected from three female participants in a pilot study for a larger research project on women mathematics graduate students. The three female participants are doctoral students in the mathematics department at a university in the Southeastern United States. All participants engaged in semi-structured, individual interviews with the two authors. Interviews were open enough to allow participants to raise issues of their own that they deemed as significant to their experiences in K-12, undergraduate, and graduate mathematics. Each interview lasted approximately one hour. The interviews were audiotaped and then transcribed.

The data were analyzed using the constant comparative method, which has three phases in the data analysis: (a) intensive analysis, (b) developing categories, and (c) developing theory (Merriam, 1998). Contradictions were also examined and conjectures were made concerning the contradictory data. The data were analyzed for significant themes as well as differences in order to convey the complexity of individuals' responses (Fine & Weiss, 1998).

The primary themes identified in the data were the competitive nature of graduate study of mathematics and in the field of mathematics, in general; support for students' lives outside of the department; the challenging nature of mathematical research; the importance of peer support and peer interactions; conflicts between teaching and research; the role of advisors; the benefits of pursuing a Master's degree prior to enrolling in a doctoral program in mathematics; and independence and isolation in graduate study of mathematics. Through careful analysis of these categories and their relationships, *talking out problems*, a type of peer interaction, emerged as an important tool in successful study of graduate mathematics and mathematical research for these participants.

In the text that follows, particularly articulate quotes are used to present and highlight common themes discussed by the participants. Quotes from each of the participants have been included to ensure that all voices have been presented. To improve readability, quotes were minimally edited to remove stutters and distracting expressions such as 'uh' and to obscure references that might reveal participants' identities.

## Findings

### *Peer Interaction During Coursework*

The competitive nature of the department was a common theme across the interviews. Yet, the participants all indicated the importance of peer interaction in their success during the coursework stage. Specifically, *talking out problems* (i.e., a peer interactions in which a student talks to peers about a problem and the difficulties in solving it in order to better process, integrate, and understand the problem and how to approach it) was consistently described as the most valuable peer interaction for these students.

In graduate level mathematics, students face difficult problems with no clear path to a solution. In addition, professors often believe that students should struggle with problems on their own and therefore, hesitate to give students help on assignments. As a result, peers become a key resource on difficult assignments. Students indicated that they wanted to figure out the problems on their own; so, peers were primarily used as sounding boards to *talk out* problems.

> …I found out that I can solve problems by just talking with other people about them and somehow come up with solutions, even if they aren't really working on the problem yet or don't know the answer.

Thus, *talking out a problem* was a tool that helped students to solve complex mathematical problems that they had not been able to solve on their own and was seen as central to their success during the coursework phase of doctoral study.

*The Elimination of Peer Interaction During Dissertation Research*

However, upon entering the second stage of their doctoral program, participants were told that *talking out a problem* was not acceptable. One of the participant's advisors went as far as to forbid the student from discussing her dissertation research with other students.

> You're expected to do your work very independently and not collaborate with anybody… I was literally told by my dissertation advisor that I was not allowed to work with anybody on anything related to my dissertation.

And because the elimination of *talking out problems* was difficult for her; she attempted to explain its importance to her advisor.

> I try to tell him, "I need to talk these things out." For some reason he thinks that means that I don't have the ability to do it myself. So, I think it's a different perception.

The participants perceived that dissertation research was characteristic of mathematical research, in general. In other words, they indicated that mathematical research is done in isolation. This led one participant to question the necessity of social isolation in mathematical research.

> You have to ask yourself if it's always going to be that way. In an interdisciplinary field, like mine, I think I could be trained to be a team player, and I would be fine that way… And unfortunately, I think it will take 20 years for the community to catch up to that… I think there is a large section of old school professors who still believe that independent research is the only true research…

As these comments indicate, students discover that peer interactions (and *talking out problems*, in particular) can be useful tool in mathematical research. Yet, as they enter into their dissertation research, they are led to believe that it is unacceptable in the community of mathematicians.

## Conclusion

The primary purpose of doctoral study of mathematics is to prepare individuals for a career in mathematics, typically as a mathematics professor and/or researcher. So, during doctoral study, students should become socialized into the community of mathematicians and mathematical researchers. At the same time, however, graduate students also learn how to successfully participate in the mathematics graduate school community. This is sometimes problematic because socialization is not uniform across individuals or communities (Turner & Thompson, 1993).

Traditionally, mathematical researchers have been stereotyped as working alone on problems and only communicating with others after a solution has been found, as peers review the findings. Yet, this stereotype is often not accurate. Although some mathematicians do work in isolation; many mathematicians work collaboratively to solve problems. For example, in an interview study of 70 research mathematicians, Burton (1999) found that all but four of the participants used collaboration in their research.

Mathematics doctoral students typically have little experience with mathematical research prior to beginning the dissertation. And, the findings from this pilot study indicate that although mathematics doctoral students develop an appreciation for peer collaboration in mathematical research; they are led to believe that it is at odds with acceptable practice in mathematics research. This is in direct contradiction to what is actually happening in the community of mathematical researchers and leads to several questions, which can be addressed in future research.

The first, and foremost question is whether doctoral students are being adequately socialized into the mathematical community? In particular, if the community of mathematical researchers values collaboration, is forcing students to work in complete isolation on their dissertations a detriment to students' socialization into the community of mathematical researchers? Second, is *talking out a problem* a gender- or culture-specific strategy that is under-valued by the dominant culture. And, if this strategy becomes more accepted in mathematical research, would more women and minorities choose to participate in mathematics and mathematical research? Finally, this pilot studied uncovered one peer interaction that appears to be a valuable tool for solving mathematical problems. Are there others that can be uncovered in future research?

*Dimensional analogy as a technique and different coordinate systems, apart from their intrinsic mathematical interest, are used in many types of applications in the sciences, engineering and art. As part of the process of the construction of an epistemic network for the subject, the identification of objects and dualities that emerge from this mathematical activity was carried out. The transformation of expressions to content through semiotic functions, and the identification of chains of signifiers and meanings, can be accomplished because of the rich layering and complexity of these mathematical concepts. Multivariate calculus students' responses to questions involving these notions were used for classification, according to the socio-epistemic network.*

## Dimensional Analogy and Different Coordinate Systems

The relationship between spatial dimension as a geometric concept, and the algebraic representation of dimension as lists of coordinates, has been recorded in textbooks as well as books and articles of general mathematical circulation, both pure and applied (Rucker, 1977; Banchoff, 1996; Tucker, 2007; Doren & Lasenby, 2007). The abstract relations are present from the beginning levels of algebra, but the present study privileges the multivariate calculus course where, as expressed in Montiel, Wilhelmi, Vidakovic and Elstak (in press):

> … it is in the multivariate calculus course where students, many for the first time, are expected to deal with space on a geometric and algebraic level after years of single variable functions and the Cartesian plane. They must define multivariable and vector functions, deal with hyperspace,… find that certain geometrical axioms for the plane do not hold over (lines cannot only intersect or be parallel, they can also be skew), and work with functions in different coordinate systems.

The issue of transiting between different coordinate systems, as well as the notion of dimension in its algebraic and geometric representations, are significant within undergraduate mathematics. Deep demands are made in both conceptual and application fields with respect to understanding and competence.

It is common to think of dimensional analogy as a method which permits the visualization of the fourth dimension (Weeks, 1985; Banchoff, 1996). To those interested in understanding the nature of multiple spatial dimensions, by taking a step back to the second dimension and trying to understand certain physical aspects**,** and then looking at the third dimension, an understanding of what the fourth spatial dimension would mean can be developed. For example, there are techniques that use generalizations, such as looking at the boundaries of one, two and three dimensional objects. On the other hand, there exist two ways of looking at dimension, that is, *extrinsically* or *intrinsically.* Briefly, the "extrinsic" point of view considers curves and surfaces, in particular lines and planes, as lying in a Euclidean space of higher dimension (for example a plane in an ambient space of three dimensions). According to the "intrinsic" point of view one

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

cannot speak of moving 'outside' the geometric object because it is considered as self-contained. The inhabitants of Flatland consider their plane from an intrinsic point of view. For them, there is no space, no third-dimension.

The mathematical activity with lists of coordinates beyond the triple is usually introduced in the linear algebra context and, although mentioned in the multivariate calculus course, it is primarily the triple that displaces the ‘ordered pair’ (although, when working with gradients, the ordered pair returns, often in a way that may not be clear to the student). However, in triple integration the functions have a three dimensional domain (and one dimensional codomain), which means that the list indicating their geometrical representation would have four components. When dealing with functions whose three dimensional domains are expressed in the cylindrical or spherical coordinate system, it is not indicated, in any of the texts that were consulted, what that fourth component might look like. These are the types of mathematical issues that this study attempts to analyze when referring to dimensional analogy and different coordinate systems.

## Conceptual Framework

*Mathematical Objects*

A mathematical object, in this study, will be considered anything that can be used, suggested or pointed to when doing, communicating or learning mathematics. The onto-semiotic approach (Godino, Batanero & Roa, 2005; Font, Godino & D’Amore, 2007) considers six primary entities which are:

(1) *Language* (terms, expressions, notations, graphics);
(2) *Situations* (problems, extra or intra-mathematical applications, exercises, etc.);
(3) *Definitions* or descriptions of mathematical notions (number, point, straight line, mean, function, etc.);
(4) *Propositions*, properties or attributes, which usually are given as statements;
(5) *Procedures* or subjects’ actions when solving mathematical tasks (operations, algorithms, techniques, procedures);
(6) *Arguments* used to validate and explain the propositions or to contrast (justify or refute) subjects’ actions. (Godino et al., 2005; Font et al. 2007)

As important as the mathematical objects are: 1) the agents that move them and the meaning (straightforward or not) that is assigned to them; 2) the concrete appearance of these objects and the reference to ideal entities; and 3) their contextual and relational function with other mathematical objects. For these reasons, in the onto-semiotic framework, the following dual dimensions are also considered when analyzing mathematical objects: (Godino et al., 2005, 5):

(1) Personal / institutional;
(2) Ostensive / non-ostensive;
(3) Intensive / Extensive;
(4) Unitary / systemic;
(5) Expression / content.

These dual dimensions demonstrate how the primary entities must not be understood in an isolated manner, but according to their function and their relation in a contextualized mathematical activity.

*Systems of Practices, Emerging Objects and Epistemic Networks*

According to the onto-semiotic approach (Godino & Batanero, 1994; Wilhelmi et al., 2007a), it is necessary to determine the meanings (plural) associated with mathematical objects in different contexts and organize them (the meanings) as a complex and coherent whole. The *operative and discursive systems of practices*, and their subsystems, understood as depending on the institutional and personal contents that are associated to a mathematical object, and the objects that emerge within these systems, form epistemic and cognitive networks. This means that if the systems of practices are institutional, the emerging mathematical objects are considered to be institutional objects, and if the systems of practices correspond to an individual, then the objects are personal, according to the duality specified above. Also, following this duality, the objects that emerge can be ostensive (such as symbols and graphs) or non-ostensive, that is, conceptual or mental. The contextualized and functional use of these objects as elemental entities cannot be divorced from their essentially relational nature that, at the end, justifies their adaptation, whether in particular or general processes.

Whereas the *meaning* of a mathematical notion represents the structured complex of a system of practices in a context, the *holistic meaning* of a mathematical notion represents the expression of the different (partial) meanings associated with the notion as one system. The holistic meaning comes from the coordination of the partial meanings associated with a mathematical notion (Wilhelmi et al. 2007b). *Flexible mathematical thinking* (FMT) is what permits the passage between different partial meanings, and the coordination or partitioning of the different meanings when necessary.

Finally, in order to capture the semiotic complexity inherent in the communication of mathematics, it is important to identify the different objects that make up the mathematical practice in specific content areas and contexts. The resulting network is called a *socio-epistemic configuration*, and it captures the interplay of the objects and relations in a particular mathematical setting. This way, the personal meanings that are constructed when individuals carry out mathematical activity can be described by cognitive configurations. Evaluation of the learning and mathematical behavior of these individuals lies in the analysis of the relation between the socio-epistemic and cognitive configurations.

*Semiotic Functions and Representation*

The onto-semiotic approach places great value on the relation between mathematical objects by means of the *semiotic function* (Godino & Batanero, 1997), as a relation between an expression and a content established by ‘someone’, according to certain rules of correspondence. Not only language, but the other types of objects such as concepts, situations, actions, properties, or arguments, can be expressions or content of semiotic functions. Font et al. (2007) pointed out that to understand representation in terms of semiotic functions has the advantage of not segregating the object from its representation. Indeed, given an object and a representation, in general it is not possible to identify a unique semiotic function between them, and even the representation can constitute the content in another context. For example, Alson (1989, 1991) shows how a Cartesian graph can be given an algebraic structure before the introduction and analytic development of the theory of functions. This fact determines an objectification process of a representation (in its broadest sense) that is prototypical in mathematics.

When talking about semiotic functions, the dependence relations can be either *representational* (one object is put in the place of another), *instrumental* (an object is used as an instrument by another) or *structural* (two or more objects conform a system out of which new objects emerge) (Godino, Batanero, & Font, 2007). An example of a representative semiotic function, as opposed to structural or instrumental and related to other questions used in the interview that are not analyzed in this paper, could be a solid presented geometrically as the expression, and the formulation of a double integral 'setup' as the content. An instrumental semiotic function could have as expression the double integral, and as content the numerical answer, while the structural (or 'cooperative') semiotic function could take some region together with a double integral in terms of "$x$ and $y$" as the expression, and the set up of a double integral in terms of "$u$ and $v$" over a simpler region (using the Jacobian) as the content. It should also be clear that the expression in one semiotic function could be the content in another.

## Research Questions

(1) Do multivariate calculus students use dimensional analogy as a result of their transit from single variable to multivariable calculus? (2) In which primary entities is dimensional analogy used (if it is used)? (3) What primary entities and semiotic functions can be identified and classified, as students relate different coordinate reference systems to their previous study of calculus in the 2-dimensional Cartesian coordinate system?

## Context, Methodology, and Instrument

The context of the present study is multivariate calculus (calculus III) as the final course of a three course calculus sequence, taught at a large public research university in the southern United States. Seven students were interviewed once in two groups, the first consisting of four students and the second of three. The interviews were video-recorded. Each interview was approximately an hour long. The students were first given a questionnaire, which is included in this text, on which they wrote down their responses, and they were then asked to explain them. For each question, the students were chosen in a different order, but it was inevitable that who spoke first would influence, in some way, the others. They were asked to explain verbally on an individual basis, but group discussion was encouraged when it presented itself. This report focuses only on the first question from the interview (table 1).

Table 1. *Question 1*

| |
|---|
| In rectangular coordinates the coordinate surfaces: $x = x_0$, $y = y_0$, $z = z_0$ are three planes.<br>*(a)* In cylindrical coordinates, what are the three surfaces described by the equations: $r = r_0$, $\theta = \theta_0$, $z = z_0$? Sketch.<br>*(b)* In spherical coordinates, what are the three surfaces described by the equations: $\rho = \rho_0$, $\theta = \theta_0$, $\phi = \phi_0$? Sketch. |

The intention of this question was to detect the students' geometrical transition to 3D-space where, in the rectangular context, much emphasis was placed at the beginning of the course on the coordinate planes and the octants. These answers were important to begin to detect the process of dimensional analogy. The interview protocol included the question of why the equations represented planes, and not just points or lines. Although we have been unable to discover any literature on the subject, through informal discussions and comparisons it has been noted that the average student has difficulty with associating the algebraic equation, say, $y = a$, with a plane parallel to the $xz$-plane, or the actual $xz$-plane if $a = 0$. The protocol also indicated that, if the sketch was correct, to ask how the angle $\theta$ 'turns into' a plane.

## Analysis Using the Onto-Semiotic Approach

While analyzing dimensional analogy and different coordinate systems within the onto-semiotic approach, it is important to remember what was mentioned in the conceptual framework about the classification of the mathematical objects and the primary entities. There are aspects that characterize each of these entities, but by no means can there be a sharp separation between them. The first question from the interview will be analyzed; as there are seven students and two groups, S1, S2, S3 and S4 will represent the participants in the first group, and S5, S6, and S7 the participants in the second interview session. The two sessions will not be differentiated as emphasis will be placed on the question itself and the mathematical content. There are also written answers which will be referred to at times. Because of the natural limitations of space in a report such as this, emphasis will be placed on the participations that are directly related to dimensional analogy and the change of coordinate systems.

The interview question will be accompanied by a table that represents the socio-epistemic configuration relevant to its content and context. In the lecture sessions, the professor (one of the authors) had a well-defined system of objects and meanings that were meant to be developed within the context of the institutional mathematical practices.

In question 1, the socio-epistemic configuration of primary objects is structured in terms of the given situation (table 1), that is, the transition between algebraic and geometric representations of surfaces immersed in 3D, in different coordinate systems. The analysis and solutions detonate the use of different concepts, procedures, propositions and previous arguments, and open the possibility that new ones emerge. The activation of these emerging objects is brought about by the processes of definition, of creation of techniques (algorithmic or not), the determination of propositions and argumentation. All these processes are only possible through the use of language in different registers, that is, the use of languages that make the codification and transference of knowledge and meanings of the mathematical objects involved possible. (figure 1).

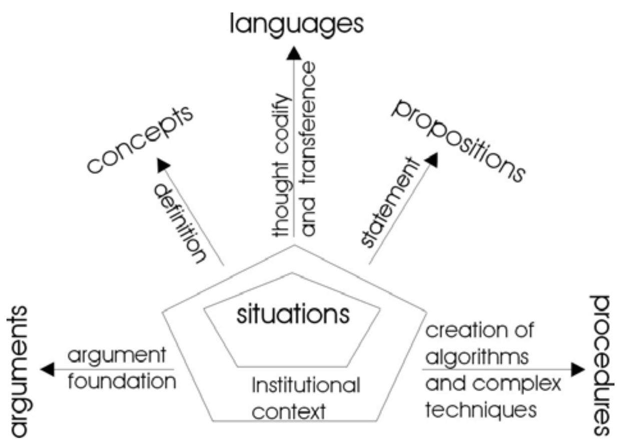

*Figure 1.* Mathematical' objects and process.

Question 1 had a marked geometrical emphasis, as students were asked to sketch what they understood by the algebraic equations representing surfaces immersed in 3D space, in the rectangular, cylindrical and spherical coordinate systems. The instructions were written in a combination of mathematical English (Wells, 2003) and symbols. The results of these instructions were sketches, a graphical language object. As institutional objects these sketches are considered language entities:

- *Verbal*: rectangular, cylindrical, spherical coordinates; dimension (3D);
- *Graphical*: graphs of the surfaces;
- *Symbolic*: $x = x_0$, $y = y_0$, $z = z_{0;}$ $r = r_0$, $\theta = \theta_0$, $z = z_{0;}$ $\rho = \rho_0$, $\theta = \theta_0$, $\phi = \phi_0$

We show in table 2 some of the previous and emergent concepts, procedures, propositions and arguments.

Table 2. *Previous and Emergent Concepts, Procedures, Propositions and Arguments*

| Objects | Previous | Emergent |
|---|---|---|
| Concepts-Definitions | • Cartesian coordinate system in 2D;<br>• Definitions of functions and relations in a single variable;<br>• Graphs of single variable functions and relations; | • Different coordinate systems in 3D;<br>• Graphs of planes;<br>• Definition of functions and relations in a multivariable context;<br>• Graphs of functions and relations in different coordinate systems in 3D;<br>• Extrinsic and intrinsic points of view |
| Procedures | • Graphing lines and curves in the plane;<br>• Evaluating and setting up single variable functions; | • Graphing planes and surfaces in 3D space;<br>• Evaluating and setting up multivariable functions in different coordinate systems; |
| Propositions | In rectangular coordinates:<br>From an intrinsical point of view:<br>• In 0D space, $x = x_0$ represents a point; in 1D space $x = x_0$, $y = y_0$ represent lines;<br>From an extrinsical point of view:<br>• In 1D space, $x = x_0$ represents a point on a line; in 2D space $x = x_0$, $y = y_0$ represent lines on a plane; $r = r_0$, $\theta = \theta_0$ represent curves on the polar plane. | From an intrinsical point of view<br>• In 2D space, $x = x_0$, $y = y_0$, $z = z_{0;}$ $r = r_0$, $\theta = \theta_0$, $z = z_{0;}$ $\rho = \rho_0$, $\theta = \theta_0$, $\phi = \phi_0$ represent surfaces.<br>From an extrinsical point of view:<br>• In 3D space, $x = x_0$, $y = y_0$, $z = z_{0;}$ $r = r_0$, $\theta = \theta_0$, $z = z_{0;}$ $\rho = \rho_0$, $\theta = \theta_0$, $\phi = \phi_0$ represent 2D surfaces immersed in 3D. |
| Arguments | Dimensions as degrees of freedom (intrinsic): a point has 0 degrees of freedom, a line has 1 degree of freedom. | Dimensions as coordinates (extrinsic in this case): a point has 1 coordinate, a line or curve in general has 2 coordinates, a plane or surface in general has 3 coordinates. |

Only S1 showed a complete grasp of the (institutional) meaning in his written work. The other students were able to translate the equations in rectangular coordinates, but their sketches of the surfaces in the cylindrical and spherical coordinate systems were, to different degrees, inaccurate.

As a reply to the question of why the equations in rectangular coordinates represented planes and not lines, S3 said “For each plane there’s only a restriction in one dimension, so that dimension is throughout the whole plane. Each other dimension can be anything, that’s how you get just one infinite plane”. The deictic signs that accompanied the verbal expression can be used to classify the relations that were established as a representational semiotic function, going from the equations, as the expression, to the sketches and gestures as content (in particular, the communication of the ‘infinite plane’ was clearly done by spatial gestures). In this same vein, an interchange with the two interviewers (I1 and I2) and S5, when asked why the equations represented planes, will be presented.

S5: I don't think I know how to verbalize why they're planes and not points.

I1: But why do you see $x = x_0$ as parallel to the $yz$ -plane?

I2: For the record, you're looking at the room.

S5: I'm looking at $zy$ $x$ and .

I2: You're pointing, what exactly are you pointing at?

S5: The corners, I'm pointing at the corners to get my head around it in space.

On the other hand, S7 used dimensional analogy to explain:

S7: When we have 2 dimensional, say $x = 2$ . We fix $x$ at 2 and $y$ could be anything. Now we have 3D, another variable which is $z$ . Instead of say, $x = 3$ and $y$ going on forever, it would be $z$ going up and down forever as well.

In the context of the cylindrical coordinate system, as was mentioned, only S1 drew all three expected answers. However, S3, once hearing and observing S1's geometrical description and representation of the three surfaces, realized he had misunderstood the question, but "it was asking the same thing as the previous one" (the three surfaces in rectangular coordinates), and offered his interpretation:

S3: $r = r_0$ would be a cylinder of infinite height, $\theta = \theta_0$, would be a slice of the cylinder and $z = z_0$ is an infinite plane, no, not a plane, it's an infinite disk at $z_0$.

I1: What is the difference between an infinite disk as opposed to a plane?

S3: It's just the coordinate system that you use, it's not rectangular coordinates any more, it's polar coordinates.

I2: But why think of it as a disk? I could think of it as an oval or a rectangular thing.

S3: It has no restriction on $\theta$, it turns into a plane with an angle of $2\pi$ , the radius has no restriction, so it goes on and on.

S1: It has to do with how you build the plane in your head. If you take one $r$ value at a time, it's just concentric disks. It's just the shape of the space.

As was established in the conceptual framework, the objects that have emerged, such as language, situations, procedures, definitions, reflect their duality. In particular, the duality ostensive (symbols, graphs, gestures) or non-ostensive, that is, conceptual or mental, can be detected in the chosen fragments related to question 1, through the semiotic functions with their expression and content.

## Synthesis, Conclusions, and Prospective

Dimensional analogy as a technique and different coordinate systems, apart from their intrinsic mathematical interest, are used in many types of applications in the sciences, engineering and art. The generic notion of representation is central in the cognitive and instructional processes involved in communicating these notions. The focus on changes of registers and on individual processes of objectification, conceptualization and meaning contributes to a coherent view of mathematical knowledge and the means of its construction and communication. Based on the onto-semiotic approach, it can be added that it is also important to emphasize the anthropological and socio-cultural character of this knowledge, indicating the tensions between the personal and institutional meanings. The primary entities and their dualities, together with the semiotic functions, allow the description of this personal-institutional tension, related to the notion of meaning and mathematical objects that are relevant, in this case, to dimension, dimensional analogy and different coordinate systems.

The onto-semiotic complexity that was identified is an empirical indicator that should guide the search for ways to improve and control the didactic systems related to the learning and teaching of notions, methods and meanings associated with dimension and different coordinate systems in the multivariate context. Dimensional analogy, as was seen in the previous section, is used by the students, especially when dealing with the primary entities of language, situations and concepts. However, this concept needs to be formalized and consciously incorporated as a technique in the communication of this mathematical subject, and others similar to it.

# PROJECT M$^2$: A RESEARCH PROJECT DEVELOPING ADVANCED GEOMETRY AND MEASUREMENT CURRICULUM FOR *ALL* PRIMARY STUDENTS

Tutita M. Casa, PhD
University of Connecticut
tutita.casa@uconn.edu

Project M$^2$: Mentoring Young Mathematicians is a 5-year National Science Foundation research grant aimed to develop advanced geometry and measurement units for K-2 students and measure the impact on student achievement. Mathematical performance has been unimpressive for U.S. students on both national and international measures, particularly diverse and poor students (Perie, Grigg, & Dion, 2005; TIMSS, 2004). Measurement and geometry are areas of particular concern. U.S. fourth graders ranked only 17$^{th}$ in geometry and 13$^{th}$ in measurement out of the 25 countries in the 2003 TIMSS (Mullis et al., 2004); similarly, geometric shapes and measures was the lowest averaging cognitive domain in the 2007 TIMSS (Gonzales et al., 2008). This performance is reflective of insufficient time devoted to geometry instruction (Clements, 2004) and weak measurement instruction in the primary grades (Clements & Stephan, 2004).

In response, Project M$^2$ is undertaking the development and research on the efficacy of geometry and measurement units in each grade, K-2. The units are focused on higher-level mathematics using research-based practices and standards in mathematics and early childhood education and augmented by exemplary gifted education practices. To address the needs of *all* students, the Project M$^2$ units are being piloted in urban, suburban, and rural classes. Following, they are being field-tested in classrooms nationwide that include underrepresented students (12 classes and $n$ ~ 240 in each the intervention and control group). Teachers from the same schools were randomly selected to teach either the units or regular curriculum. Performance-based tasks, criterion-referenced unit tests, and standardized tests are being used to determine the impact of the Project M$^2$ units. This session will report on the research endeavors and curricular innovations as well as lessons learned from the first two years of the grant.

# CHANGING STUDENTS' MINDS ABOUT MATHEMATICS: EXAMINING SHORT-TERM CHANGES IN THE BELIEFS OF MIDDLE-SCHOOL STUDENTS

Megan W. Taylor
Stanford University
ilovemath@mac.com

*This study was designed to determine if a 5-week summer school program could change both beliefs about mathematics and intelligence and, if so, to examine how these changes coincided with changes in students' effort and achievement. A curriculum was designed to expose students to difficult mathematics via rich, open-ended problems that necessitated daily group work, presentation, and discussion and that focused on teachers providing specific, qualitative feedback in lieu of scores or grades. This "learning-focused" curriculum was delivered to 23 seventh- and eighth-grade students, all of whom were required to complete a summer make-up course to pass into the next grade. Results suggest in part that specific curricula and instruction can change the beliefs and increase the performance of low-performing students, even in a short amount of time.*

## Introduction and Significance

The question of why beliefs[1] matter in education research is a complicated one to answer. If we care most about helping students be successful in mathematics, which for now at a minimum means passing math classes and achieving proficient scores on state math tests, perhaps what students believe or don't believe is irrelevant. Furthermore, for many studies positing that beliefs do impact achievement there are others arguing beliefs actually follow from successes or failures in school. What is clear, however, is that there are indeed certain beliefs and theories held by secondary math students that affect both their motivation and achievement. We know that a junior high math student's theory of intelligence as unchanging or evolving affects his/her classroom motivation and is a strong predictor of achievement in mathematics (Blackwell, Trzesniewski, & Dweck, 2007), for example, and children's beliefs about mathematics and mathematics learning, especially when the beliefs have remain unchanged for many years, affect their future effort (Haladyna, Shaughnessy, & Shaughnessy, 1983) and achievement (Mason, 2003). Furthermore, research suggests that "negative experiences have lasting negative effects [on achievement] *primarily* when they affect an individual's beliefs" (Blackwell, et al., 2007).

The majority of beliefs research seems to confirm that *strong* beliefs about oneself and one's learning are resistant to change and do impact achievement, including affecting both cognition and behavior (Krosnick, 2007). In a study by Peter Kloosterman and Frances Stage, six categories of "strong" math beliefs were identified as being salient across student populations, then used to design a set of beliefs scales (Kloosterman & Stage, 1992). Part of the impetus for the study was from prior research suggesting that there are certain beliefs students hold about mathematics that exist across different secondary math classrooms (Schoenfeld, 1989). From a national assessment in 1985 for example, 83% of eighth-grade students reported to agree or strongly agree with the statement, "There is always a rule to follow in mathematics" (Dossey, Mullis, Lindquist, & Chambers, 1988). The six beliefs measured by the Indiana Mathematics Beliefs Scales (IMBS) are:

- Belief 1: I can solve time-consuming mathematics problems.

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

- Belief 2: There are word problems that cannot be solved with simple, step-by-step procedures.
- Belief 3: Understanding concepts is important in mathematics.
- Belief 4: Word problems are important in mathematics.
- Belief 5: Effort can increase mathematical ability.
- Belief 6: Mathematics is useful and relevant to my life.

Another set of “strong” beliefs that have recently been found to affect achievement in mathematics is students’ implicit theories of intelligence. While some students believe that intelligence is fixed (“entity theorists”) others believe it is malleable (“incremental theorists”), viewpoints which shape students’ responses to academic challenges quite differently (Dweck, 2000). Incremental theorists, for example, tend to display mastery-oriented responses to failure more than entity theorists because they believe in the utility of effort given a roadblock or setback. In a study by Elliott and Dweck, researchers manipulated the value of a goal (as either learning-focused or performance-focused) and students’ perceived ability (as either high or low) to examine affects on problem-solving strategies and persistence. The students in the performance-goal, low-perceived-ability group manifested rapid strategy deterioration, increased failure attribution and increased negative affect, including learned helplessness (Elliott & Dweck, 1988). The findings suggest that learning-focused environments for learning mathematics may be most effective for maximizing student self-efficacy, persistence and achievement.

To our knowledge, no research has examined both beliefs about mathematics and beliefs about intelligence in the same study, despite that it is reasonable to expect these two sets of beliefs to be related. Recently however, some curricular and programmatic efforts have been implemented to expose students to learning-focused mathematics education that both bolsters students’ achievement in mathematics and changes their beliefs about mathematics and mathematics learning. In 2005 for example, Boaler and colleagues wrote and taught a summer math curriculum in which students were encouraged to perform daily “meta-cognitive acts,” including mathematical summarizing, questioning, clarifying and predicting (Boaler, et al., under review). Prior to Boaler’s study, much research had shown that engaging in metacognitive acts positively affects achievement and engagement in mathematics (see White & Frederikson, 1998; Palincasar & Brown, 1984; Adey & Shaher, 1994). In just five weeks the students in the summer math program showed both math achievement gains and positive attitudinal shifts. Boaler says that “supporting and knowledgeable teachers, open and interesting tasks, and classroom culture of peer collaboration tasks, all of which characterized our summer school intervention, made it very likely that virtually all students would find intellectual stimulation and feel valued as mathematical thinkers.”

In the study described here we intend to replicate and expand on the model designed by Boaler and colleagues in the summer of 2005, in order to measure if changes in students’ beliefs about mathematics (if they exist) coincide with changes in students’ beliefs about the malleability of intelligence. The research questions addressed are:

1. Do students’ beliefs about mathematics and mathematics learning change over five weeks of a learning-focused math program? If so, which ones?
2. Are students’ beliefs about mathematics and mathematics learning correlated with their belief about the nature of intelligence?
3. Does a change in a student’s beliefs about the nature of mathematics and/or intelligence coincide with a change in achievement or effort?

## Methods

*Subjects*

The subjects were one class of 23 seventh- and eighth-grade mathematics students in a summer school program in the Bay Area. Most students were allocated to classes randomly by the registrar, but some were switched by the principal for behavioral and motivational reasons.[2] The experimental class was a heterogeneous mix of students from several different middle schools. Though technically students can elect to attend summer school program to "get ahead" the next year, 90% of students this particular summer had been mandated to attend and pass summer courses to move on to the next grade, and all students in the experimental class were there because they needed enrichment in mathematics and/or had earned a D or F in Math the previous year (Stoffal, principal, personal communication 2008). Specifically, according to an introductory survey, 22 of 23 students in the course reported being there because they had failed mathematics the previous school year.

*The Curriculum*

The "learning-focused" curriculum used in the experimental class was designed to necessitate collaborative problem-solving and emphasized both the debriefing of final answers and the sharing and discussing of mistakes and roadblocks. To motivate students to persevere, frequent, qualitative feedback from the teacher on students' progress toward the standards for the course was given, and final grades for the summer were *pass* or *fail*, where a pass was achieved by participating meaningfully in group work, presentations and whole-class discussions. For consistent formative assessment and to develop personal relationships with the students, the teacher wrote individualized responses to students' journal entries completed at the end of each day. Finally, the activities and debriefs focused on students developing and justifying their own conclusions about mathematics, and not necessarily on right answers or complete work.

The curriculum had four middle-school math content area emphases, four computational emphases and four process emphases. The content emphases, probability and number theory, proportional reasoning, patterns and generalizability and the four representations of data, were drawn from both state and national standards for 7th and 8th grade mathematics and represent topics middle-school students tend to struggle with and that are important for success in Algebra. The computational emphases, chosen for similar reasons, included students getting practice with and deepening conceptual understanding of fractions, decimals and percents, exponents and roots, ratios and proportions and order of operations. Finally, the process emphases, organization, communication, justification and questioning, came from the National Council of Teachers of Mathematics standards for mathematical thinking.

*Belief Measures*

In order to measure students' beliefs about mathematics and intelligence, on the first day of class all students were given a survey consisting of randomly-ordered questions from the Indiana Mathematics Beliefs Scales (IMBS) (Kloosterman & Cougan, 1994) and from the Implicit Theories of Intelligence Scale for Children (ITIS) (Dweck, 2000). Items assessing one of the IMBS factors, "*Word problems are important in mathematics*," were omitted because the researcher worried the phrase "word problems" might have been unfamiliar to some students or defined in a variety of ways. For this reason, items measuring the belief "*There are word problems that cannot be solved with simple, step-by-step procedures,*" used the phrase "*math problems*" instead of "*word problems*."

For the purposes of this paper, scores from both measures will be referred to as "beliefs scores." The final survey consisted of 36 items: six items measuring each of six belief factors (5 beliefs about mathematics factors and 1 belief about intelligence factor). Both scales were tested in prior research by their designers for stability and test-rest reliability and have been used in prior empirical research. The students' scores on the survey items were directionally-adjusted so that a score of 1 consistently correlated with a more negative belief and a 5 correlated with a more positive belief.

*Achievement and Effort*

In order to measure general achievement, on the second day of class all students solved two problems from the 2000 Math Assessment Collaborative (MAC) for eighth grade, consisting of an open-ended patterns and proportional reasoning problem. These particular problems were chosen because they were unrelated directly to content from the course, but were two, different measures of general problem-solving ability. First, each assessment was scored using a rubric and given a numerical score for correctness ("Paths" problem out of 4 points; "Lockers" problem out of 6 points). These scores and rubrics were derived from the existing scoring methods from the designers of the problems. As a measure of effort, each assessment was also given a binary score for completeness, based on whether or not the subject tried all parts of the problem. Two scorers scored all assessments, compared scores, then discussed disparities and came to agreements on final scores before analyses began. Because of absenteeism only 17 of 23 students took the post-assessment.

## Results

*Changes in Achievement and Effort*

The change from pre-test to post-test in achievement scores was significant ($t$=1.80 $p$=0.046), as well as the change in effort scores ($t$=2.7, $p$=0.007) (Tables 1.1, 1.2).

*Table 1.1*

Comparison of Pre- and Post-test Achievement Scores (N=17)

| | **Pre-Test** | | **Post-Test** | | ***Change*** |
|---|---|---|---|---|---|

*Note*. **p* < 0.025, ***p* < 0.05, ****p* < 0.01

*Correlations between Beliefs and Achievement*

The correlation between change in beliefs and change in achievement was (R=0.12, NS). It is clear from the scatterplot that the four greatest changes in achievement scores were correlated with large changes in beliefs scores. There was a more positive correlation between changes in effort scores and changes in achievement scores (R=0.42).

## Discussion

The main findings of this study are that students' beliefs about mathematics and mathematics learning can change over five weeks of a learning-focused math program. The largest change was found in students' beliefs about the importance of understanding concepts in learning mathematics. There were also significant, positive changes in students' achievement and effort scores. Despite these findings, there was no significant change in students' beliefs about the malleability of intelligence, nor significant correlations between changes among any of the beliefs. Overall, changes in students' achievement scores correlated only weakly with changes in students' beliefs, but much more strongly with changes in effort scores.

The fact that a large number of the analyses shown above resulted in non-significant results is not surprising, considering the small sample size and short time frame for implementing the learning-focused curriculum. This makes the significant results, however, much more interesting and important for future research. Clearly students' beliefs can be changed in a short amount of time, as evidenced by the four small but significant changes and overall significant change in scores. These beliefs were:

- "Effort can increase mathematical ability."
- "I can solve time-consuming mathematics problems."
- "Understanding concepts is important in mathematics."
- "Mathematics is useful and relevant to my life."

The fact that these beliefs changed and not the other beliefs ("*Intelligence is malleable*" and "*There are problems that cannot be solved with simple, step-by-step procedures*") can be qualified in part by certain characteristics of the curriculum used. Specifically, the curriculum was focused primarily on large, open-ended problems that we both asked students to try their best on (as opposed to solve completely) and persevere on as long as possible. Students spent a great deal of time trying things out and were never discouraged from attempting a particular method even if it was clearly wrong. In class debriefs and discussions the students then came together to share processes and answers and often went back to work afterward. It was an important part of the design of the curriculum for students to both grapple with difficult mathematics but also have enough access so they wouldn't shut down. It is not surprising that after five weeks of doing mathematics in this way students would have different beliefs about effort's role in what defines "mathematical ability" and more confidence solving time-consuming math problems. The former is a pleasing result considering that Americans tend to be one of few groups internationally who believe you are either born with math ability or not (TIMSS, 1999). Additionally, the focus on explanation, justification and questioning in the curriculum could have contributed to the positive changes in students' beliefs about the importance of conceptual understanding in mathematics as well.

These same curricular characteristics, however, make the non-significant change in students' beliefs about the quality of math problems curious. It would be expected that students feeling more confident in their ability to solve tough problems and believing that effort has more to do with ability than not would also believe that solving math problems has less to do with following one, correct procedure than it does with hypothesizing, testing, manipulating, etc. Furthermore, students' beliefs about the nature of intelligence generally did not change over the course of the summer. This could be explained perhaps by the fact that these questions were blended in with the other 30 questions focused on mathematics, and thus could have been misinterpreted. Perhaps some students' engrained beliefs that they *personally* are not "intelligent" mathematically overrode the fact that the questions were intended to measure beliefs about intelligence *in general*. Or perhaps some students assumed the questions were referring to their beliefs about themselves and not their beliefs about general intelligence. This kind of measurement error would need to be addressed in future studies.

Another explanation for any of the changes in beliefs could come from the social desirability of certain answers. By the end of the five weeks, it is possible that some students may have circled certain responses in order to impress or satisfy the teacher. But there are two reasons why this is probably not the case. First, both achievement and effort scores significantly increased form pre- to post-program. This provides evidence that even if students had grown to like the teacher enough to falsify answers on their survey, it is unlikely they all, as well, “decided” to get a higher score on the post-assessment. Second, in a study where both entity and incremental options were given to students on a survey, children showed “a tendency to endorse incremental statements,” despite actually believing different things about the malleability of intelligence (Erdley & Dweck, 1993). Though this suggests that students may generally have ideas about what they should or should not believe about intelligence, on this survey the only two non-significant changes *included* beliefs about intelligence.

Clearly the small sample size of the students is problematic, and could partly explain why not all changes in beliefs scores were significant or that those that were small in magnitude. Perhaps if these latter changes had been larger, we would have seen a significant change in beliefs 3 and 4 as well. If this were true, it would imply that certain changes in certain beliefs about mathematics are correlated with changes in students’ beliefs about intelligence.

It is not surprising that the change in achievement was correlated to some degree with change in effort. This could explain the change in achievement entirely, in fact. Perhaps if students had actually grown more confident in some way over the course of the five weeks in trying problems, even tough ones, their willingness to try the post-assessment problems had increased, and not necessarily their problem-solving ability. The correlation between changes in beliefs and achievement, though weak, provides some support for the argument that it was not effort entirely that might explain achievement gains. Though no causal claims of any kind can be made from this data, this finding provides impetus to examine the connection between changes in these beliefs, due to this kind of curriculum, and changes in achievement. Looking at the scatterplots from Diagram 4, for example, it may be true that above a certain level of achievement there is an interaction between achievement and beliefs such that a high level of achievement is associated with a high change in belief (the 4 plots in the upper right hand corner). It would be interesting to manipulate belief in a math class without doing any problems (e.g. work to convey to the class they are special, good problem-solvers, intelligent, etc. in other ways) and see if problem-solving still improves.

## Endnotes

1. The concept *beliefs* is defined here as “the personal assumptions from which individuals make decisions about the actions they will undertake” (Kloosterman, Raymond, & Emenaker, 1996).

2. For example, one student had failed math the year before in a class taught by one of the summer school teachers. The registrar had randomly placed him in her class for the summer program, so he was manually switched into another teachers’ class with hopes that exposure to a different teacher might help motivate him to do better.

University of Colorado at Boulder

*This study explores undergraduate students' self-reported gains in college mathematics courses and how these relate to the inquiry-based learning (IBL) methods used in their courses. These experiences were studied against the qualities and development of students' beliefs, motivation and strategies for learning and solving mathematical problems. Pre- and post survey data during one semester-long course showed that students found the instructional practices beneficial and reported cognitive, affective and social gains due to the course. Clear positive correlations appeared between students' gains and their experiences of instructional practices as well as between the gains and their beliefs, motivation and strategies. Moreover, positive changes between pre- and post-surveys in beliefs, motivation and strategies indicate the positive impact of the classes on students' perceptions and practices in studying college mathematics.*

## Background

The important role of beliefs, affect, and motivation in learning mathematics is well acknowledged in mathematics education research. Students' mathematical beliefs and attitudes have powerful impacts on their engagement and achievement, especially on problem solving. Students' beliefs about the nature of mathematical knowledge and skills, about mathematical problem-solving, and about their own mathematical capability, often determine their level of attendance and learning. Negative attitudes and emotions, together with inadequate self-regulatory behaviors, are often connected with students' preventive beliefs and perceptions in mathematics learning situations (DeBellis & Goldin, 2006; Malmivuori, 2001, 2007; McLeod, 1992; Schoenfeld, 1992). Such beliefs and behaviors derive from students' previous classroom experiences, both positive and negative; they are highly stable and difficult to change (e.g., Bishop, 2001; Cobb, Yackel & McCain, 2000).

Students who choose to study college mathematics differ from those studying secondary and high school mathematics, as does their learning context. College students who study mathematics as their major or minor subject usually show positive attitudes towards mathematics and high motivation, but nonetheless have varying goals for their study of mathematics and varying beliefs about mathematics and mathematical problem solving, for example in their beliefs about mathematical proofs (Selden & Selden, 2007; Sowder & Harel, 2003). Other students, required to take mathematics courses for another major, may exhibit less positive attitudes. Pre-service teachers represent a third group of college students with distinct beliefs, goals and attitudes.

All these various personal, social and instructional aspects determine the context in which students develop knowledge, beliefs and attitudes. Active teaching approaches all share goals of engaging students in their own learning processes and activating their responsibility for their own learning (Prince, 2004). Inquiry-based learning (IBL) is one such approach. Closely related to discovery learning or guided discovery (Bruner, 1961; Dewey, 1938) and problem-based learning (e.g., Savin-Baden & Major, 2004), IBL provides opportunities for students to engage in knowledge creation and argumentation (Rasmussen & Kwon, 2007) and promotes problem solving skills, independent thinking and intellectual growth (Buch & Wolff, 2000; Duch, Gron &

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

Allen, 2001). In addition, pedagogical practices that emphasize cooperative learning are seen to foster student dialogue, build positive interdependence within groups, and promote higher-order thinking (Gillies, 2007; King, 2002). Such instructional approaches offer a context that clearly differs from the lecturing, exams and transmittance model of providing content knowledge that are traditional in college mathematics courses. This study explores undergraduate students' beliefs, experiences and learning gains in this kind of an active instructional context.

## Objectives of the Study

This study reports preliminary findings on undergraduate mathematics students' beliefs, motivation, strategies and gains with respect to their experiences of instructional practices during one semester of college mathematics applying IBL instructional methods. The main focus is on students' beliefs, goals and experiences students while studying college mathematics, and how these are related to their achievement, measured in the form of self-reported learning gains. The results also show changes in students' beliefs, motivation, and strategies during their IBL mathematics course, and, further, how these changes are related to their learning gains.

## Methodology

*Subjects of the Study*

Survey data was gathered from undergraduate students studying mathematics in four different US research universities during one term. The students represent mostly general math major and minor students in advanced mathematics courses; three sections of elementary and secondary pre-service teachers were also included. A structured, paper-and-pencil questionnaire was administered in the beginning and end of each course. The data derive from 13 different IBL sections with 192 students responding to the pre- and post-surveys. Four additional IBL sections were included in the analysis of post-survey data, for a total of 233 students.

*Instrument*

The first part of the survey was constructed on the basis of theory about mathematical beliefs, affect, goals and strategies of learning and problem solving. It was tested and revised using item analysis. The seven sections measured students' interest in and enjoyment of mathematics, goals in studying mathematics, learning and problem solving actions taken while doing mathematics, and beliefs about learning mathematics, problem solving, and proofs. Responses varied on a seven-point Likert-scale (e.g., from "not at all important" to "extremely important").

The post-survey included the same items, plus six additional sections. Four sections asked about students' experiences of instructional practices: how much various practices helped their learning, on a five-point scale from "no help" to "a great help." Two sections measured students' learning gains in understanding, attitudes, confidence and capabilities, on a five-point scale from "no gain" to "great gain". These sections were based on the SALG instrument (Student Assessment of their Learning Gains; SALG, 2008), which was developed to enable faculty and program evaluators to gather formative and summative data on classroom practices. Both the pre- and post-surveys gathered information on students' personal and mathematical background.

*Variables and Data Analysis*

New composite variables were constructed on the basis of the designed scales and exploratory factor analyses: 17 measures of beliefs, motivation, affect and strategies; 5 measures of instructional practices; and 4 measures of gains (see Table 1). Scores varied between 1 and 7 (where 4 points to a neutral or average view) or between 1 and 5 (where 3 refers to moderate help or gain). Reliability scores for these scales varied between 0.64 and 0.96. Statistical analysis included descriptive statistics, correlation analysis, and parametric tests (T-tests, ANOVA).

Table 1. *Composite Variables Measuring Student Beliefs, Experiences and Learning Gains*

| **Variable** | **items** | **scale** | **Emphasis of items** |
|---|---|---|---|
| Motivation | | | |
| *Interest* | 3 | 7 | Interest in learning and discussing mathematics |
| *Math major* | 1 | 7 | Desire to graduate with a math major |
| *Math future* | 2 | 7 | Desire to pursue math in future work or education |
| *Teaching* | 1 | 7 | Desire to teach math |
| Enjoyment | 7 | 7 | Pleasure in doing and discovering mathematics |
| Goals for studying math | | | |
| *Intrinsic* | 4 | 7 | Learning new ways to think & to apply math |
| *Extrinsic* | 4 | 7 | Meeting requirements; degree, good grades |
| *Communicating* | 2 | 7 | Communication of mathematical ideas to others |
| Beliefs about learning | | | |
| *Instructor-driven* | 5 | 7 | Exams, lectures, instructor activities |
| *Group work* | 3 | 7 | Whole-class or small group work |
| *Exchange of ideas* | 3 | 7 | Active verbal interaction with other students |
| Beliefs about problem-solving | | | |
| *Practice* | 2 | 7 | Repeated practice, remembering |
| *Reasoning* | 5 | 7 | Rigorous reasoning, flexibility in solving |
| Beliefs about proofs (Yoo & Smith, 2007) | | | |
| *Constructive* | 4 | 7 | Process view; revealing mathematical ideas |
| *Confirming* | 4 | 7 | Product view; recall and confirming conjectures |
| Strategies | | | |
| *Independent* | 4 | 7 | Finding one's own way to think & solve problems |
| *Collaborative* | 4 | 7 | Seeking help, actively sharing with others |
| *Self-regulatory* | 6 | 7 | Planning, organizing, reviewing one's own work |
| Experience of classroom practices (what helped me learn) | | | |
| *Overall* | 7 | 5 | Teaching approach, atmosphere, pace, workload |
| *Active participation* | 5 | 5 | Personal engagement in discussion & group work |
| *Individual work* | 4 | 5 | Studying & problem-solving on one's own |
| *Assignments* | 8 | 5 | Nature of tests, homework, other assigned tasks |
| *Personal interactions* | 6 | | Interaction with peers & instructor, in/out of class |
| Learning gains | | | |
| *Mathematical thinking* | 4 | 5 | Understanding concepts, how mathematicians think |
| *Application* | 3 | 5 | Applying ideas elsewhere, understanding others' ideas |
| *Empowerment* | 10 | 5 | Confidence to do math, appreciation, persistence |
| *Working with others* | 3 | 5 | Working with others, seeking help |

## Results

*Experiences of Instructional Practices and Gains*

Table 2 shows the average ratings of students' experiences of the helpfulness to them of various classroom practices and of their self-reported gains due to participating in a college IBL mathematics course. These are reported separately for each campus with more than one section and advanced mathematics students (CM1-CM3) are distinguished from pre-service teachers at one campus (CT4).

Table 2. *Average Ratings of Experiences of Classroom Practices and Self-reported Learning Gains*

| | | CAMPUS | | | |
|---|---|---|---|---|---|
| | | CM1 | CM2 | CM3 | CT4 |
| Classroom practices (5-point scale) | *overall* | 3.99 | 3.43 | 3.56 | 2.56 |
| | *active participation* | 4.18 | 3.84 | 4.05 | 3.65 |
| | *individual work* | 4.09 | 3.94 | 3.77 | 3.32 |
| | *assignments* | 3.87 | 3.36 | 3.42 | 2.63 |
| | *interactions* | 4.14 | 3.89 | 3.95 | 3.57 |
| Learning gains (5-point scale) | *mathematical thinking* | 4.37 | 3.89 | 4.01 | 2.72 |
| | *application* | 3.19 | 3.03 | 3.45 | 2.26 |
| | *empowerment* | 3.72 | 3.45 | 3.59 | 2.41 |
| | *working with others* | 3.66 | 3.39 | 3.92 | 2.86 |

** N = 34-77 for each campus.*

The averages in Table 2 reflect that students on each campus found IBL instructional practices helpful to their learning. Averages near or above 4.0 further indicate that many students experienced great help due to their participation in the IBL class. Students reported the most help to their learning from active participation and interaction during class work, while the particular assignments were least helpful.

Table 2 further shows that students' experiences slightly varied between the campuses. Pre-service teachers (CT4) found less benefit in the instructional practices than other undergraduate mathematics students. Lower ratings on the overall approach to teaching and learning and class atmosphere may reflect what students reported (in separate interviews) to be high workloads. This was valid especially for pre-service teachers, but also appeared among the advanced mathematics students. Campus 1 students (CM1) seemed to find their classroom experiences slightly more helpful than students at other campuses, but the differences were not large and probably reflected real variation in the actual instructional practices among classes.

Averages for the four learning gain variables show that students reported moderate or good gains due to their course work. Again, averages near and above 4.0 indicate that many students felt they made great gains in their IBL class. Among all groups, the highest gains were reported in understanding mathematical thinking and concepts, with lower gains in understanding how the course ideas were applied outside mathematics or how to make mathematics understandable for other people. Again, pre-service teachers reported weaker gains than did advanced mathematics students; relatively speaking, they reported stronger gains in learning to work well with others.

Campus 2 students (CM2) reported lower gains than other students, consistent with their slightly less positive reports of benefits from the instructional practices in their courses. On the other hand, students at Campus 3 (CM3) had the highest gains in working with others. Unlike Campus 2 students, they found interaction and active participation more helpful than individual work. These variations among student groups may thus reflect the differences in actual instructional practices, consistent with our (separate) observations of classroom sessions. For example, individual work may have been more emphasized at Campus 2 than elsewhere.

Analysis of the correlations among the instructional practices and learning gains for all students revealed statistically significant positive correlations between all the variables (from 0.297 to 0.749). That is, those students who experienced various class practices and interactions as clearly helpful also reported higher gains from their class, and vice versa. These correlations indicate that students found IBL instructional approaches beneficial to their learning.

*Beliefs, Motivation, and Strategies*

Table 3 lists the averages on scales for mathematical beliefs, motivation and strategies for learning and problem solving. The results concern advanced mathematics students (not pre-service teachers) in 10 IBL sections at four campuses who took both pre- and post-surveys.

Table 3. *Averages for Measures of Beliefs, Motivation, and Strategies for Pre- and Post Surveys*

| | | AVERAGES (7-point scale) | | |
|---|---|---|---|---|
| VARIABLE | | Pre survey | Post survey | Sig. level |
| Motivation | *interest* | 4.68 | 5.08 | ** |
| | *math major* | 4.49 | 5.12 | * |
| | *math future* | 6.20 | 6.19 | |

| | *self-regulatory* | 5.10 | 5.20 | |

** N =112-184; p < .05*, p < .01**.*

Table 3 indicates that these students had rather strong motivation and promotive beliefs that emphasized rigorous reasoning, flexibility and construction in problem solving. They stressed the value of interaction in learning and were motivated both by intrinsic and extrinsic goals and an ability to communicate about mathematics. In their preferred strategies for learning and problem solving, students emphasized both individual work and collaboration and reported a high level of self-regulatory activities.

Despite these rather high initial averages, some general changes between the pre- and post-surveys could nonetheless be observed in students' beliefs, motivation and strategies. Most of these involved increases in the strength of students' beliefs about the importance of collaboration and group work in studying mathematics, and in their motivation and their use of effective problem-solving strategies. Females showed increases from pre- to post-surveys more often than males. Students reported more use of both individual and collaborative ways to learn after the IBL course. They also reported higher interest in mathematics in general, in graduating with a college math major, and a slightly higher likelihood that they would teach mathematics in the future. Moreover, the observed changes showed some growth in a constructive view of proving and in seeing the importance of rigorous reasoning and multiple approaches in solving math problems—views more consistent with mathematicians' views. Finally, students showed declines in a transmittal view of learning that emphasized instructor explanation and seeing similar examples to their homework. All these changes suggest a positive impact of IBL classes on students' perceptions of mathematics and on their practices in studying college mathematics.

*Connections Between Beliefs, Motivation, Strategies and Gains*

Correlations were computed between the constructed post-survey variables and gains for all four campuses. Table 4 displays the strongest correlations between the four gain scales and the post-survey scales on beliefs, motivation, and strategies for learning mathematics.

Table 4. *The Strongest Correlations between Learning Gains and Post-survey Beliefs, Motivation, and Strategies, among all Students*

| VARIABLE | | GAINS | | | |
|---|---|---|---|---|---|
| | | Mathematical thinking | Application | Empowerment | Working with others |
| Motivation | *interest* | 0.515 | 0.338 | 0.466 | 0.220 |
| Goals | *intrinsic* | 0.505 | 0.371 | 0.469 | 0.261 |
| Enjoyment | | 0.564 | 0.346 | 0.489 | 0.182 |
| Beliefs about learning | *interactions* | 0.272 | 0.307 | 0.343 | 0.296 |
| Beliefs about problem solving | *reasoning* | 0.421 | 0.319 | 0.327 | 0.247 |
| Beliefs about proofs | *constructive* | 0.412 | 0.289 | 0.289 | 0.222 |
| Strategies | *independence* | 0.452 | 0.249 | 0.351 | 0.226 |
| | *self-regulation* | 0.359 | 0.320 | 0.415 | 0.355 |

* *All correlations are significant at the level $p < .01$* ** *$N = 197$-$222$*

Table 4 shows clear positive connections between students' cognitive, affective, and social gains and their beliefs, motivation and learning strategies. The strongest correlations related to students' gains in understanding mathematical concepts and thinking, and to their gains in empowerment: confidence, positive attitude, persistence, and ability to improve their own mathematical capacity. High interest, enjoyment and intrinsic goals for learning college mathematics were the most positively related to learning gains. Interestingly, these motivational connections were clearest among pre-service teachers—among whom interest and enjoyment were initially lower. Students' preference for independent thinking strategies was most strongly linked to higher gains in mathematical thinking, while strategies of active self-regulation in solving problems were most clearly linked to higher empowerment.

Students' gains in mathematical thinking were linked to beliefs about the importance of rigorous reasoning and flexibility in solving problems, and to constructive views of mathematical proof. The belief that it is important to have active interaction with other students when learning mathematics was also clearly related to cognitive, affective and social gains. Unsurprisingly, this relation was strongest for students' gains in willingness and ability to work with others.

Comparisons between Tables 3 and 4 indicate that the strongest correlations to gains were represented by those variables that also showed increases from pre- to post-surveys. This applied in particular to students' interest and independence of learning but also to the importance they attached to rigorous reasoning and flexibility in solving mathematical problems and to constructive views of proofs. Positive changes in these views and approaches may have a critical role in affecting students' learning gains, not only among these students in IBL classes but also among college mathematics students more generally.

## Discussion

The role of beliefs, affect, and motivation has been widely studied in secondary school contexts, but less so among college mathematics students. Teaching methods applying inquiry-based learning with active collaboration create a context different from traditional college mathematics instruction. Active engagement of students in their own learning processes, with responsibility, collaboration, and creative use of personal resources, is seen to enhance growth of thinking and problem solving (Prince & Felder, 2007) and social skills (Duch et al., 2001; Jordan & Metais, 1997). Promotion of cognitive, affective and social skills in such learning contexts may then be reflected in students' beliefs, experiences, and activities (e.g., Kwon, Rasmussen, & Allen, 2005; Smith, 2006). Our preliminary findings point to such positive impacts.

The advanced math students in this study began with high motivation and adequate beliefs about mathematics learning and problem solving. However, participation in an IBL mathematics course seemed to further promote these views and approaches. Students gained interest in and motivation to study mathematics and exhibited less belief in rote learning methods. They attached greater importance to group work and active collaboration, and to communicating mathematical ideas. Their choice of problem-solving strategies emphasized both independent thinking and collaboration. After taking an IBL course, they saw rigorous reasoning in solving problems as more important and reflected a more process-based view of mathematical proofs.

Students reported rather high cognitive, affective and social gains due to their participation in an IBL course and reported IBL classroom practices as helpful, especially their own active participation and interaction during the class work. Pre-service teachers reported lower gains and less benefit from IBL learning approaches than advanced math students.

The results also showed important, direct connections between these cognitive, affective, and social gains and students' beliefs, motivation, and use of particular learning and problem solving strategies. Higher interest, enjoyment, and intrinsic goals for learning college mathematics were most clearly connected to higher gains. The strongest connections to gains appeared in the beliefs, motivation and strategies that also showed increases during an IBL course.

Limitations to the study include a rather low sample size and large variation in the instructional practices, nature of courses, and in student backgrounds within and between the campus sections. More data are needed to confirm these preliminary findings. However, the results indicate that use of active instructional methods with inquiry and collaboration represents a learning context that may have powerful effects on students' learning and positive attitudes toward college mathematics. Future study will show how these gains and experiences vary between different student groups, especially with respect to gender and in comparison with students experiencing more traditional college mathematics teaching.

*Acknowledgement.* The Educational Advancement Foundation has funded the IBL evaluation research project used for gathering the data for this report.

# STRATEGIZING DEVELOPMENTAL MATHEMATICS AT A LARGE AND DIVERSE STATE UNIVERSITY

Babette M. Benken
California State University, Long Beach
bbenken@csulb.edu

Xuhui Li
California State University, Long Beach
xli2@csulb.edu

*This study investigated the current status of developmental mathematics at a large and diverse state university, as it existed within national practices and recommendations. Findings suggest that students' attitudes toward mathematics and learning, the time they are willing to spend, knowledge of how to learn mathematics, and learning experiences within remedial courses all play a critical role in their academic success. Strategies for improving the quality of student learning in developmental mathematics are proposed.*

## Objectives and Research Perspective

Statistics indicate that almost sixty percent of students who enroll in community colleges must take developmental mathematics before entering college-level coursework (Schwartz, 2007). This statistic is also alarming at the university level, primarily at universities intended for non-traditional and local student populations. For example, the largest proportion (80%) of 1st-year college students taking a developmental course at public, 4-year institutions in 2000 took developmental mathematics (Duranczyk & Higbee, 2006). When students face remediation, it means they have a longer road to completing their mathematics degree requirements. Many give up before they finish the sequence of courses. Additionally, taking remedial courses the entire first year is costly, as well as delays graduation for those needing mathematics courses. Time for remediation can also dissuade students from seeking majors requiring mathematics. Alternative pathways are needed to help facilitate students' expeditious and successful completion of remediation, as well as help students arrive on university campuses ready for undergraduate mathematics. One common theme in this literature on instruction in developmental mathematics courses is that no single set of practices will be effective with every student (Biswas, 2007; Schwartz & Jenkins, 2007). There is a broad consensus in the literature that educators ought to take a holistic approach to developmental education.

Our university has a highly diverse student population of nearly 38,000. Each year approximately one-third of the first-time freshmen need to take and pass pre-baccalaureate developmental mathematics courses before moving on to the next level (general education). Some of the students taking developmental mathematics struggle to successfully complete it in one year; approximately 30% of them do not return for a second year. In order to understand the current situation of developmental mathematics within our Department (Mathematics and Statistics), as well as propose strategies for improving the experience and completion rates of our developmental students, we embarked on a research study. Our Department and the larger University were eager to carefully examine the current situation of the program after recent changes to both placement and course structure, and strategize future possible changes, including specific pilot studies.

Two primary research questions guided our work:

1. What is the current situation of developmental mathematics at our university?
2. What practically should be implemented over the next two years to improve the existing program?

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

## Methodology

As neither of us had previously conducted research in the area of remedial mathematics, we began by casting a large net across both the existing literature and other programs. We sought to accomplish the following: gain knowledge of what other institutions have tried and are currently trying, generate a portrait of what existing literature tells relative to the design and implementation of effective developmental mathematics programs, compile other existing data and completed analyses from our Department and the campus community, examine students' experiences, expectations, attitudes and success in developmental mathematics courses, and gather insights from key individuals and other departments on campus on how to handle the difficult process of developmental mathematics.

Our primary data sources included:

- Relevant literature in developmental mathematics and mathematics education;
- Website searches (California State University campuses, similar universities in California and across nation, etc.);
- Email communication with colleagues at universities and community colleges across the nation;
- Existing data (Department, University);
- Surveys administered to developmental mathematics students at the beginning and end of the Fall 2008 semester (380 responses), a subset of students who had just finished developmental mathematics in Spring 2008 (28 responses), and developmental mathematics instructors (6 responses);
- Interviews with individuals (10) within our Department, Department of English, and University administrators;
- Town meetings (3) with key individuals across campus (e.g., higher administration, academic advisors).

Student surveys contained both open-ended and Likert-type questions (1-6 scale) and asked about their expectations for and experiences within the developmental mathematics courses, their anxiety and attitudes toward mathematics and mathematics learning, their level of skill preparation (pre- and post-course), and impressions of course and instructor. Instructor surveys included only open-ended questions regarding their experiences teaching developmental courses, observations of their students' learning and needs, and recommendations for our Department and future iterations of all courses they had taught. All interviews were semi-structured and informal in nature.

## Results

*Key Findings from Relevant Literature*

Two fundamental factors have proven to be crucial to student success in mathematics remediation: (1) the existence of an early alarm system for remediation needs, and (2) a strong alignment between college mathematics placement tests and high school mathematics curriculum and assessments (Brown & Niemi, 2007; California Partnership for Achieving Student Success, 2008; Hill, 2008). However, students often do not perceive the need for intervention, and a student's pathway within a given high school context is dependent upon his/her success at the middle school level.

Once in a college or university environment, traditional approaches to instruction (e.g., lecture) in developmental mathematics courses do not engage students (e.g.,McGlynn, 2008). A focus on rote memorization of formulas and rules is a hindrance to students at the developmental level. Developmental mathematics courses need to focus on critical thinking and how to be an effective student of mathematics, and spend time and attention to enhancing the students' work, study habits and concentration skills. Non-traditional instructional methods in developmental mathematics education can work; for example, cooperative learning can lesson students' "fear of mathematics" and the "fear of failing" (e.g., NADE Mathematics Special Professional Interest Network, 2002, 2003). Guided instruction appears to be more effective for low performing students than structured instruction (e.g., Kroesbergen & van Luit, 2002). Students' negative attitudes and anxiety toward mathematics must be overtly addressed (Tobias, 1993).

Technology could be integrated where appropriate to encourage active learning and help students explore concepts and visualize real-world data. Computer-based instruction is most successful when it is used as a supplement to regular classroom activities in developmental courses. In order for technology to be effective, the student-teacher interaction must be the main form of formal instruction with technology "acting as a conduit" for this to take place effectively (Robinson, 1995).

Students in developmental courses need to be motivated and inspired, hence the role of teacher is critical. Teachers must listen carefully to students and meet them at their level or place of cognition, and attack students' mathematics anxiety–one good strategy is to instill a participatory, non-threatening classroom environment (e.g., Ironsmith, Marva, Harju, & Eppler, 2003). Teachers must have training in and appropriate attitudes toward working with this special population of students. Research suggests that teachers' attitudes impact instruction and student achievement (Richardson, 1996; Thompson, 1992).

*Prevalent Models and Strategies*

Across higher education institutions in the United States, we have isolated three models for developmental mathematics courses that are most prevalent:

*(1) The Supplement Model*. This model retains the basic structure of the traditional course, supplements lectures and textbooks with technology-based, out-of-class activities, or small-group or individual tutoring.

*(2) The Replacement Model*. This model reduces the number of in-class meetings and replaces with out-of-class, online, interactive learning activities in computer-labs. The in-class meetings could be combined into large sections and team-taught by multiple instructors.

*(3) The Emporium* (*or Fully-online*) *Model*. This model replaces all class meetings with a learning resource center featuring online materials, multi-media resources, commercial software, on-demand personalized assistance, automatically evaluated assessments with guided feedback and alternative staffing. Course material is often organized into modules, which students will complete at individualized paces.

Within any model, there are recommended considerations for the most valuable developmental mathematics experience. These include: (1) Proper placement of students through the administering of placement tests into appropriate courses is essential to student success; (2) A clearly defined philosophy for the program, accompanied by clearly specified goals and objectives; (3) On-going communication among those who teach developmental courses with centralized supervision; (4) A strong counseling component; counseling components should be integrated into the overall structure of the developmental program and be carried out by counselors specifically trained to work with developmental students; and (5) Tutoring for students; tutoring is most effective when the tutors are trained to work with students at developmental levels.

*Major Findings from Student Surveys*

In September 2008, we conducted surveys with two groups of CSULB students: (1) Those students who had just finished taking an intermediate algebra course in Spring 2008 and were currently enrolled in a general education course (on our campus intermediate algebra is the second level of developmental mathematics course), and (2) Those students who had just begun intermediate algebra. In December 2008, an end-of-course follow-up survey was conducted with the students in the second group. Some common themes were identified across the three groups of responses:

- Over three-quarters of the students took two semesters of mathematics in the senior year in high school;
- On a scale of 1 to 6 (6 highest), 70% of the students entering intermediate algebra chose 3 or 4 in rating the levels of their own mathematics skills and enjoyment. At the end of the course, such percentage increased to 80%;
- Almost all of the students thought the state-level placement exam was important or necessary, but did no or very little preparation for it;
- The majority of the students felt the developmental mathematics placement was fair or necessary, with a few expressing surprise over the placement;
- Students did not believe they were informed of various opportunities and resources available;
- Besides the in-class time, 80% of the students spent only 2 – 4 hours per week on studying for the course. More than half of the students believed they should have spent more time for better understanding;
- As a result of taking the course, the majority of the students expressed that they were "somewhat" or "a little" better in mathematics. Many felt that this class reviewed or "refreshed" what they had studied in high school;
- Over 90% of the students believed the class met their expectations, and the instructor and instruction were helpful over the semester;
- On the December 2008 end-of-course survey, around 90% of the students felt "somewhat" or "very" confident in passing the class, which showed increased confidence levels than in September when they just started.

*Lessons Learned from Interviews with Key Individuals*

Interviews revealed that many aspects of existing practice are critical to students' success in developmental mathematics. First, effort matters. For every additional hour that students study in our Department's remedial courses, the effect on their performances is significant. The passing rate for those who spend three hours per week in developmental courses is 61%. For those who spend four hours per week, the rate is 67%. And, for those students who spend five hours per week, the passing rate jumps to 78%. Students who are most successful in developmental mathematics courses understand the importance of attending class, studying, and completing developmental mathematics early.

Second, the most at-risk students need to be appropriately mentored; they have low or unclear personal expectations and drift easily. As part of this process, resources that help them study can be available, and they can be pushed to meet deadlines and encouraged in all aspects of their learning. As part of this process, mathematics information should be disseminated in the spring prior to students' arrival at the University. In general, we need to push these students to make preparations for learning and inform them of resources and supports.

Third, more tutoring should be made available to developmental students, with tutors who are experienced in working with this special student population.

Fourth, relative to instruction, students need to be: motivated through alternative approaches, evaluated through less formal assessments, and taught through a well-structured curriculum. Intermediate algebra instructors interviewed had varied views on the nature and goals of the course; goals should be aligned. One example existed within the English Department; their remedial sections have a common exit requirement (portfolio) to hold instructors accountable; instructors meet regularly and work collaboratively toward common goals.

Fifth and finally, the Department has provided ongoing, formal professional development for graduate teaching assistants; this training should include specific attention to this special population of students.

## Proposed Strategies

Based on the reality of mathematics instruction and practice in our Department and the aforementioned findings, we proposed the following strategies at town meetings across the University for improving students' success in our developmental mathematics program:

- Organize mathematics placement exam workshops for those graduating high school in the spring;
- Offer mathematics courses to selected incoming freshmen in the summer, in order to reduce the number of students needing remediation in their freshman year;
- Revise the developmental mathematics curriculum, particularly in intermediate algebra;
- Implement common structures, assessments, and final exams across all sections of a given course, particularly intermediate algebra;
- Increase course time each week in intermediate algebra by one hour for individual or group tutoring or Supplemental Instruction sessions;
- Assign experienced graduate teaching assistants (as opposed to part-time instructors) to teach developmental mathematics courses, thereby allowing for a more aligned program;
- Provide ongoing professional development to teaching assistants and tutors (with respect to mathematics content, pedagogy, student needs, etc.);
- Identify and provide additional support to students with special needs, such as double pre-baccalaureate students (those needing remediation in both mathematics and English) and student athletes.

Based on feedback relative to our proposed strategies, we suggested to the Department and University a number of pilot studies that could examine changes to our existing Developmental Mathematics Program. Highlights include:

(1) Provide 1-2 daylong placement exam workshops for the State-level exam to high school seniors on campus in Spring on the Saturday prior to the testing dates. Garner information (pre-test, survey) during first hour in order to sort students by ability. The objectives are to help participants prepare for the exam, gain insight into participants' expectations for and attitudes toward the exam and mathematics at the University, and decrease the number of students needing developmental mathematics in fall. Data would include pre-post student tests, pre-post student surveys, student interviews, and placement exam scores.

(2) Revise the intermediate algebra course curriculum to better reflect the nature of the course and these students' needs. As part of this process, generate common assessments (e.g., final exam). The goal is to develop a curriculum that is more appropriate to developmental level students, as well as assessments that are required by all instructors,

with improvement in students' passing rates. Data would include artifacts (e.g., assessments), detailed record of curriculum development, instructor surveys, and passing rates of future course sections.

(3) Expand the number of developmental courses offered in summer and actively recruit from surrounding districts to target students who have just missed the placement exam cut-off score to bypass remediation. The goals are to decrease number of students needing developmental mathematics in fall and better understand the background and attitudes of students selecting this option. Data would include pre-post student surveys, passing rates of these summer sections, and numbers of students completing remediation as a result of this offering prior to freshman year.

(4) Have graduate students teach as many sections of intermediate algebra as possible to provide structured and on-going support led by an assigned coordinator that addresses pedagogy, content, and special needs of students. The goals are to improve the students' passing rate and enhance the learning experience for all students. Data would include pre-post student surveys, students' passing rate, graduate student instructor surveys and interviews, and interviews with the graduate student coordinator.

(5) Increase the weekly course length of intermediate algebra by one hour for individual or group tutoring or Supplemental Instruction sessions (computer-based software, online system, human tutors or SI leaders). The expected outcomes include improved student passing rate and increased time to address affective and support the needs of students in this developmental course. Data would include pre-post student surveys, students' passing and completion rates, and instructor interviews.

## Discussion

Within this paper we carefully describe our methodology, as well as results from both of our research questions. Presenting our work in this manner allows it to serve as a model for how other institutions can examine their own developmental mathematics programs and make the changes/revisions necessary to address this nation-wide problem. While popular perception is that most students needing remediation either did not take mathematics in their last year of high school or did not successfully complete prerequisite courses, we have found, and the literature supports, that this perception is not accurate. Students' attitudes toward mathematics and learning, the time they are willing to spend, knowledge of how to learn mathematics, and learning experiences within remedial courses all play a critical role in their academic success. Developmental programs, particularly those serving diverse student populations, must examine both the content and pedagogy within courses and the structure by which students' learning is supported. More research of a long-term nature that qualitatively studies student success and learning experiences in developmental mathematics programs is needed.

# A CASE STUDY OF RESILIENCE BASED ON MATHEMATICS SELF-EFFICACY AND SOCIAL IDENTITY

Dedra Eatmon
North Carolina Agricultural & Technical State University
deatmon@ncat.edu

*Despite statistics showing African-American students' less than average mathematics performance), there exists a population of African-American students with records of mathematics achievement. This paper highlights one such student enrolled at a two-year residential high school in the Southeast. Her academic strategies and ideology were uncovered to determine their influence on her mathematical success. This analysis is part of a larger study highlighting the academic and social strategies of mathematically successful African-American students attending Caldwell Academy and factors contributing to that success and social balance, and how both contribute to resilience. The study also investigated the lack of enrollment in higher-level mathematics classes among eligible African-American students.*

## Purpose

African-American students have historically not performed as well mathematically as their White and Asian counterparts (http://nces.ed.gov, 2007). However, at specialized schools like the one in this study, students generally enter on a much more level academic playing field than in traditional high schools based largely on the acceptance criteria. At Caldwell Academy, a specialized residential high school, African-Americans were not enrolling in higher level advanced mathematics course for which they were eligible.

The study developed as the result of concerns that African-American students at Caldwell academy were not enrolling in higher-level mathematics courses, despite their academic eligibility. To uncover the reasons why students were not taking courses, it became necessary to determine how the students felt about their mathematical abilities, then identify the academic and social strategies they employed to be mathematically successful. Reasons for not taking the courses were shared by students during final stages of the study. Shared here is the portrait of one African-American student who attributed her mathematics success to her work ethic; her ideology – one indicative of inclusion and success – is also perceived to be directly related to her mathematics success.

## Theoretical Framework

Resilience theory serves as the primary framework for the study. While resilience theory outlines the interventions, protective mechanisms, and coping strategies employed by students to surmount obstacles (Nettles, 1993), academic resilience focuses on the latter two (Floyd, 1996; Lee, 1991; Steward, 1996). Both high-levels of mathematics self-efficacy and positive social identity can be factors contributing to the academic resilience of African-American students. Resilient students have been shown both to possess high levels of self-perceived ability (efficacy) and to rely on others in their social circles for guidance and support (Lee, 1991; Wade & Oskeola, 2002). Without both strategies, students are less able to employ the coping strategies necessary for resilience.

Self-efficacy and racial and social identity development are secondary frameworks. Race can be used to predict mathematics self-efficacy (O'Brien, Martinez-Ponz, & Kopala, 1999). That

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

self-efficacy, in turn, is strongly related to interest (and performance) in mathematics courses and STEM-based career fields. A high level of mathematics self-efficacy is the result of a student's belief in their own mathematics ability. It is generally perceived as task-specific (Hackett & Betz, 1989) and for the purposes of this study was addressed from a more general perspective in terms of mathematics courses which study participants believed they could take and successfully complete with a passing grade.

Positive social identity for African-American adolescents generally develops as they progress though the stages of *nigrescence,* as defined by Cross (1991). Cross' five stages include: pre-encounter, encounter, immersion/emersion, internalization, and commitment. The significance of race and how central it is to the identity of African-Americans can change during each stage of nigrescence. Race is not as significant during pre-encounter, but becomes much more so after on experiences some type of encounter that causes and African-American to become more aware of their race and how they are perceived by others based on race.

Though there is disagreement about the age at which encounter occurs, Tatum argues that it can occur as early as middle school (1997). During adolescence, African-Americans are thought to become more aware of their race as it pertains to mainstream society and in comparison (or contrast) to their peers. Encounter precipitates immersion/emersion where many adolescents become focused on race and associate strongly with Black culture to define them and prove their "Blackness." They also begin to negotiate between their sometimes contrasting school and home environments. In those situations, African-American adolescents may have one set of friends or peers in the classroom while they choose a social circle comprised of more African-American peers with whom they share experiences that are non-academic. In a residential high school, like Caldwell Academy, the students' school and home environments overlap and there may not be any distinction between those with whom they share academic and social experiences.

Internalization and commitment occur after one matures to allow incorporating the values and ideas of mainstream society without jeopardizing their racial identity. This occurs for many students in college after they are exposed to more opportunities to take African-American history classes and join Black organizations.

## Methodology

A qualitative study using phenomenological methods was used to capture the experiences of the study participants in their own words. Phenomenology allowed the researcher to use the students' experiences while inserting one's own understanding of the phenomenon to convey their experiences (Tesch, 1987).

The larger study was designed to determine what factors contributed to low African-American enrollment in higher-level mathematics courses at a specialized, residential, high school. The following research questions were posed to identify those factors:

1. How confident do African-American students feel about their ability to successfully complete mathematics courses?
2. What academic and social strategies do mathematically successful African-American students employ?
3. What type of shift occurs in the development of racial and social identity of African-American adolescents at a specialized, residential high school?

Caldwell Academy, the two-year residential school that served as the setting for the study, is a state-funded high school in the Southeastern United States. A member of the National Consortium of Specialized Secondary Schools of Science, Mathematics, and Technology, Caldwell Academy required a strong academic history and records of achievement from the applicants chosen to attend. Application to Caldwell is open to all state residents and students are chosen during the spring of their sophomore year to attend the school during their junior and senior years. The admissions process was based on academic records, teacher recommendations, standardized tests scores, student activities, and an essay. Student enrollment at the time of the study was over 600 students. At a state-funded institution Caldwell Academy maintains an enrollment goal that reflects that composition of the state population. At the time of the study, African-American population in the state was 21.6% while 71 of the students at Caldwell Academy were African-American (less than 12%).

Participants in the study were chosen by criteria sampling based on their eligibility to enroll in mathematics courses beyond Calculus. At Caldwell Academy, a mathematically successful student was one who earned a B- or higher in their Precalculus their junior year, as well as those who entered the school enrolled in Calculus or higher. This allowed the student met the prerequisites for mathematics courses that were considered more advanced and required a stronger mathematics foundation.

Each study participant completed a mathematics autobiography, racial identity assessment (developed by Sellers, etc.), and a semi-structured individual interview. Questions from the autobiography and select items from the interview addressed mathematics efficacy and academic strategies. Other interview items addressed the social strategies the students employed to remain successful at Caldwell Academy, including their social circles and support systems. The racial identity assessment was used as an added dimension to interpret students' reported strategies and responses to interview questions.

The mathematics autobiography was designed to help students identify when and how their confidence in their individual mathematical abilities developed. By responding to items such as "When did you first realize you were good at mathematics?" and "Who helped you value mathematics?" students reflected on their relationships with mathematics and the events contributing to their levels of mathematical self-efficacy. The mathematics autobiography also asked that they share a strong (positive or negative) mathematics memory and the mathematics teacher they considered to be their favorite.

The racial assessment used for the study was the Multidimensional Inventory of Black Identity (MIBI) developed by Sellers, Smith, Shelton, Rowley, and Chavous (1998). The MIBI is based on their Multidimensional Model of Racial Identity (MMRI) which creates a composite model of racial identity combining the universal properties of African-Americans with the specific qualitative nuances of individual African-Americans. Sellers, Smith, Shelton, Rowley, & Chavous identified four dimensions that collectively define African-Americans while acknowledging individual experiences. The four dimensions of the MMRI are salience, centrality, regard, and ideology. Salience, how aware a person is of their own racial identity, can be situation-specific and is considered less stable than the other three dimensions. The remaining dimensions, centrality, regard, and ideology serve as the subscales of the MIBI. Centrality measures how much race comes before other aspects in regard to an individual's sense of identity and self. How an individual feels about Black people and how they believe others perceive Black people, are personal and private regard, respectively. Ideology has four different categories to identify in which one would characterize their perspectives on African-American in America and where their priorities lie in relating to other African-Americans, minorities, American, and humans. The ideology subscales are not exclusive and many African-Americans demonstrate some form of each. The items from each subscale are presented in a 7-point Likert scale and are averaged to produce a unique profile of each participant.

The individual interviews were conducted after study participants completed the mathematics autobiography and the racial identity assessment. The items from the interview were a combination of those created during a pilot to address the students' academic and social strategies and other questions that were developed specifically for each participant as a result of the previous two instruments. Each student was asked to describe academic and social experiences at their home schools prior to attending Caldwell Academy, and then describe the same experiences after enrollment. The students were asked to about their perceived mathematics ability, effort, and performance at their home schools and at Caldwell Academy. They were also asked to describe the social circles they created at both schools.

## Findings

Jackie was one of 71 African-American students enrolled at the time of the study, with approximately 20 in the senior class. Her initial mathematics placement exam placed her in Precalculus. Because she completed Honors Precalculus at her home school Jackie requested to be re-tested. Based on her second score, she was enrolled in Calculus as a junior at Caldwell Academy. Enrolling in Calculus during her junior year meant Jackie could meet the mathematics graduation requirement by taking *any* mathematics courses during her senior year. She was the only student in the study enrolled in higher level mathematics courses.

Jackie's individual portrait highlighted her strong self-concept and diverse social circle. She credited her mother for her developed confidence in her mathematical abilities. According to Jackie, her mother helped her realize her mathematical talent, while her teachers were surprised. She was constantly and consistently encouraged by her mother, despite the fact that others doubted her academic ability. The constant encouragement helped her feel strongly about being re-tested. In describing her own perception of her mathematics ability in her autobiography, Jackie stated:

> I liked to learn anything when I was younger, math was an easier thing to learn because I soon realized that there were formulas and tricks. I never considered myself a "math person" but I knew I was good at it. I liked the cut and dry, right/wrong angle to math.

The MIBI revealed Jackie's unique experience as an African-American and could be used to add dimension to her responses to other assessment instruments. Her centrality was a bit higher than average for study participants, suggesting that being Black was important to her, but not the only thing that defined her. Jackie's private regard was higher than average, while her public regard was lower than average. Of the ideology subscales, Jackie scored highest as an assimilationist, suggesting that she believed in working within the mainstream American system to be most effective in changing it. Her ideology also explained her perspective on taking advantage of opportunities available.

Jackie revealed a multi-faceted definition of success during her interview. Although she perceived the majority of the students at Caldwell Academy to be focused primarily on academic endeavors, her interests varied and she believed that a student with few or no other activities should always be academically successful. In contrast to the academics-only model, Jackie embraced a definition of success based on involvement in activities outside of the classroom as well. She had interests that included athletics, music, and performing arts and chose to surround herself with others possessing similar interests.

Jackie perceived her academic ability to be as strong after attending Caldwell Academy as she did prior to enrollment. However, she acknowledged that she had to spend more time working to understand mathematics at Caldwell Academy and that her performance was not as great. She described spending down time during basketball practice working on Calculus and going to see her instructor much more than was necessary at her previous school. Jackie believed that work ethic could contribute to mathematical success just as much as natural ability. Although she was the only African-American student enrolled in her any higher-level mathematics class, not just her own, Jackie did not place emphasis on that. She was accustomed to that scenario and focused more on her work. She also shared that mathematics was easier at Caldwell Academy after she discarded the idea that mathematics came from formulas and began to demonstrate a more conceptual understanding of mathematics, as opposed to the procedural understanding to which she was accustomed.

Social identity was the aspect that Jackie believed suffered more from being African-American at Caldwell Academy than her academic identity. She believed it was because she didn't feel compelled to spend time and create relationships with other Black students based on race alone; she needed more core values and interests in common with those in her social circle. As a result, her social circle was very diverse, both prior to enrollment at Caldwell Academy and while enrolled. The foundations on which she based her relationships allowed her to rely on her friends to help her through both academic and social challenges. Academically, Jackie thought students at Caldwell Academy could take advantage of the available resources to further develop their academic and personal interests.

## Discussion

Jackie's resilience appeared to be the result of a high level of mathematics self-efficacy and support systems – both familial and social. Jackie was the only student in the study enrolled in a higher level mathematics course although she could have taken less advanced courses to meet her graduation requirements. She enrolled in the mathematics courses for the academic challenge and relied on her work ethic to help her complete the courses with a passing grade.

Jackie possessed a sense of her mathematics ability of which she became aware by a series of mathematics successes. It was also consistently fostered by her mother's consistent belief in her. Jackie's previous mathematics experiences, support systems and ideology contributed to her strong work ethic and ability to create diverse social circles. She was accustomed to being the minority and was not as affected by that as others in the study. She attributed her success to her work ethic and was determined to be successful by taking advantage of academic opportunities.

As the US population becomes more diverse and the workforce becomes more mathematically driven, mathematic success is necessary to enter students in the pipeline for Science, Technology, Engineering, and Mathematics (STEM) fields. It then becomes necessary to identify the factors contributing to academic resilience. Once identified, these factors can be used to create nurturing learning environments that recognize and incorporate the unique challenges and needs of minority students, particularly those that vary from mainstream culture. Using Jackie's experiences help create a template for improving African-American participation in advanced mathematics.

# THE INFLUENCE OF REACTANCE ON ELEMENTARY SCHOOL TEACHERS' WILLINGNESS TO CHANGE THEIR CLASSROOM PRACTICE

Candice L. Ridlon
University of Maryland Eastern Shore
cridlon@umes.edu

*The gap between teachers' perceptions of how they teach mathematics and their actual classroom practice has been well-documented. To understand this disparity, data was collected for three years on pre-service and in-service elementary school teachers. The Dowd Therapeutic Reactance Scale (TRS) was used to identify psychological reactance that may predispose teachers' willingness to change, thus influencing their efforts to incorporate reform strategies into their practice. Data analysis shows that teachers tend to be low in reactance, implying a greater desire to impress and to be socially appropriate. Scores indicate a low locus of self-control and a preference for high levels of professional advice and structured support.*

## Background and Perspectives

In 2000, the National Council of Teachers of Mathematics (NCTM) revised their standards for teaching mathematics. Over 95 percent of teachers in the U.S. claim to be aware of the these standards and 70 percent indicated, when questioned, that researchers would find proof of standards-based teaching in their classrooms. However, very little evidence of reform instruction has actually been found when teachers were observed (Stigler & Hiebert, 1999). Ma found that most practicing elementary teachers in the U.S. believed mathematics was "an arbitrary collection of facts and rules in which doing mathematics means following set procedures step-by-step to arrive at answers" (1999, p. 123). Thus when teachers engage in pre-service methods courses at the university or in professional development courses later in their career that focus on "understanding concepts," they often face uncomfortable confrontations with their existing attitudes as well as their own knowledge of mathematics.

*Factors Involved in Changing Teachers' Beliefs, Attitudes, and Classroom Practice*

Reconstructing beliefs is more complex than providing teachers with standards-based curricula and workshops on implementation of those standards. As Schifter and Fosnot (1993) point out, "... significant and enduring change in the way teachers teach cannot be induced by a course of lectures, a handful of workshops, or even books...no matter how informative or persuasive." Instead, teachers change more readily "in ecologically embedded settings of real classroom practices, real students, and real curricula - elements that teachers define as central to their profession" (Confrey, 2000, p. 100). Learning occurs when teachers are given the opportunity to reflect on and communicate about the mathematical thinking of their students (Franke et al., 2001; Margolinas et al., 2005). They must examine their beliefs about how children come to know mathematics and discover ways to teach given that information.

These issues are compounded by tensions that exist in school settings that actually sustain traditional teaching rather than supporting reform (Gregg, 1995). Furthermore, Remillard and Bryans (2004) found that a teacher's orientation towards a curriculum influences how he or she engages those materials in the classroom as much as the curriculum itself. As mathematics educators have already discovered, supplying standards-based materials does not necessarily translate into any discernable change in classroom practice. Since teachers' beliefs can either support or constrain their students' learning, mathematics teacher educators need to attend

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

carefully to teacher beliefs (Warfield et al, 2005). If the gap between teachers' perceptions of how they teach mathematics and their actual classroom practice is ever to be rectified, all of these obstacles must be overcome.

*The Influence of Reactance*

Any change in classroom practice is further complicated by a teacher's individual character traits. Research shows that personality factors such as psychological reactance, extroversion, anxiety, independence, and self-control affect an individual's ability to change (Bartram, 1995). The Theory of Psychological Reactance (Brehm, 1966; Brehm & Brehm, 1981) postulates that:

> Individuals possess "free behaviors" that can be engaged in at a moment or at some future time and that the motivational state of psychological reactance will be aroused whenever any of these free behaviors are eliminated or threatened with elimination. This motivational state will be directed toward the restoration of the eliminated or threatened behavior and will result in behavior known as reactance effects (Dowd, Milne, & Wise, 1991).

Psychological reactance theory offers a helpful framework for understanding oppositional behavior in individuals. For instance, therapy clients who are high in reactance - a "state of mind aroused by a threat to one's perceived legitimate freedom" (Brehm, 1966) - have low expectations for change and low therapy outcomes (Dowd & Wallbrown, 1993). Counselors who are high in reactance prefer unstructured supervision and greater degrees of professional freedom. In contrast, those counselors who are low in reactance were most extreme in their preference for structured supervision (Tracey, Ellickson, & Sherry, 1989). In another study, low-reactant patients reduced cigarette consumption more when they were provided with high amounts of physician advice. However, high-reactant patients perceived high amounts of physician advice as a threat, especially if that advice was negatively toned. For these patients, the best interaction was a low amount of negatively toned advice (Graybar et al., 1989).

Reactance potential, like other personality traits, may be higher in some individuals than it is in others (Brehm, 1966) and is believed to remain relatively stable over an individual's lifetime. And, as is often the case with other personality factors, there may be a correlation between reactance, career choice, and eventual success at an individual's chosen occupation.

Extrapolating from the psychotherapy literature to education, then, it is probable that teachers who are high in reactance might engage in oppositional behavior when confronted with requests to adapt reform strategies. They would view standards-based curricula and workshops as a threat to their autonomy and exhibit a decreased willingness to change classroom practice. Teachers who are low in reactance would feel less threatened by outside attempts to reform their teaching practice and be more willing to change. However, they would desire higher levels of advice and structured support from perceived authority. Although "research on the relationship between teachers' characteristics and teacher effectiveness as been underway for over a century" (Rockoff et al., 2008), little empirical research exists in the area of reactance, so this study explores teaching dynamics from the unique perspective of considering the social and emotional dimensions of teachers.

## Research Question

How does the psychological reactance of elementary school teacher influence their willingness to incorporate mathematics reform strategies in classroom practice?

## Participants, Methods, and Data Sources

From 2004 - 2007, data was collected on 191 pre-service and 65 in-service teachers. The pre-service teachers attended the same university and were in eleven cohort groups spread out over six semesters. The in-service teachers were employed at four different local elementary schools during this time frame. In one instance during the study, two of the pre-service teachers were hired and became in-service teachers at one of the schools.

Participants completed a personality measure called the Therapeutic Reactance Scale (TRS; Dowd, Milne, & Wise, 1991) which gives scores on psychological reactance. The TRS is a one-page, 28-item test using a 4-point Likert scale. Several of the items are reverse-keyed to eliminate any effect from acquiescence response sets. The instrument is based on normative data and has a very slightly positively skewed normal distribution. The usual mean is 67.78 and the median 67.75. The minimum and maximum attainable scores are 28 and 112, respectively. The TRS has an internal consistency ranging from .75 to .84. This clinical measure of reactance has been used in psychometric applications, such as counseling and human resource management, for more than a decade.

## Results

Descriptive statistics were calculated for each of the eleven pre-service and four in-service groups separately. ANOVA: Single Factor was performed on all possible combinations, taken two at a time, to yield a simple analysis of variance on data for the samples. This analysis tested the hypothesis that each sample was drawn from the same underlying probability distribution against the alternative hypothesis that the underlying probability distributions were not the same for all samples. In each instance, the $p > 0.90$, which did not lend sufficient support to reject the null hypothesis. In other words, the groups were sufficiently similar that they likely represented the same population.

The data from all teachers was then combined into “composite” pre-service and in-service scores, yielding means of 62.43 and 61.99 respectively (see Table 1.) Another ANOVA was performed on the composite scores, producing a $p = 0.909$. This confirmed that the null hypothesis should not be rejected: teachers, regardless of teaching experience, had relatively similar scores and thus represented similar populations. Interestingly, performing ANOVA against the “normal” TRS scores yielded a $p < 0.05$, showing that elementary teachers’ scores did differ significantly from usual scores used to normalize the TRS. In this case, the alternate hypothesis would be supported: Teachers had significantly lower scores in psychological reactance than the general population.

A t-Test (two-sample assuming unequal variances) was also performed (see Table 1). This t-test form assumed that the two data sets came from distributions with unequal variances (a heteroscedastic t-test) since descriptive statistics had exhibited this disparity. Results from this analysis supported the ANOVA results. They indicated that the two samples were likely to have come from distributions with equal population means.

Table 1. *T-test: Two-sample Assuming Unequal Variances*

| | Pre-service | In-Service |
|---|---|---|
| Mean | 62.43455497 | 61.99230769 |
| Variance | 45.2338523 | 62.23040865 |
| Observations | 191 | 65 |
| Hypoth Mean Difference | 0.5 | |
| Df | 98 | |
| t Stat | -0.052848266 | |
| P(T<=t) one-tail | 0.478980192 | |
| t Critical one-tail | 1.660551218 | |
| P(T<=t) two-tail | 0.957960383 | |
| t Critical two-tail | 1.984467404 | |

Graphing the data from the two groups provided some interesting results (see Figures 1 and 2). A class width of 3.4 was chosen to display TRS scores, which ranged from 44.5 to 78. In both instances, the data was bi-modal. One mode was near TRS's normative central tendency measures (mean 67.78 and median 67.75). However, there was a second mode at a lower reactance score (54.8 to 58) for both sets of teachers. This less-reactant mode accounted for the shift to an overall lower mean and median reactance score.

**Figure 2: In-Service Teacher Reactance**

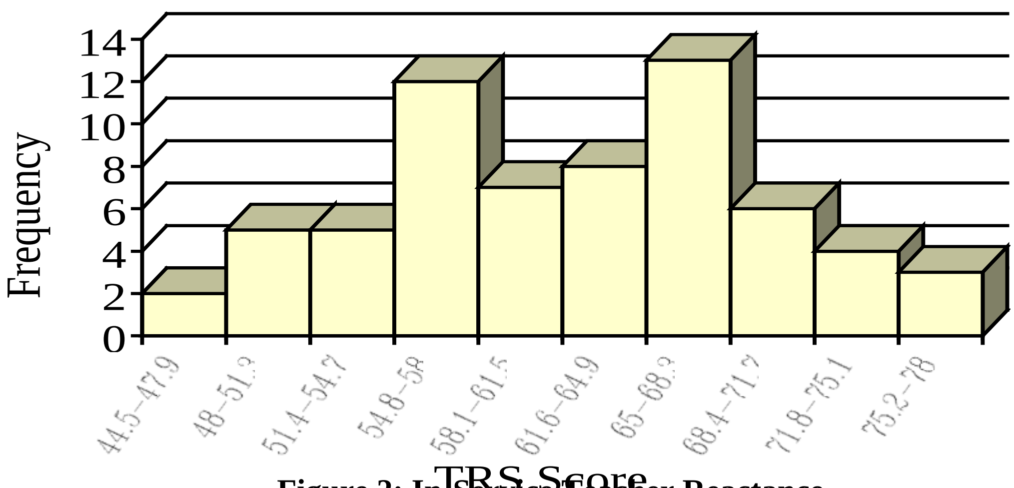

**Figure 2: In-Service Teacher Reactance**

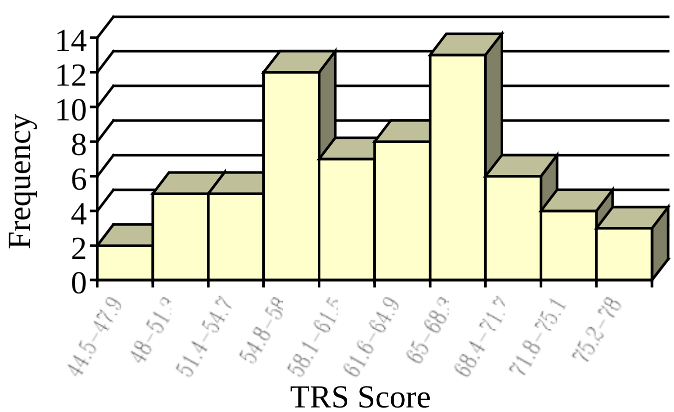

## Discussion

The gap between teachers' perceptions of how they teach and their actual classroom practice has been studied from a variety of perspectives. This mismatch of belief and behavior appears to exist at several levels. For instance, Schussler, Bercaw, and Stocksberry (2008) found that an inverse relationship exists between teacher awareness and assumptions. In research focusing on the moral disposition of teachers, Johnson (2008) found an inconsistency between teacher candidates' quantitative assessments (tests) and qualitative data (contextual written assignments), suggesting that teachers had an inaccurate picture of their own beliefs and how they put those beliefs into action. When Singh and Stoloff (2008) examined teacher dispositions, they discovered that teachers gave lip service to research based instructional strategies, but needed to reshape their behavior in order to actually engage in those practices. Perhaps matching perception to actual behavior is a common human dilemma; certainly teachers are not exempt from exhibiting this disparity.

The analysis of TRS data yielded some interesting findings. First, the mean reactance value for teachers is low, whatever their career stage. In fact, as a group, elementary school teachers are significantly lower in reactance than the general population. It is interesting to speculate that certain personality types may be drawn (and perhaps better suited) to particular careers. Decades of research in vocational studies would certainly give both theoretical and empirical support for that hypothesis, as the goal of vocational counseling is to match the client with a vocation in which he will be both satisfied and satisfactory (Botterbusch, 1978; Ehrhart & Makransky, 2007; Whitehead, 2005).

The bimodal nature of TRS scores suggest that one group of teachers is about average in reactance, but many more individuals than expected from the general population tend to fall below the normative level. In fact, the second mode indicates a large proportion of teachers are grouped around an unusually low reactance value. Teachers with these low TRS scores are unlikely to feel threatened by reform strategies. Because reactance is a personality trait that remains fairly constant over time, it is not surprising to note that pre-service and in-service teachers exhibit the same distributions. (After all, the ANOVA and t-Test indicated that the two samples were likely to have come from distributions with equal population means.)

Research evidence has suggested that reactance potential may mediate compliance with behavioral tasks. Brehm and Brehm (1966) found that the tendency to resist overt influence is positively correlated with internal locus of control. Thus, individuals with Type A personality may possess a lower threshold of threat for arousal of reactance than Type B personalities (Dowd, Milne, & Wise, 1991). What does this mean in terms of low reactant elementary school teachers? It means that teachers have a lesser tendency to resist influence - correlated with a low locus of control - and demonstrate more expectation of changing their behavior (Rohrbaugh et al., 1981). Also, low-reactant people become significantly less anxious than high-reactant individuals when confronted with pressures from the "outside" (Dowd, Milne, & Wise, 1991). Low reactance could be a distinct advantage in a profession that requires its workers to incorporate an ever-changing landscape of external demands levied by administrators, parents, politicians, and mathematics educators.

Low reactance is also related to a greater desire to impress others and to be socially appropriate (Dowd, Milne, & Wise, 1991). As teachers work in the public arena (regardless of whether they are employed in a public or private school), this desire might actually increase their willingness to change teaching practice if modifications are perceived as socially acceptable. Teacher preparation and development courses would therefore be more effective at changing classroom practice if teachers worked in communities of respected peers, and if they experienced support, acceptance, and positive reinforcement from administrators and persons of recognized social authority.

A final implication of low reactance is closely related to the desire to be socially acceptable. Research has shown low-reactant individuals change their behavior more readily with high levels of professional advice, and they are more extreme in their preference for structured support (Dowd, Milne, & Wise, 1991; Tracey, Ellickson, & Sherry, 1989). Elementary school teachers' low reactance would thus indicate the desire for perceived "experts" to design highly structured methods and professional development courses. Mathematics educators, mathematics specialists, and others with professional expertise must be available to answer questions and provide supportive counsel on a regular basis. Contrary to oppositional behavior, low-reactant individuals like elementary school teachers want suggestions from more experienced leaders because they value such guidance when trying to implement a change in their own behavior.

Any discussion of the use of psychological measures (such as reactance testing) in educational settings should include some attention to ethical concerns. Without question, tests that have been used successfully for clinical diagnosis and to reveal psychopathology are best administered by a clinician with specialized training in their interpretation. One must also consider the potential implications of using clinical tests and the relevance of personality constructs and their validity if the results of these tests are directed at pre-employment screening or post-employment evaluation. Camara and Merenda (2000) suggest that the fear of litigation resulting from testing that is used in an exclusionary manner (such as for pre-employment screening) may be the primary disincentive for using personality tests inappropriately. Even "psychologists are increasingly on 'thin ice' in using clinical instruments to make high stakes decisions in employment settings" (Camara & Merenda, 2000, p. 1183). However, these ethical constraints play little or no role in this study. A licensed clinical psychologist is involved in the research. The TRS was only used to identify psychological reactance that may predispose teachers' willingness to change in order to suggest more effective strategies for delivering mathematics education courses to teachers.

However, reactance scores by themselves contribute only one small piece to the complex jigsaw puzzle of designing effective teacher education courses. Additional data associated with this study is currently under analysis to examine the interplay of reactance with other personality traits, while tracking the change in classroom practice that is anticipated from standards-based instruction. Participants took a second personality measure called the 16PF Questionnaire (Cattell, Cattell, & Cattell, 1993). The 16PF is a 185 item self-report which measures normal adult personality dimensions (i.e. extraversion, anxiety, tough-mindedness, independence). In addition, teachers in this study have been involved in either a university mathematics methods course or a school-wide two-year long biweekly professional development (PD) course (or both, as was the case for two of the pre-service teachers who were hired by the participating school districts). These courses have been aimed at instruction in NCTM reform beliefs and practice.

To measure beliefs and attitudes about teaching mathematics, each participant took the Integrating Mathematics and Pedagogy Beliefs Survey (IMAP, Philipp, 2002). This belief-assessment instrument is a web-based, in-context survey using video clips that allow respondents to interpret and react to student actions in well-defined situations. Participants took the IMAP twice - at the beginning and end of their coursework – thus data has been collected to examine any change or beliefs or attitudes that might likely have occurred due to the reform-based instruction.

To document change in classroom practice (perceived or actual), in-service teachers completed self-assessments to rate their own progress at reforming their teaching practices. In addition, an outside evaluator made formal observations of each teacher's classroom practice during regular mathematics lessons twice a year. The collaborative lessons associated with both the methods and the PD courses were formally observed. Pre-service and in-service teachers' reflective journals were collected. Qualitative data from self-assessments, observations, and teacher writings is being coded for emergent themes and trends. The findings and correlates from these analyses will be reported and should give a more accurate picture of the dynamics of personality and willingness/ability to change classroom practice.

## Use of Results Related to PME-NA Goals

Because teachers are individuals, they respond to training differently. Research needs to identify these differences and make suggestions for adapting methods and professional development courses to meet teacher needs. This study hopes to gain a deeper understanding of the influence of psychological reactance that may predispose teachers' willingness to change, thus influencing their efforts to incorporate reform strategies into classroom practice. These findings meet the goal of embracing the diverse perspectives of teachers in order to benefit the children they teach.

# TAKING A CLOSER LOOK AT PRACTICE AND PARTICIPATION: TEACHER INTERACTIONS AND ENGAGEMENT IN AN URBAN MIDDLE SCHOOL MATHEMATICS CLASSROOM

Lou Pedrick
Plainfield Public Schools
Plainfield, New Jersey
loupedrick@gmail.com

Alice Alston
Rutgers University
New Brunswick, New Jersey
Alston@rci.rutgers.edu

*From the detailed analysis of videotapes in an urban middle school classroom taken as part of a larger study, we provide interpretation of the notion of an "emotionally safe environment." This "teacher research" project looks at proposed ways of describing a complex behavioral, social, and affective environment that can enhance or hinder students' motivation to engage mathematically. The analysis presented here focuses on three categories: reframing frustration and impasse; reframing the mathematical problem solving process; and maintaining high cognitive demand and motivational potential in the selection and implementation of mathematical problems.*

## Background and Theoretical Framework

This analysis investigates features of a classroom that are perceived to promote an emotionally safe environment for student exploration of conceptually challenging mathematics. The research reported here is part of a larger study investigating the occurrence and development of powerful affect around conceptually challenging mathematics. Its focus is on urban middle school classrooms serving low-income students primarily of African American, Latino, and Caribbean descent. The class is one of three urban, middle school mathematics classes (in two different districts), that were studied in depth over the course of a school year, starting in September and ending in late May. The teachers were selected based on evidence of strong mathematics teaching skill, research interest, and their likely ability to elicit powerful affect around conceptually challenging mathematics. Data were collected during five cycles of twenty visits. For each cycle, data included videotapes of two consecutive lessons, pre- and post-interviews with the teacher, and videotaped stimulated-recall interviews with four focus students. Three cameras were used for each class session: two following the focus students, and the third stationary camera capturing an overall view of the class. Additional data included students' written work, observers' field notes and earlier analysis (Alston *et al*., 2007; Alston *et al*., 2008). The classroom teacher joined the research team subsequent to the school year and is participating in the analysis; he is the first author of the present report.

Teachers face the general problem of how to create effective learning environments in mathematics, and the specific problem of how to interact most effectively with students engaged in conceptually challenging mathematical activity. Current literature suggests the value of attending to issues of affect, context, social interactions, race, and culture in helping students gain confidence, motivation, and improving performance (Ball & Bass, 2003; Cobb & Yackel, 1998, Goldin, Epstein, & Schorr, 2007, Goldin, 2000a, 2000b; Martin, 2000; Moschkovich, 2002; Stigler & Hiebert, 1998). As students and teachers engage in conceptually challenging mathematics, a variety of emotional feelings occur that may influence instruction, motivation, and learning. These issues have immediate implications for learners in the mathematics classroom. Existing mathematics education research highlights the reciprocal relationship

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

between teacher actions and student behaviors--actions and behaviors that, in turn, appear to contribute to an interactive classroom environment where students are engaging with conceptually challenging mathematics (e.g., Carpenter, & Lehrer, 1999; Kaput, 1999; Martino, & Maher, 1999; Schorr, Warner, Gearhart, & Samuels, 2007; Stein, M. K., Smith, M. S., Henningsen, M. A., & Silver, E. A., 2000; Warner, Schorr, Arias & Sanchez, in press). In taking this stance the role of the teacher needs to be carefully considered when it comes to students engaging in exploring conceptually challenging mathematics and valuing their mathematical thinking as they construct, reason, and justify their solutions (Hiebert *et. al.,* 1997).

Conceptually challenging mathematics is defined as mathematical content that requires some development of new concepts or changes in existing ones (Schorr, & Goldin, 2008), thus making it cognitively demanding. This frequently involves figuring something out within a problem situation in a "relational" manner (Skemp, 1976). Classroom social interactions around such mathematics may include students presenting ideas that are challenged publicly by their peers. Problem-solving efforts are likely to evoke discussions, explorations, and challenges to individuals' thinking. Some students' conjectures may turn out to be incorrect while the teacher or the class accepts others. Valid conjectures may at times be rejected as well. Students may lose track of underlying mathematical concepts as they bring personal details to the situation and experience impasse (Schoenfeld, 1992).

An emotionally safe environment for exploring conceptually challenging mathematics is defined as one where students' ideas and solutions are valued. Students are encouraged to share ideas. Mistakes are not criticized but transformed into opportunities for learning. Argumentation, reasoning, and proof are seen as part of the process in working out mathematical ideas (Ecceles, & Midgley, 1989; Goldin, Epstein, & Schorr, 2007; Maher, 1998; Maher, Davis, & Alston, 1991a; Schorr & Goldin, 2008, Yackel & Cobb, 1996).

The affective domain refers to emotional feelings, attitudes, beliefs, and values in relation to mathematics (DeBellis & Goldin, 2006; Evans, 2000; Evans, Morgan, & Tsatsaroni, 2006; Malmivuori, 2001; McLeod, 1994; Phillip, 2007). Powerful affect refers to those patterns of affect and behavior that lead to interest, engagement, persistence, and mathematical success. It is not restricted to positive emotions, such as curiosity, pleasure, and satisfaction, but includes the effective management and uses of feelings such as bewilderment and frustration (Epstein, Goldin, & Schorr, 2007; Goldin, 2000a,b; Gomez-Chacon, 2000a,b; Hannula, 2002; Malmivuori, 2006; Schorr & Goldin, 2008). The conjecture of several of the researchers cited above is that powerful affect in relation to conceptually challenging mathematics is fundamental to developing mathematical ability and essential to present and future mathematical achievement.

## Research Questions and Methods

This report will focus on the following qualitative research question: What teacher interactions foster engagement during exploration of conceptually challenging mathematics?

This analysis focuses on data from class sessions with students during the second cycle. The lesson was based on the unit project from "Stretching and Shrinking," a unit of *Connected Mathematics 2* (Lappan et. al., 2006). The activity began the night before when for homework students were instructed to bring in either a hand drawn picture or print out of their favorite cartoon character or television/music celebrity of their choice. The students were to enlarge their figures after applying them to a grid, plotting the points that would recreate their character, and apply a rule to the coordinates to enlarge them by a scale factor of at least four. This investigation continues for three more class periods of which analysis is ongoing.

With input from colleagues (Epstein et. al., 2008) involved with the larger study emerged some examples for exploring features of a classroom that promotes an emotionally safe environment for student exploration of conceptually challenging mathematics. The following abbreviated list builds from this collaboration with a focus on teacher strategies that foster engagement: 1) Reframing frustration and impasse (RFI); 2) Reframing the mathematical problem solving process (RP); and 3) Maintaining high cognitive demand and motivational potential in the selection and implementation of mathematical problems (HCD). At this early stage in analysis, we make no claim regarding the reliability of coding. The categories are preliminary and conjectural, though intended to lay the groundwork for future work.

## Results

The students were working in small groups attempting to take their figure from its original state to a scale factor at least four times larger than the original. The initial goal was a bit confusing and the teacher reframed impasse (RFI) by having some students simplify their character to a boxier version to convert to the coordinate grid system and to enlarge their figure by applying a rule to the coordinates. He also had students trace their figure on a transparency to enlarge using an overhead projector and compare a sampling of measurements from the original to the enlargement to determine the scale factor (RP). The teacher also encourages another student to stay course with the original plan because he believed the student would have success (HCD). In the tables that follow are examples of reframing frustration and impasse (RFI), reframing the mathematical problem solving process (RP), and maintaining high cognitive demand and motivational potential in the selection and implementation of mathematical problems (HCD).

Mari (M) wanted to work with a television wrestler named Batista. The teacher suggested she make a championship belt with the wrester’s name in the middle. This provided an opportunity for the student to stay engaged while she plotted points for her belt that kept in line with the mathematical goals of the lesson.

| | | | |
|---|---|---|---|
| 22:43 | Mr. P | Just to stay simple I would make little lines but I would do like a um like that. You could write the name in between and go, some thing like that, you happy with that? | RP |
| 23:09 | M | Uh huh (smiling) | |
| 23:10 | Mr. P | So something like that, so put it on there | |
| 23:11 | M | So can I do that and then put it on the other | |
| 23:12 | Mr. P | And then you would make sure that you’re able to put his name, you’re going to have to make block letters like this, making them curve might be rough but you’re if you want to make a B it might look like this (teacher draws boxy B) | |

Mari comes back at a later point to get assistance with the writing of the letters in block form to put on the coordinate grid.

| | | | |
|---|---|---|---|
| 41:52 | M | Can I just write them in? | |
| 41:53 | Mr. P | Yes, but you want them to know um can I see your pencil? Okay so B, like you did okay, A that one’s actually pretty easy A right? ‘cause you just need, you might need 3 points here to make that curve. You might need to start back on the belt and across, you understand? And the S you’re gonna have to | RFI |

| | | | |
|---|---|---|---|
| | | make one of these kind of S's. I is just right? | |
| 42:52 | M | Yeah and then there's a T and another A. | |
| 42:56 | Mr. P | Okay so i'll just do that part. You're gonna need to do the points in the middle right? You're gonna have to tell me where these points are but you know you got your lines here, that's fine, yeah I think this will work out good. | |
| 43:21 | M | And now I gotta put it on the bigger paper? | |
| 43:23 | Mr. P | Well now the goal, yeah, now the goal is to tell me where all these coordinates are. Do you know where all these points are? | HCD |
| 43:31 | M | Oh like if it's 1 and 15 and something like that | |
| 43:34 | Mr. P | Yes and then, and then we want to apply a formula to it or a rule | HCD |

Petri (P) had spent a good portion of the period trying to find a character and apply it to the grid. Her group was trying to explain to her that she could make Stewie from the television show "Family Guy" into a diamond to be able to graph it easier. Petri didn't understand and became frustrated. Tyanna (T) also comes to the teacher to try and get some help. Mr. P suggests to her to put her character on a transparency and use the overhead projector to enlarge the figure. He also sees Petri is frustrated and suggest she do the same.

| | | | |
|---|---|---|---|
| 48:49 | E | Mines was easier. | |
| 48:52 | P | You could just make a box. | |
| 48:56 | R | I should make a football. | |
| 49:00 | E | Make a big diamond. | |
| 49:03 | R | Yeah a big diamond head | |
| 49:04 | P | What character is a big diamond head? | |
| 49:06 | R | Stewie, it's a football head but it's diamond | |
| 49:10 | G | Oh yeah you just do it like that, yeah look | |
| 49:16 | P | What ya'll talking about? | |
| 49:17 | R | You see this look, um cube forms like that. It's a diamond. | |
| 49:23 | P | You guys are strange. You're saying make his head a diamond. It's gonna be ugly (laughs) | |
| 49:33 | G | You don't even know how to draw a diamond. Oh my god. | |
| 49:38 | P | Ah ya'll aggravating. | |
| 49:52 | E | My dog has small hands. This dog. (Q comes to table) | |
| 49:57 | R | What? | |
| 49:59 | Q | Where? | |
| 50:00 | R | Diamond head. | |
| 50:03 | P | I don't got no diamond head | |
| 50:04 | R | Oh yeah that's the same one as yours. | |
| 50:10 | P | I'm gonna make a box with some ears. | |
| 50:17 | Q | She in my seat, I don't know why she in my seat. Are you the one they supposed to record? | |
| 50:22 | P | Shut up Q, you're retarded | |
| 50:25 | Q | No I'm not. get up. | |
| 50:49 | E | Ha ha look at my dog. | |
| 50:53 | R | He's hungry | |
| 50:55 | Mr. P | Are you getting frustrated? | RFI |
| 50:57 | T | Uh ha | |

| | | | |
|---|---|---|---|
| 50:58 | Mr. P | Draw him on the plastic paper and then you can enlarge him and you can find the scale factor from using the ruler instead of all the coordinates. Does that sound like something you'd rather do? | RP, HCD |
| 51:08 | T | Um hm. I need a marker | |
| 51:10 | Mr. P | Take one, use a permanent marker. I don't…I don't have the other ones | |
| 51:19 | P | Mr. P, I'm fed up! | |
| 51:21 | Mr. P | Yes? You're fed up too | RFI |
| 51:23 | P | Yes I'm just gonna draw something | |
| 51:24 | Mr. P | Okay you can either, the option is to use either boxes. Glenda did you make that printout at home? Good job. | |
| 51:32 | P | Okay this right here. | |
| 51:36 | Mr. P | What? | |
| 51:38 | E | I made a new one but it's smaller | |
| 51:40 | Mr. P | Okay | |
| 51:43 | P | Can I make a crown or something? | |
| 51:45 | Mr. P | You could do a crown or who was your original person? Stewie? | RFI |
| 51:48 | P | Yes | |
| 51:50 | Mr. P | Some of you - some of you that are getting frustrated | RFI |
| 51:52 | R | I don't k now how to do this square thing. It's not that, I can do it but it's too many dots. Stewie's easy. Not the square thing. You know how to do the square? | |
| 52:09 | Mr. P | After you get it on a large piece of paper then we'll have to use measurement to find the scale factor | RP, HCD |
| 52:11 | P | Okay | |
| 52:14 | Mr. P | 'Cause I don't want you to get too frustrated here. | RFI |

Ryan (R) who is an excellent artist was plugging along and trying to apply his talent to this mathematical situation. He approaches the teacher to see how he is progressing.

| | | | |
|---|---|---|---|
| 43:52 | R | What number do I got to go up to? | |
| 43:56 | Mr. P | Yours is very detailed. You're gonna need a lot of points. Um that's fine if you stop there. | HCD |
| 44:01 | M | Who is that - Sponge Bob? | |
| 44:03 | R | Yeah, that's Sponge Bob. | |
| 44:05 | Mr. P | Um the only thing, this is the only thing, I don't want you to start over Bryant but one of the things, and I didn't do a good job explaining it. If you're gonna make Sponge Bob think about him more | RFI, HCD |
| 44:25 | R | Cubed? More easier? | |
| 44:26 | Mr. P | I'm not saying you have to do it over but um it might make your enlargement easier too. Here I'm having trouble drawing it, let me see him again how is he? He's wide on, so yeah so you need right? Is that it? Something like this and then for his eyes you might want to make them uh | RFI, HCD |
| 45:04 | R | Hexagon | |
| 45:06 | Mr. P | Yeah because see how the sharp edges you can put on the lines easier. I think yours is very detailed and beautiful but it might be hard to make a bigger one. All right? Because these are a lot of points to identify so either you can go ahead with this one or try and just make him, and then if you want to do your X's in the middle like you have, you can be able to do you know what I'm saying like if you want to keep with that theme with the | RFI, HCD |

| | | | |
|---|---|---|---|
| | | Jamaican flag is that what it is or Dominican? | |
| 45:37 | R | Dominican | |
| 45:38 | Mr. P | Dominican flag in the middle then you can still do that and then when you make his nose, you're gonna make it square like this | |
| 45:53 | R | 'Cause if I stick with this I don't know what number to go up to. | |
| 45:56 | Mr. P | You would have to go up really far, you would need a lot more points right? Well you don't really need that many, you can go as high as you want but you can keep going with this theme, I don't see any problem with it, you can tell who it is. 'Cause you've done, you've done some boxy shapes on the sides, you just now need to identify the points. So like where is that point? | RFI |
| 46:22 | R | Like at 8, 3? | |

A bit later after a few students were encouraged to use another method due to being frustrated by the first method but Mr. P encourages Ryan to continue using his original method.

| | | | |
|---|---|---|---|
| 53:04 | Mr. P | No no you don't have to do it on other paper. If you're doing that method, there's a somewhat different method and if I'm I'm pushing first for you to graph the points and make your thing because we want a library of good characters for the next group of kids so that we don't just have to use the wumps. Right? | HCD |
| 53:26 | R | Yeah so this is a good character? | |
| 53:27 | Mr. P | Yeah so if you're not too flustered, just keep pushing on. Okay? | HCD |
| 53:32 | R | I'm a do the coordinates in this picture | |
| 53:33 | Mr. P | Yeah I think you're doing fine Ryan, you can handle it. | HCD |

## Conclusions and Implications

This analysis documents the value of students' bringing personal interests to mathematical concepts. The task itself brings interest to scaling figures larger or smaller with some reframing by the teacher. During this lesson the mathematical goal of scale factor seemed to move to the background while students focused on creating the likeness of their character. Despite the students' struggles transforming their characters during the lesson, the agency and personalization that students exhibited are valuable and need to be navigated with care as to not disengage them. Furthermore these findings hope to shed light on the time, consideration, and decisions it takes to engage learners from a perspective that involves motivation and affect during the course of a lesson. Reframing problems, frustration, and impasse while maintaining high cognitive demand are relevant issues in mathematics education and need to be highly considered when choosing tasks and engaging learners. Teachers try to understand the mathematical strategies and representations a student might use in solving a particular problem. If we can understand and represent teacher interactions and student behaviors that enhance or impede emotional safety and mathematical engagement, it could be useful for creating other environments that encourage students to make mathematical meaning for themselves. Being the voice of the teacher in the classroom where the data were collected enhances the qualitative research paradigm by allowing for exploration of the unique features surrounding these particular cases and perhaps arriving at what Paul Ernest describes as the, "truth derived from identification with, and living through, a story with the richness and complex interrelationships of social, and human life" (Ernest 1994, p. 34). By adopting this perspective the present research affords an opportunity to understand the situation in a way that may be valuable to other practitioners facing similar challenges.

## Endnote

Alston@rci.rutgers.edu

*From the detailed analysis of videotapes in an urban middle school classroom taken as part of a larger study, we provide interpretation of the notion of an "emotionally safe environment." This "teacher research" project looks at proposed ways of describing a complex behavioral, social, and affective environment that can enhance or hinder students' motivation to engage mathematically. The analysis presented here focuses on three categories: reframing frustration and impasse; reframing the mathematical problem solving process; and maintaining high cognitive demand and motivational potential in the selection and implementation of mathematical problems.*

## Background and Theoretical Framework

This analysis investigates features of a classroom that are perceived to promote an emotionally safe environment for student exploration of conceptually challenging mathematics. The research reported here is part of a larger study investigating the occurrence and development of powerful affect around conceptually challenging mathematics. Its focus is on urban middle school classrooms serving low-income students primarily of African American, Latino, and Caribbean descent. The class is one of three urban, middle school mathematics classes (in two different districts), that were studied in depth over the course of a school year, starting in September and ending in late May. The teachers were selected based on evidence of strong mathematics teaching skill, research interest, and their likely ability to elicit powerful affect around conceptually challenging mathematics. Data were collected during five cycles of twenty visits. For each cycle, data included videotapes of two consecutive lessons, pre- and post-interviews with the teacher, and videotaped stimulated-recall interviews with four focus students. Three cameras were used for each class session: two following the focus students, and the third stationary camera capturing an overall view of the class. Additional data included students' written work, observers' field notes and earlier analysis (Alston *et al*., 2007; Alston *et al*., 2008). The classroom teacher joined the research team subsequent to the school year and is participating in the analysis; he is the first author of the present report.

Teachers face the general problem of how to create effective learning environments in mathematics, and the specific problem of how to interact most effectively with students engaged in conceptually challenging mathematical activity. Current literature suggests the value of attending to issues of affect, context, social interactions, race, and culture in helping students gain confidence, motivation, and improving performance (Ball & Bass, 2003; Cobb & Yackel, 1998, Goldin, Epstein, & Schorr, 2007, Goldin, 2000a, 2000b; Martin, 2000; Moschkovich, 2002; Stigler & Hiebert, 1998). As students and teachers engage in conceptually challenging mathematics, a variety of emotional feelings occur that may influence instruction, motivation, and learning. These issues have immediate implications for learners in the mathematics classroom. Existing mathematics education research highlights the reciprocal relationship between teacher actions and student behaviors--actions and behaviors that, in turn, appear to contribute to an interactive classroom environment where students are engaging with conceptually challenging mathematics (e.g., Carpenter, & Lehrer, 1999; Kaput, 1999; Martino, & Maher, 1999; Schorr, Warner, Gearhart, & Samuels, 2007; Stein, M. K., Smith, M. S., Henningsen, M. A., & Silver, E. A., 2000; Warner, Schorr, Arias & Sanchez, in press). In taking this stance the role of the teacher needs to be carefully considered when it comes to students engaging in exploring conceptually challenging mathematics and valuing their mathematical thinking as they construct, reason, and justify their solutions (Hiebert *et. al.,* 1997).

Conceptually challenging mathematics is defined as mathematical content that requires some development of new concepts or changes in existing ones (Schorr, & Goldin, 2008), thus making it cognitively demanding. This frequently involves figuring something out within a problem situation in a "relational" manner (Skemp, 1976). Classroom social interactions around such mathematics may include students presenting ideas that are challenged publicly by their peers. Problem-solving efforts are likely to evoke discussions, explorations, and challenges to individuals' thinking. Some students' conjectures may turn out to be incorrect while the teacher or the class accepts others. Valid conjectures may at times be rejected as well. Students may lose track of underlying mathematical concepts as they bring personal details to the situation and experience impasse (Schoenfeld, 1992).

An emotionally safe environment for exploring conceptually challenging mathematics is defined as one where students' ideas and solutions are valued. Students are encouraged to share ideas. Mistakes are not criticized but transformed into opportunities for learning. Argumentation, reasoning, and proof are seen as part of the process in working out mathematical ideas (Ecceles, & Midgley, 1989; Goldin, Epstein, & Schorr, 2007; Maher, 1998; Maher, Davis, & Alston, 1991a; Schorr & Goldin, 2008, Yackel & Cobb, 1996).

The affective domain refers to emotional feelings, attitudes, beliefs, and values in relation to mathematics (DeBellis & Goldin, 2006; Evans, 2000; Evans, Morgan, & Tsatsaroni, 2006; Malmivuori, 2001; McLeod, 1994; Phillip, 2007). Powerful affect refers to those patterns of affect and behavior that lead to interest, engagement, persistence, and mathematical success. It is not restricted to positive emotions, such as curiosity, pleasure, and satisfaction, but includes the effective management and uses of feelings such as bewilderment and frustration (Epstein, Goldin, & Schorr, 2007; Goldin, 2000a,b; Gomez-Chacon, 2000a,b; Hannula, 2002; Malmivuori, 2006; Schorr & Goldin, 2008). The conjecture of several of the researchers cited above is that powerful affect in relation to conceptually challenging mathematics is fundamental to developing mathematical ability and essential to present and future mathematical achievement.

## Research Questions and Methods

This report will focus on the following qualitative research question: What teacher interactions foster engagement during exploration of conceptually challenging mathematics?

This analysis focuses on data from class sessions with students during the second cycle. The lesson was based on the unit project from "Stretching and Shrinking," a unit of *Connected Mathematics 2* (Lappan et. al., 2006). The activity began the night before when for homework students were instructed to bring in either a hand drawn picture or print out of their favorite cartoon character or television/music celebrity of their choice. The students were to enlarge their figures after applying them to a grid, plotting the points that would recreate their character, and apply a rule to the coordinates to enlarge them by a scale factor of at least four. This investigation continues for three more class periods of which analysis is ongoing.

With input from colleagues (Epstein et. al., 2008) involved with the larger study emerged some examples for exploring features of a classroom that promotes an emotionally safe environment for student exploration of conceptually challenging mathematics. The following abbreviated list builds from this collaboration with a focus on teacher strategies that foster engagement: 1) Reframing frustration and impasse (RFI); 2) Reframing the mathematical problem solving process (RP); and 3) Maintaining high cognitive demand and motivational potential in the selection and implementation of mathematical problems (HCD). At this early stage in analysis, we make no claim regarding the reliability of coding. The categories are preliminary and conjectural, though intended to lay the groundwork for future work.

## Results

The students were working in small groups attempting to take their figure from its original state to a scale factor at least four times larger than the original. The initial goal was a bit confusing and the teacher reframed impasse (RFI) by having some students simplify their character to a boxier version to convert to the coordinate grid system and to enlarge their figure by applying a rule to the coordinates. He also had students trace their figure on a transparency to enlarge using an overhead projector and compare a sampling of measurements from the original to the enlargement to determine the scale factor (RP). The teacher also encourages another student to stay course with the original plan because he believed the student would have success (HCD). In the tables that follow are examples of reframing frustration and impasse (RFI), reframing the mathematical problem solving process (RP), and maintaining high cognitive demand and motivational potential in the selection and implementation of mathematical problems (HCD).

Mari (M) wanted to work with a television wrestler named Batista. The teacher suggested she make a championship belt with the wrester’s name in the middle. This provided an opportunity for the student to stay engaged while she plotted points for her belt that kept in line with the mathematical goals of the lesson.

| | | | |
|---|---|---|---|
| 22:43 | Mr. P | Just to stay simple I would make little lines but I would do like a um like that. You could write the name in between and go, some thing like that, you happy with that? | RP |
| 23:09 | M | Uh huh (smiling) | |
| 23:10 | Mr. P | So something like that, so put it on there | |
| 23:11 | M | So can I do that and then put it on the other | |
| 23:12 | Mr. P | And then you would make sure that you’re able to put his name, you’re going to have to make block letters like this, making them curve might be rough but you’re if you want to make a B it might look like this (teacher draws boxy B) | |

Mari comes back at a later point to get assistance with the writing of the letters in block form to put on the coordinate grid.

| | | | |
|---|---|---|---|
| 41:52 | M | Can I just write them in? | |
| 41:53 | Mr. P | Yes, but you want them to know um can I see your pencil? Okay so B, like you did okay, A that one’s actually pretty easy A right? ‘cause you just need, you might need 3 points here to make that curve. You might need to start back on the belt and across, you understand? And the S you’re gonna have to | RFI |

| | | | |
|---|---|---|---|
| | | make one of these kind of S's. I is just right? | |
| 42:52 | M | Yeah and then there's a T and another A. | |
| 42:56 | Mr. P | Okay so i'll just do that part. You're gonna need to do the points in the middle right? You're gonna have to tell me where these points are but you know you got your lines here, that's fine, yeah I think this will work out good. | |
| 43:21 | M | And now I gotta put it on the bigger paper? | |
| 43:23 | Mr. P | Well now the goal, yeah, now the goal is to tell me where all these coordinates are. Do you know where all these points are? | HCD |
| 43:31 | M | Oh like if it's 1 and 15 and something like that | |
| 43:34 | Mr. P | Yes and then, and then we want to apply a formula to it or a rule | HCD |

Petri (P) had spent a good portion of the period trying to find a character and apply it to the grid. Her group was trying to explain to her that she could make Stewie from the television show "Family Guy" into a diamond to be able to graph it easier. Petri didn't understand and became frustrated. Tyanna (T) also comes to the teacher to try and get some help. Mr. P suggests to her to put her character on a transparency and use the overhead projector to enlarge the figure. He also sees Petri is frustrated and suggest she do the same.

| | | | |
|---|---|---|---|
| 48:49 | E | Mines was easier. | |
| 48:52 | P | You could just make a box. | |
| 48:56 | R | I should make a football. | |
| 49:00 | E | Make a big diamond. | |
| 49:03 | R | Yeah a big diamond head | |
| 49:04 | P | What character is a big diamond head? | |
| 49:06 | R | Stewie, it's a football head but it's diamond | |
| 49:10 | G | Oh yeah you just do it like that, yeah look | |
| 49:16 | P | What ya'll talking about? | |
| 49:17 | R | You see this look, um cube forms like that. It's a diamond. | |
| 49:23 | P | You guys are strange. You're saying make his head a diamond. It's gonna be ugly (laughs) | |
| 49:33 | G | You don't even know how to draw a diamond. Oh my god. | |
| 49:38 | P | Ah ya'll aggravating. | |
| 49:52 | E | My dog has small hands. This dog. (Q comes to table) | |
| 49:57 | R | What? | |
| 49:59 | Q | Where? | |
| 50:00 | R | Diamond head. | |
| 50:03 | P | I don't got no diamond head | |
| 50:04 | R | Oh yeah that's the same one as yours. | |
| 50:10 | P | I'm gonna make a box with some ears. | |
| 50:17 | Q | She in my seat, I don't know why she in my seat. Are you the one they supposed to record? | |
| 50:22 | P | Shut up Q, you're retarded | |
| 50:25 | Q | No I'm not. get up. | |
| 50:49 | E | Ha ha look at my dog. | |
| 50:53 | R | He's hungry | |
| 50:55 | Mr. P | Are you getting frustrated? | RFI |
| 50:57 | T | Uh ha | |

| | | | |
|---|---|---|---|
| 50:58 | Mr. P | Draw him on the plastic paper and then you can enlarge him and you can find the scale factor from using the ruler instead of all the coordinates. Does that sound like something you'd rather do? | RP, HCD |
| 51:08 | T | Um hm. I need a marker | |
| 51:10 | Mr. P | Take one, use a permanent marker. I don't…I don't have the other ones | |
| 51:19 | P | Mr. P, I'm fed up! | |
| 51:21 | Mr. P | Yes? You're fed up too | RFI |
| 51:23 | P | Yes I'm just gonna draw something | |
| 51:24 | Mr. P | Okay you can either, the option is to use either boxes. Glenda did you make that printout at home? Good job. | |
| 51:32 | P | Okay this right here. | |
| 51:36 | Mr. P | What? | |
| 51:38 | E | I made a new one but it's smaller | |
| 51:40 | Mr. P | Okay | |
| 51:43 | P | Can I make a crown or something? | |
| 51:45 | Mr. P | You could do a crown or who was your original person? Stewie? | RFI |
| 51:48 | P | Yes | |
| 51:50 | Mr. P | Some of you - some of you that are getting frustrated | RFI |
| 51:52 | R | I don't k now how to do this square thing. It's not that, I can do it but it's too many dots. Stewie's easy. Not the square thing. You know how to do the square? | |
| 52:09 | Mr. P | After you get it on a large piece of paper then we'll have to use measurement to find the scale factor | RP, HCD |
| 52:11 | P | Okay | |
| 52:14 | Mr. P | 'Cause I don't want you to get too frustrated here. | RFI |

Ryan (R) who is an excellent artist was plugging along and trying to apply his talent to this mathematical situation. He approaches the teacher to see how he is progressing.

| | | | |
|---|---|---|---|
| 43:52 | R | What number do I got to go up to? | |
| 43:56 | Mr. P | Yours is very detailed. You're gonna need a lot of points. Um that's fine if you stop there. | HCD |
| 44:01 | M | Who is that - Sponge Bob? | |
| 44:03 | R | Yeah, that's Sponge Bob. | |
| 44:05 | Mr. P | Um the only thing, this is the only thing, I don't want you to start over Bryant but one of the things, and I didn't do a good job explaining it. If you're gonna make Sponge Bob think about him more | RFI, HCD |
| 44:25 | R | Cubed? More easier? | |
| 44:26 | Mr. P | I'm not saying you have to do it over but um it might make your enlargement easier too. Here I'm having trouble drawing it, let me see him again how is he? He's wide on, so yeah so you need right? Is that it? Something like this and then for his eyes you might want to make them uh | RFI, HCD |
| 45:04 | R | Hexagon | |
| 45:06 | Mr. P | Yeah because see how the sharp edges you can put on the lines easier. I think yours is very detailed and beautiful but it might be hard to make a bigger one. All right? Because these are a lot of points to identify so either you can go ahead with this one or try and just make him, and then if you want to do your X's in the middle like you have, you can be able to do you know what I'm saying like if you want to keep with that theme with the | RFI, HCD |

| | | | |
|---|---|---|---|
| | | Jamaican flag is that what it is or Dominican? | |
| 45:37 | R | Dominican | |
| 45:38 | Mr. P | Dominican flag in the middle then you can still do that and then when you make his nose, you’re gonna make it square like this | |
| 45:53 | R | ‘Cause if I stick with this I don’t know what number to go up to. | |
| 45:56 | Mr. P | You would have to go up really far, you would need a lot more points right? Well you don’t really need that many, you can go as high as you want but you can keep going with this theme, I don’t see any problem with it, you can tell who it is. ‘Cause you’ve done, you’ve done some boxy shapes on the sides, you just now need to identify the points. So like where is that point? | RFI |
| 46:22 | R | Like at 8, 3? | |

A bit later after a few students were encouraged to use another method due to being frustrated by the first method but Mr. P encourages Ryan to continue using his original method.

| | | | |
|---|---|---|---|
| 53:04 | Mr. P | No no you don’t have to do it on other paper. If you’re doing that method, there’s a somewhat different method and if I’m I’m pushing first for you to graph the points and make your thing because we want a library of good characters for the next group of kids so that we don’t just have to use the wumps. Right? | HCD |
| 53:26 | R | Yeah so this is a good character? | |
| 53:27 | Mr. P | Yeah so if you’re not too flustered, just keep pushing on. Okay? | HCD |
| 53:32 | R | I’m a do the coordinates in this picture | |
| 53:33 | Mr. P | Yeah I think you’re doing fine Ryan, you can handle it. | HCD |

## Conclusions and Implications

This analysis documents the value of students’ bringing personal interests to mathematical concepts. The task itself brings interest to scaling figures larger or smaller with some reframing by the teacher. During this lesson the mathematical goal of scale factor seemed to move to the background while students focused on creating the likeness of their character. Despite the students’ struggles transforming their characters during the lesson, the agency and personalization that students exhibited are valuable and need to be navigated with care as to not disengage them. Furthermore these findings hope to shed light on the time, consideration, and decisions it takes to engage learners from a perspective that involves motivation and affect during the course of a lesson. Reframing problems, frustration, and impasse while maintaining high cognitive demand are relevant issues in mathematics education and need to be highly considered when choosing tasks and engaging learners. Teachers try to understand the mathematical strategies and representations a student might use in solving a particular problem. If we can understand and represent teacher interactions and student behaviors that enhance or impede emotional safety and mathematical engagement, it could be useful for creating other environments that encourage students to make mathematical meaning for themselves. Being the voice of the teacher in the classroom where the data were collected enhances the qualitative research paradigm by allowing for exploration of the unique features surrounding these particular cases and perhaps arriving at what Paul Ernest describes as the, “truth derived from identification with, and living through, a story with the richness and complex interrelationships of social, and human life” (Ernest 1994, p. 34). By adopting this perspective the present research affords an opportunity to understand the situation in a way that may be valuable to other practitioners facing similar challenges.

# CONCEPTUALIZING PROSPECTIVE SECONDARY MATHEMATICS TEACHERS' AFFECTIVE, META-COGNITIVE, AND MATHEMATICAL BEHAVIOR DURING PROBLEM-SOLVING

Belinda P. Edwards
Kennesaw State University
bedwards@kennesaw.edu

Early studies in problem-solving were concerned with the aspects of a problem that made solving the problem difficult (Geiger and Galbraith, 1998). The concern focused on the cognitive aspects of problem-solving without taking into account the background or characteristics of the problem-solver. Geiger and Galbraith (1998) suggested that the relationship between the learner and a problem is what is of significance and not so much the difficulty level of the problem. Schoenfeld (1992) explained that purely cognitive behavior is rare, and that learners perform most mathematics task within the context established by their perspectives on the nature of those tasks. Only a few studies give attention to understanding the interrelationship between affect and cognitive processes during mathematics learning and problem-solving.

The purpose of this grounded theory study was to investigate the interplay of prospective secondary mathematics teachers' affect, metacognition, and mathematical cognition in a problem-solving context. Constructivist grounded theory methodology (Charmaz, 2005) was used to answer the question: What is the characterization of the interplay among prospective teachers' mathematical beliefs, metacognition, and mathematical knowledge in the context of solving mathematics problems? Over a ten-week period, I conducted four interviews with four prospective secondary mathematics teachers enrolled in an undergraduate mathematics problem-solving course. One of the interviews included a think-aloud (Ericsson & Simon, 1993) problem-solving episode. Participant artifacts, observations, and researcher reflections were regularly recorded and included as part of the data collection.

In this poster, I present the results of the study in the form of a model. The interpretive model that emerged from the study describes the interplay among affect, metacognition, and mathematical cognition during problem-solving as meta-affect, persistence and autonomy, and meta-strategic knowledge. The analysis of data showed that, for the participants, "Knowing How and Knowing Why" mathematics procedures work, having the ability to justify their reasoning and problem solutions, and persisting in difficult problem-solving situations represented mathematics knowledge and understanding that could empower them to become productive problem-solvers and effective secondary mathematics teachers.

# MOTIVATION IN COLLEGE MATHEMATICS: DOES IT EVEN EXIST?

Alexis Johnston
Virginia Tech
alexis05@vt.edu

One belief that impacts both attitudes towards mathematics (including motivation) and mathematics achievement is self-efficacy. Self-efficacy influences attitudes and behavior in several considerable ways. Choice, effort and persistence are just a few of the ways that self-efficacy influences behavior (Schunk & Pajares, 2005). One of the ways that self-efficacy influences attitude is that the amount of stress and anxiety that a student may or may not experience during a task (Pajares, 2002).

It has been found that self-ratings of overall academic ability, self-efficacy in the domain of mathematics, and expectancy of success in college mathematics are all significant predictors of achievement in college mathematics (House, 2001). However, it has also been found that there is a significant difference in the level of mathematics self-efficacy between freshman college students enrolled in an intermediate or developmental algebra course and freshman college students enrolled in a calculus course (Hall & Ponton, 2005). This in-progress study seeks to explore these differences in more detail.

Data will be collected from freshman college students enrolled in calculus classes and in college algebra classes. Students' self-beliefs about mathematics will be measured using four scales from the Fennema-Sherman Mathematics Attitudes Scales: Attitude Towards Success in Mathematics scale, Confidence in Learning Mathematics scale, Mathematics Anxiety scale, and Effectance Motivation in Mathematics scale. In addition to measuring students' self-beliefs and motivation in mathematics, students' mathematics achievement will also be measured throughout the semester through students' exam scores.

The plan for analysis of this study is to make use of simple t-tests to determine whether or not there is a significant difference in self-beliefs and motivation between the two groups of students. Also, multiple regression will be used in the analysis of this study to determine the effect of each of the FSMAS domains on mathematics achievement.

Because it is becoming increasingly common for colleges and universities to require all students to successfully complete a quantitative course during their undergraduate studies, the results of the study could be useful for college mathematics professors. Possible implications of the study are for the teaching and learning of college mathematics, particularly when it comes to the design and structure of developmental college algebra courses.

# THE NATURE AND DEVELOPMENT OF EXPERTS' STRATEGY FLEXIBILITY FOR SOLVING EQUATIONS

Jon R. Star
Harvard University
jon_star@harvard.edu

Kristie J. Newton
Temple University
kjnewton@temple.edu

*Absent from the literature on flexibility is a consideration of experts' flexibility. Do experts exhibit strategy flexibility, as one might assume? If so, how do experts perceive that this capacity developed? We describe results from interviews with eight content experts to explore strategy flexibility for solving equations. Our analysis indicates that experts were capable of making subtle judgments about the most appropriate strategy for a given problem, based on factors including mental and rapid testing of strategies, the problem solver's goals, and familiarity with a given problem type. Implications for future research on flexibility and on mathematics instruction are discussed.*

## Introduction

Success in algebra has been and continues to be a concern among educators and policy makers because of its important role as a gateway to college (National Mathematics Advisory Panel, 2008). Increasingly, proficiency with algebra and mathematics in general is considered to involve more than just skill; it involves an integration of skill and understanding that allows for flexible, adaptive, and appropriate use of algorithms, all of which contribute to efficiency, problem solving, and transfer of ideas to new situations (Baroody & Dowker, 2003; National Research Council, 2001)). Yet, research on flexibility and how it develops is only emerging, particularly in the post-elementary years. Existing research suggests that flexibility can be enhanced through appropriate instruction (Blöte, Van der Burg, & Klein, 2001; Rittle-Johnson & Star, 2007; Star & Rittle-Johnson, in press; Star & Seifert, 2006), but much more research is needed to fully understand the development of flexibility.

Largely absent from the emerging literature on flexibility is a consideration of experts' flexibility. If researchers are to fully understand the trajectory of flexible problem solving in school mathematics, then it seems important to examine experts' approaches to advanced school topics such as algebra. Do experts exhibit strategy flexibility with algebra, as one might assume? If so, how do experts perceive that this capacity developed in themselves? Do experts feel that flexibility is an important instructional outcome in school mathematics? In this paper, we describe results from several interviews with experts to explore strategy flexibility for solving equations.

### *Strategy Flexibility*

Flexibility, particularly in terms of flexible use of strategies, is not a construct that has been consistently defined by researchers. Some distinguish flexibility from adaptability, while others equate the two terms. In this paper, we take the latter perspective by defining *flexibility* as knowledge of multiple solutions as well as the ability and tendency to adaptively select the most appropriate ones for a given problem and a particular goal (Star & Rittle-Johnson, 2008; Star & Seifert, 2006).

Several recent studies have examined the development of flexibility among school-aged learners, and this work has identified promising instructional interventions that appear to improve students' flexibility (e.g., Blöte et al., 2001; Rittle-Johnson & Star, 2007; Star & Seifert,

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

2006). However, if flexibility is an important component of students' proficiency in mathematics (Kilpatrick et al., 2001), it also seems critical to have more in-depth knowledge of what this capacity looks like in experts. Do experts exhibit flexibility? How and when do experts become flexible? As discussed below, the literature on experts' flexibility is quite limited and yields inconsistent results.

*Experts and Flexibility*

Although many studies have examined differences between experts and novices with regard to complex academic tasks (particularly in physics; Chi, Feltovich, & Glaser, 1981; Larkin, McDermott, Simon, & Simon, 1980), few have focused specifically on strategy flexibility in mathematics. The limited research suggests that experts do tend to have multiple, efficient strategies for solving problems, but findings are inconsistent about the extent to which experts employ these strategies.

For example, Dowker (1992) found that mathematicians not only exhibited a high level of accuracy, but they used a variety of strategies, and the strategies tended to illustrate their knowledge of number properties and relationships. Similarly, Cortés (2003) found that experts were not only efficient, but they rapidly analyzed the task and decided on an approach based on the characteristics of the problem. In contrast, Carry and colleagues (Carry, Lewis, & Bernard, 1979) reported that the primary difference between more and less able solvers was *not* that experts knew and used a greater number of strategies but rather that more able solvers tended to make fewer errors. These and other studies provide a useful starting point for understanding experts' flexibility. However, there are several key weaknesses to this literature that suggest the need for additional studies.

First, existing research does not explore the *development* of flexibility. Do experts attribute their flexibility to prior instruction? If not, how did they become flexible problem solvers? Do they believe instruction has a role in developing flexibility? Second, existing research does not sufficiently explore the *nature* of experts' flexibility. In particular, research does not clearly distinguish between experts' use of algorithms, knowledge of alternate methods, and preference for particular strategies. Finally, existing studies have provided limited opportunities for experts to demonstrate flexibility. Although some problems that allow for efficient or elegant solutions have been used in past research, the primary purpose of most studies was to understand experts' strategies and accuracy in general, not to explore flexibility per se. As a result, they were given few problems that were explicitly designed to test strategy flexibility.

*Current Study*

The current study attempts to address the above weaknesses in the literature on experts' flexibility. Specifically, we designed tasks that provided opportunities for experts to demonstrate flexibility; we probed experts about the approaches they noticed and preferred; and we asked experts to reflect on the emergence of this capacity in their own learning. Similar to Cortés (2003), we explored flexibility among experts from several different fields, including mathematics, mathematics education, engineering, and secondary mathematics instruction. Our analysis of experts' interviews and problem solving focuses on the following issues.

First, we are interested in the *nature* of experts' flexibility for solving algebra problems. Prior research has shown that, while experts are less likely to exhibit errors in problem solving than novices, the degree to which experts show knowledge of multiple strategies and the ability to adaptively select the most appropriate strategy has varied across studies. Our investigation of experts' flexibility will focus on several aspects of strategy choice, including use of multiple strategies, knowledge of multiple strategies, and preferences for certain strategies. A second focus of the current work is *development* of experts' flexibility developed. We believe that this developmental perspective on flexibility among experts has not been well-explored in prior research. Related issues include whether experts believe that flexibility is an important outcome and how experts believe flexibility can or should be fostered in school mathematics. As such, several research questions guided our study. To what extent do experts use multiple approaches and adaptively select the most appropriate strategies for a given problem? How do experts select problem solving strategies? Do experts hold preferences for particular strategies for certain problems, and, if so, what are these preferences based on? How do experts become flexible, and what are their views about the role of instruction in developing flexibility?

## Method

### *Participants*

Participants for the current study included eight experts in school algebra. Specifically, a convenience sample of two mathematicians, two mathematics educators, two secondary mathematics teachers, and two engineers were included in the study. One of the mathematicians, (Mark; pseudonyms are used for all experts), held a doctorate in mathematics and had worked for years in a university mathematics department. The other mathematician (Matthew) was finishing his doctorate in mathematics but had also taught high school mathematics and worked with teachers for many years. Both mathematics educators held masters degrees in mathematics; one also held a doctorate in educational studies with a concentration in mathematics education (Evelyn), and the other was finishing her doctorate in mathematics education at the time of data collection (Ellen). One of the mathematics teachers was a veteran secondary teacher with a bachelors degree in physics and a masters in education with a mathematics emphasis (Tara). The other teacher held degrees in psychology and sociology (Timothy) but had been a professional tutor for many years and often taught high school mathematics in the summer. One of the engineers held bachelors degrees in mathematics and in aerospace engineering (Nathan). His job included writing flight simulations for rockets and satellites, which involved extensive use of algebra, calculus, and other areas of mathematics. The other was a mechanical engineer, with both a bachelors and a masters degree in the field. His job involved designing and testing electrical tools (Nicholas). These types of experts were chosen in order to provide a range of perspectives on flexibility and potentially different approaches to solving problems. Participants were from five different states, all within in the eastern United States. Five of the experts were male and three were female.

### *Measures*

Opportunities to assess flexibility were embedded in a researcher-designed algebra test. The 55-item test was originally designed to be used as a final examination for a three-week summer course for high school students that reviewed more advanced topics from a first year of school algebra. Test items were symbolic mathematics problems taken or adapted from a standard algebra text on solving and graphing both linear and quadratic equations, as well as simplifying expressions with exponents and square roots. The exam was edited to ensure opportunities to demonstrate flexibility. For example, one problem in the form $a(\mathrm{x} + b) = c$ was altered such that $c$ was divisible by $a$. Whereas students are often taught to distribute first for equations that include parentheses, dividing both sides of the equation by $a$ is an alternative first step to solving this equation.

Semi-structured interviews were conducted to probe experts' thinking about their strategies for solving algebraic problems. Experts were asked to explain how they solved certain problems, why they chose the strategies, whether they knew of other ways to solve the problems, and which strategies they preferred. Problems were selected based on their possible relevance for exploring issues of flexibility. After explaining their thinking on these problems, experts were asked about own experiences that led to becoming flexible and whether they thought flexibility should be or could be taught in schools.

*Procedure*

The algebra test was administered in a one-on-one setting to the experts at a time and place convenient to them. At the beginning of the test administration, experts were told that the focus would be on the methods they used to solve the problems. As such, showing work was encouraged. They were informed that an interview would follow the test in which they would be asked about selected problems, but they were not told in advance which particular problems would be selected. The test was not timed, but most of the experts completed it within 20 minutes. The interviews were conducted immediately following completion of the test. Interview times varied, ranging from about 10 to 30 minutes. Interviews were audiotaped and subsequently transcribed.

## Results

We begin by reporting results on the nature of experts' flexibility, followed by an analysis of experts' views on how their flexibility developed.

*The Nature of Experts' Flexibility*

It is important to first note that the eight experts interviewed in this study were quite successful on the mathematics tasks that they were asked to complete. Consistent with prior work on experts in mathematics and other domains, our experts rarely made errors. When errors were made, experts quickly noticed and corrected them. Our interest, however, was more on the strategies that experts used and their flexibility. We found that the experts interviewed were quite flexible. They exhibited knowledge of and use of multiple strategies for solving a range of problems, and they generally used and/or expressed a preference for the most adaptive strategies for a given problem.

*Choice of strategies.* We first consider the criteria that experts used to select their chosen strategy (which was often the optimal strategy) for a given problem. Overwhelmingly, experts indicated a preference for strategies that they deemed to be easiest. In general, the easiest strategy was the one that was "faster, quicker, less steps" (Tara). However, fewer steps was not the only consideration for choosing an easy or efficient strategy; reducing effort was also important. As one expert suggested, "It's not about extra steps. I don't mind putting in extra steps if extra steps makes it easier." (Nathan). Referring to the problem, $7(n + 13) = 42$, one expert noted, "I wanted to minimize the effort. So another way to do it is distribute, but I didn't want to do that" (Matthew).

The experts also referred to the "neatness" of a strategy in explaining their strategy choices. For example, one expert noted that to solve the above problem, he felt it was best to use division by seven as the first step because "That was evenly divisible. If it wasn't divisible it wouldn't get a nice, clean answer" (Nicholas). Similarly, another expert also noted that, "Distributing, I would have had to deal with fractions and finding common denominators and things wouldn't have been as nice" (Tara). Avoiding fractions was of particular interest to many of the experts. One expert explained that she did not like to work with fractions because they are "slower to operate with" (Ellen). In general, reducing the arithmetic complexity of the problem was important for both speed and accuracy. On expert explained, "I'm less likely to make a calculation error"

(Ellen). Another expert concurred, stating that "I am not real quick at arithmetic, so I like to keep the arithmetic as simple as possible" (Evelyn).

In addition to selecting a strategy based on its perceived ease of execution, experts also considered the specific characteristics (e.g., structure and coefficients) of problems in selecting a strategy. This criteria for selecting strategies was particularly noticeable when the experts solved systems of linear equations. For example, when solving the system which included the lines $3y + 4x = 0$ and $y = x - 7$, one expert explained "I used substitution because it was set-up that way" (Timothy). Presumably Timothy is referring to the fact that the second line is already written in the form $y$ = ?, which makes it particularly amenable to substitution in the other equation. Similarly, when another expert solved the system containing the lines $2x + y = 1$ and $x + y = 3$, he explained that he used the addition/subtraction method because "you have to get rid of something and in this case you just observed that $y$ is the same, so subtraction will get rid of it" (Mark).

*Failure to choose optimal strategy.* Consistent with prior research (Carry et al., 1979), experts did not always choose the most efficient strategy for a given problem. Typically, when experts failed to choose the optimal strategy and were subsequently asked about their strategy choice, they tended to note that they "weren't thinking." For example, one expert solved $7(n + 13) = 42$ by distributing the seven as his first step. When he later noticed that it would have been more efficient to divide both sides by seven first, he stated, "I just didn't think about it at the time. I just blew through it" (Nathan). In addition to "not thinking," other experts indicated that their initial choice of non-optimal strategies came because of well-practiced, automatized approaches that they initiated very quickly after seeing a problem. For example, another expert, who also used distribution as the first step to solve this same problem, explained his choice as, "For some reason I just went straight to the formula. I guess [I was] in that mindset" (Timothy).

However, experts' rationales for their strategy choices clearly indicated their strong tendency to prefer elegant, efficient strategies even when these strategies were not used for solving a given problem. For the problem $1/3(x + 5) + 2/3(x + 5) = 7$, both Ellen and Nathan multiplied both sides of the equation by 3 in an attempt to avoid calculating with fractions. However, when asked if they knew of another way to solve the problem, both said a better first step would be to combine "like" terms, obtaining $x + 5 = 7$, and both expressed a preference for this method. When asked why she preferred the second method, Ellen suggested, "There's something about recognizing that those two things equal one that I, I don't know, that I like….There is something pretty about it." After noticing this alternate approach, Nathan described his original strategy as "incredibly convoluted," adding that, "In this case, my fixation on getting rid of the denominators kind of obscured the problem there."

*Development of Experts' Flexibility*

Toward the end of the interview, experts were introduced to the construct of flexibility (as we conceptualize it here) and were asked to reflect on their flexibility. After learning about flexibility, not surprisingly experts uniformly believed that they themselves were flexible. Furthermore, when considering how their own flexibility developed, experts did not believe that flexibility was an overt instructional goal for their K-12 or university mathematics instructors. A typical response to being asked if they were taught flexibility was, "No, never!" (Evelyn). Instead, experts offered two explanations for how they developed strategy flexibility.

First, several experts felt that their own flexibility had emerged as a natural consequence of exposure to seeing similar kinds of problems over and over again, combined with a desire to solve problems as quickly as possible. One expert stated, "My best guess is just a lot of repetition and when you to do small equations over and over and over you're going to want to find the quickest way of doing things to get done faster" (Tara). This desire to complete problems as quickly as possible could have been present because of disinterest (e.g., wanting to complete math homework as quickly as possible), but among those we interviewed, it seemed more common that experts found the search for the quickest and easiest strategies for given problems to be intellectually challenging and interesting. Experts did not report that their mathematics instructors had pushed them to search for optimal strategies, but rather that this was a desire that they themselves brought to problem solving. As one expert stated, "It's a challenge to solve them in different ways, but then you start to learn which methods are quickest or easiest for certain problems, and you notice certain patterns" (Nathan).

Another explanation that several experts favored was that their flexibility was the result of their teaching. As one expert explained, "I've taught this stuff. I guess when you teach kids you get to know ten different ways of doing it based on what kids like" (Matthew). When describing how he developed flexibility, Timothy suggested, "I tutor students mainly who struggle, so I have just learned that if they can't see it one way, often trying another way helps them see something they didn't see before." It appears that, through interactions with students -- both having to explain problems in multiple ways to struggling students and also by exposure to the idiosyncratic, original, or even erroneous strategies that students produce -- experts developed more robust knowledge of multiple strategies for solving algebra problems.

Overall, the experts appeared to value flexibility and felt that it was an integral part of doing mathematics. As one expert described, "Problem solving is a general skill, and you have to be adaptable and flexible to the context" (Nathan). However, and consistent with experts' views on how their own flexibility developed, there was variation as to whether experts felt it was a good idea to teach students to be flexible. Some experts thought that teaching flexibility was a good way to teach students to notice the mathematical structure in problems and that it would help "the students understand the mathematics more deeply" (Evelyn). Yet others thought that teaching for flexibility would confuse students and that students should learn from trial and error. One expert stated, "You can learn some tricks from your teachers, but eventually it all comes down to doing it yourself" (Mark).

## Discussion

The purpose of this study was to explore the strategy flexibility of experts. Despite the recent emergence of a literature on students' flexibility, relatively little research exists on experts' flexibility. Our results indicated that our experts did exhibit strategy flexibility on the tasks that they were asked to complete: Experts showed knowledge of multiple strategies and the ability to select appropriate strategies for given problems. Experts expressed a strong preference for strategies that they deemed to be easiest, where the easiest strategies were those which resulted in the fewest steps, the least effort to execute, and/or the reduction of arithmetic complexity. Experts also considered the specific characteristics of problems (including a problem's structure and its coefficients) when selecting a strategy. Consistent with prior research, we found that experts did not always select the optimal strategy for a given problem, despite their knowledge of and preference for the most efficient strategies. With respect to the development of their own flexibility, experts did not believe that flexibility had been an overt instructional goal for their prior mathematics instructors. Rather, the experts interviewed here believed that their flexibility emerged from their own initiative and/or as a consequence of their teaching experiences.

Below, we discuss several implications of our results, for research on flexibility and for mathematics instruction more generally.

*Implications for Mathematics Instruction*

The experts interviewed here were in agreement that flexibility was *not* an explicit focus of their K-12 and university mathematics experience (as Evelyn noted, “No, never!”). One interpretation of experts’ views would be that flexibility should not be an instructional target in elementary and secondary schools – that flexibility is best developed implicitly and individually by the repeated problem solving experiences of learners. According to this interpretation, developing flexibility requires a significant amount of personal initiative and thus may be considered as an advanced instructional goal – one that was only available to those with a great deal of talent in mathematics and an exceptional drive to develop this competency in themselves, largely without the aid of teachers.

This point of view runs counter to the current emphasis in the US on the importance of flexibility for *all* students in K-12 mathematics instruction (e.g., National Mathematics Advisory Council, 2008; Kilpatrick et al., 2001). A proponent of this current emphasis on flexibility for all might point out that much has changed in the years since these experts attended elementary and secondary school, including a greater variety of curricula, greater diversity in instructional methods, and more generally increased attention to providing quality mathematics instruction to all students. Improvements such as these suggest that, despite some experts’ views to the contrary, it may be possible to consider flexibility as an instructional goal for all students, rather than as an outcome that is only available to future experts who pursue it themselves.

*Future Research on Flexibility*

This study underscores the importance in future research of using tasks that are specifically designed to elucidate flexibility. Prior work with students has shown that knowledge of innovative strategies for problem solving often precedes the ability to implement these strategies (e.g., Star & Rittle-Johnson, 2008). Similarly, this study and others (e.g., Carry et al., 1980) suggests that even experts do not always use the most efficient strategy for solving a given problem. As a result, merely giving students a list of problems to solve may not be a good indicator of flexibility; students may choose to use the same strategy for all problems, even when it is not the most efficient choice, and despite their knowledge of alternative approaches.

In this study and in our prior work, we have used two kinds of tasks to more effectively assess students’ flexibility. First, we have conducted interviews to accompany problem solving, asking participants to explain and justify their choices of strategies. And second, we have incorporated different kinds of problems into our assessments to better tap participants’ flexibility. In some cases, we have merely changed problem coefficients, to accentuate the benefits of using an alternative strategy. For example, instead of using a problem such as $3(x + 1) = 22$, we might alter the problem to $3(x + 1) = 21$, to perhaps increase the likelihood that participants who were aware that they could divide both sides by 3 first would actually implement this strategy. In addition, we also devised other kinds of tasks to tap flexibility, including asking participants to solve the same problem in more than one way and to identify which strategy was optimal.

## Conclusion

Strategy flexibility is an important instructional goal in mathematics instruction at all levels. An emerging research base on students’ flexibility is beginning to provide helpful guidance on the development of flexibility and instructional tasks that reliably lead to greater flexibility. However, experts’ flexibility has been relatively unexplored. This paper provides initial evidence about experts’ views on the nature, development of and importance of flexibility. Despite expert agreement that flexibility was not emphasized in their own learning of mathematics, experts in this study had a natural and pervasive tendency to value and use efficient, elegant strategies to solve algebra problems. This tendency seems to be deeply related to their knowledge of the subject, underscoring the need to include flexibility as a goal for instruction at the secondary level.

# SEVENTH GRADERS' USE OF ADDITIVE AND MULTIPLICATIVE REASONING FOR ENUMERATIVE COMBINATORIAL PROBLEMS

Jaehong Shin
University of Georgia
jhshin@uga.edu

Leslie P. Steffe
University of Georgia
lsteffe@uga.edu

*In a year-long teaching experiment with two 7th grade students, this study investigated how those students dealt with enumerative combinatorial problems based on their additive and multiplicative reasoning. The results show that three distinctive levels of enumeration appeared in the students' mathematical behavior: additive enumeration, multiplicative enumeration, and recursive multiplicative enumeration. Permutation problems of more than five elements seem to involve conceptual constructs beyond recursive multiplicative enumeration.*

## Background

Research on combinatorics in mathematics education has not been studied extensively when compared with other topics such as whole number arithmetic and fractions. Further, ever since Piaget and his colleagues conducted a number of studies investigating the development of children's combinatoric operations (e.g. Piaget, 1975), combinatorial reasoning as a research topic has been given little attention although combinatorial problems have been adapted for the research on students' development of proof justification or verification strategies (Eizenberg & Zaslavsky, 2004; Maher, 2005; Maher & Martino, 1996). However, as Piaget and Inhelder (1975) pointed out, children's combinatorial reasoning is a very fundamental mathematical idea, whose basis is in additive and multiplicative reasoning.

> The general characteristic is to start from the additive idea of juxtaposition and not from the intersection or interference, that is, from multiplicative association. … His ability to presuppose this multiplicative association would be necessary to construct a complete operative system. (Piaget & Inhelder, 1975, p.169)

Therefore, this study was conducted using a year-long teaching experiment with two 7th graders in order to investigate how those students dealt with combinatorial problems based on their additive and multiplicative reasoning and whether distinctive features, which can be regarded as combinatorial reasoning, would be drawn from their mathematical operations in those problem situations. For this report, students' mathematical activities in the problems related to enumerative combinatorics will be the focus.

## Theoretical Perspectives

Enumerative combinatorial problems are basically counting problems. That is, children are asked to count the number of ways that certain patterns can be formed. However, when compared with a simple counting problem such as "How many apples are on the table?" there is a huge difference between the two counting situations because enumerative combinatorial problems involve more than children's basic counting schemes. In other words, in a combinatorial problem, children attend, first of all, to units of the indefinite quantity to be counted in the problem situation and, further, to monitoring their counting activity to decide when to stop counting. For example, consider the outfit problem, "If you have two shirts and three pairs of pants, how many outfits can you make?" For this problem, children must construct the units to be counted as the combination of one shirt and a pair of pants. The countable unit is a pair of units rather than a singleton unit as in most counting situations children encounter.

Piaget and Inhelder (1975) suggested three stages of children's combinatorial operations in enumerative combination, permutation, and arrangement problems through clinical interviews with children from six to twelve years old. At the first stage of empirical operations, children construct countable units for the problem without establishing a systematic way to make pairs of units as countable. That is, for a two card arrangement problem with three different cards, they take any card, combine with any other one, and simply look around next to see if that pair is already on the board. At the second stage, children have a sense of regularity, but it always remains empirical at the beginning. In other words, they quickly understand that the combinations can be ordered according to the first numbers (1, 2, or 3) in each arrangement, but this is only an empirical discovery. Finally, the third stage of understanding of the system, children can construct the law $n^2$ for two card arrangements with n cards. However, this is only empirical generalization, which does not bring about a reflective and anticipatory scheme. Later, based on Piaget's works, English (1991) addressed the *odometer strategy*, which holds one item constant while systematically varying each of the other items. She showed that children seven years of age demonstrated such systemic operations and argued that the combinatorial domain should be considered as a topic of investigation in the elementary school curriculum. However, there remains an unexplained aspect in her research results in that she did not provide operative explanations based on children' additive and multiplicative reasoning even though Piaget and Inhelder (1975) already mentioned that combinatorial operations should be rooted in additive juxtaposition and multiplicative association.

Steffe (1992) observed children's construction of such mathematical operations and referred to them as *lexicographic units-coordinating operations*, which have similar observable features to English's (1991) odometer strategy. A *units-coordination* means "to distribute a composite unit over the elements of another composite unit" (p.279). The first multiplicative concept occurred as a recursive counting scheme, which was used to produce the first units-coordination. It follows that children's construction of units-coordinating operations is crucial in their transition from an additive to a multiplicative world and researchers must understand these operations when investigating the status of children's additive and multiplicative reasoning. Specifically, children's units-coordinating operations that are involved when making possible pairs, for instance, with three numeral cards and seven letter cards are called lexicographical operations because of the dictionary ordering of the pairs. Thus, it is possible that the construction of lexicographic units-coordinating operations and symbolizing actions for those operations open pathways for children's construction of combinatorial reasoning. So the main concern in the analysis of the teaching experiment data was to investigate how children's construction of unit-coordinating operations emerged and was transformed through their mathematical activities in combinatorial problem situations.

## Methods of Inquiry

The data for this report were collected from a year-long constructivist teaching experiment (Steffe & Thompson, 2000), in which a pair of seventh-grade students were taught at a rural middle school in north Georgia from October 2007 to May 2008. The experiment is a part of the larger, longitudinal study called the Ontogenesis of Algebraic Knowing (OAK), whose purpose is to bring forth and understand middle school students' algebraic reasoning. Two students for the research were chosen after individual selection interviews conducted during September and

October of 2007. The criteria for selection of the students were that they should be able to use three levels of units for solving multiplication and division problems. During the teaching experiment, the two students were met twice a week in 40-minute teaching episodes. All teaching episodes were videotaped with two cameras for on-going and retrospective analysis. One camera usually captured the whole picture of interactions among the pair of students and the teacher-researcher, and the other camera followed the students' written or computer work with the aid of two witness-researchers. The role of the witness-researcher was not only assisting in video recording but also in providing other perspectives during all three phases of the experiment: the actual teaching episodes, the on-going analysis between episodes during the experiment, and the retrospective analysis of the videotapes. In terms of data analysis, the first type of analysis was ongoing analysis that occurred by watching videos of the teaching episodes and debating and planning future episodes. The second type of analysis, which was conducted after the data had been collected, was retrospective analysis. The purpose of the retrospective analysis was to make models of the students' ways of operating mathematically.

## Data Excerpts

*Additive Enumeration and Multiplicative Enumeration*

The two students, Carol and Damon, demonstrated that they were able to execute *additive enumeration,* in which they attended to a unit to be counted and executed counting additively. For example, on February 4, Carol and Damon solved the following coloring-window problem based on their additive counting, "Find how many ways to paint four windows with two colors." Carol and Damon were given a picture of a window consisting of four sub-windows. Carol tried to draw pictorial symbols for all possible windows and counted them whereas Damon repeated writing and erasing the letter 'r' for red and 'b' for black on a given window while adding tally marks above the window to keep track of his 'r' and 'b' entries (see Figure 1 and 2). Finally, Damon found sixteen cases although he wrote fifteen tally marks down, but Carol got fourteen at first, missing two cases.

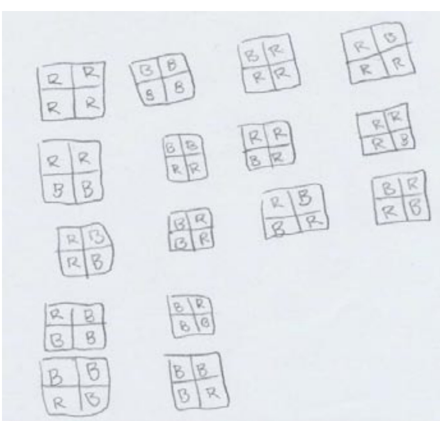

*Figure 1.* Carol's final pictorial representation.

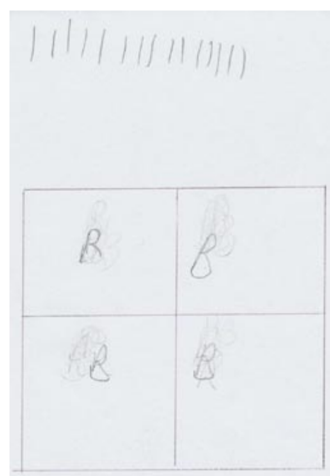

*Figure 2.* Damon's final representation using using tally marks.

Carol represented units of her unit-coordinating operations by drawing identical-looking windows like the given window, whereas Damon symbolized his results of units-coordinating

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

operations using tally marks with an aid of writing possible initial letters for each window. Carol's missing two cases indicated that she engaged in additive enumeration because she proceeded sequentially and lost track of where she was at in enumerating the windows. Further, the continuing activities of the two students revealed a crucial difference in their reasoning about the problem situation that was important in their development of combinatorial reasoning. Right after checking out his answer with the teacher, Damon exclaimed, "Look at it. There is an easier way!" His explanation indicated that he constructed a multiplicative structure for counting his windows. He argued that the answer could be easily found as two to the fourth because we could use two colors for four squares (sub-windows). Damon's reflective way of counting might be considered as multiplicative enumeration in that he counted the countable units by producing two to the fourth. Carol did not even seem to assimilate Damon's explanation because she did not organize her activity as multiplicative although she finally drew her missing two windows and got sixteen as an answer. In Damon's case, even though he said, "two to the fourth", the structure seemed to be a product of his operating rather than as a given in recursively operating further because he could not provide a satisfactory justification for why two to the fourth worked. This conjecture was corroborated on February 11 while solving a two-digit number problem: "How many two-digit numbers can you make?"

For the two-digit number problem, Damon started to write two-digit numerals from ten to ninety in a column and kept writing eleven, twenty-one, thirty-one, …, ninety-one making another column and then stopped (cf. Figure 3). After murmuring something, he wrote '81' a little away from two columns as an answer, but resumed writing two-digit numbers for making sure of his answer because the teacher commented, "go ahead (keep writing) and check your answer." Then he finally corrected it as '90'. As an explanation, he claimed that zero in one-digit place could go with nine numbers in ten-digit place and so did the other numbers in one-digit place. However, he could not find the right answer until he finished writing down tabular forms of numerals for all possible two-digit numbers.

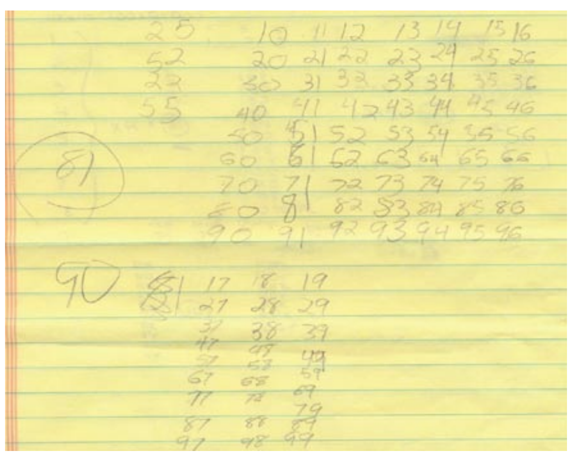

*Figure 3*. Damon's answer for two-digit number problem.

His comment that he thought his table was going to be a nine by nine table in the middle of his solving process when he said "eighty-one" and the fact that he had to transform all possible units-coordinating operations into written notation for him to be able to complete his counting activity indicate that his construction of a multiplicative structure for this combinatorial problem was a product of operating and not available for analysis prior to operating. For example, he could have transformed his counting activity into a compressed form of symbols like '9x10 = 90' just as he exclaimed $2^4$ in the coloring-window problem. Similarly, Carol made a table for arranging all possible two-digit numbers and after writing all possible two-digit numbers, she wrote '9x10 = 90' under the table (see Figure 4).

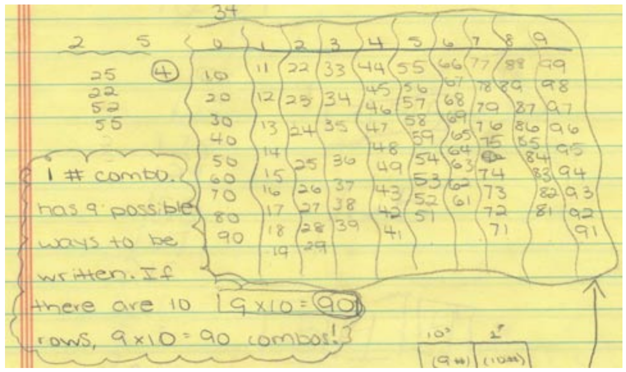

*Figure 4.* Carol's answer for two-digit number problem.

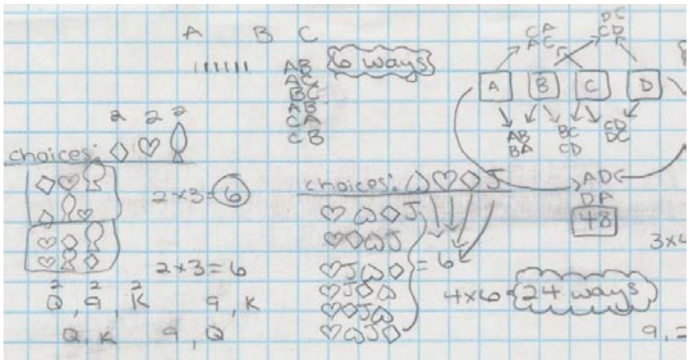
After getting the solution, she exclaimed "I know a faster way. I could have done that. Oh~" and she explained "nine different combinations (pointing out columns) in each way. There are ten rows (actually ten columns) and ten times nine is ninety… If I figured out that each row has nine, I could have just done that." Nevertheless, an inference that her numerical symbols and her reflective explanation concerning how she could organize her work were available to her prior to actually engaging in operating was not warranted. That is, an inference that Carol's construction of the problem situation and her mathematical operations for the solution were transformed into the numerical symbols, '9x10 = 90' prior to operating would be too strong. Rather, as Skemp (1987) illustrated as one of the functions of symbols, Carol's numeral table for her solution made possible her reflective thinking and reorganization of the situation. Her retrospective analysis using her table led her to represent her construction of the situation and operations for the answer by writing a compressed form using numerical notation. Thus, at this moment, Carol did not seem to produce a multiplicative structure as a given for the solution prior to operating. To construct a multiplicative structure and use it to find an indefinite quantity is an important mathematical modification because such a structure permits a child to curtail her counting activity, and further helps her interiorize conducted actions and operations so that she could use them a priori for the construction of more abstracted combinatorial reasoning, that is, recursive multiplicative reasoning.

*Recursive Multiplicative Enumeration*

The teaching episode on February 13 was focused on card arrangement problems not allowing a repeated use of any card. For instance, "There are five different cards. How many different ways can you arrange those cards?" Carol and Damon began with a two-card arrangement problem and went through a five-card arrangement problem. While solving those problems, they used similar representations in that they symbolized by writing all possible units-coordinating operations of card arrangements (see Figure 5 and 6).



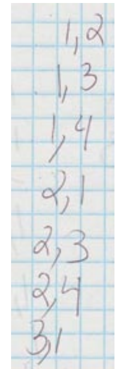


*Figure 5*. Carol's card arrangement. *Figure 6*. Damon's card arrangement.

However, when they were faced with the five-card arrangement problem, a distinct feature from the previous card arrangement problems was observed. Damon tried to write down all possible arrangements of five cards by fixing '1' for the first card, but seemed to lose track of his systematic way of proceeding. After two minutes passed, he suddenly wrote down '120' on his worksheet. After the teacher's requested an explanation for his answer, he said he fixed the first two cards as '1' and '2' and counted all possible five-card arrangements with the fixed two numbers, which were six cases and then he got one hundred twenty by multiplying by four and five in order. However, he could not provide a satisfactory justification for why he multiplied by four and five. On the other hand, Carol represented those possible cases more systemically and provided a clearer explanation than Damon did (see Figure 7).

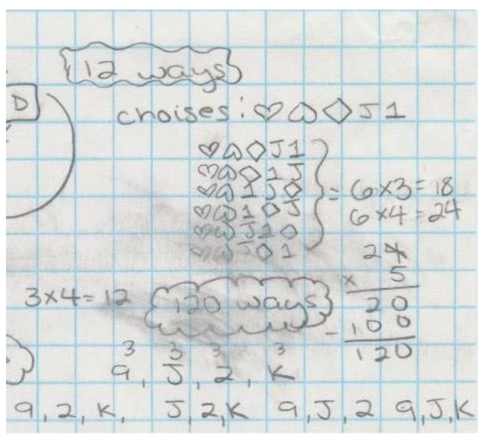

*Figure 7*. Carol's solution for five-card arrangement problem.

Nonetheless, whether Carol, let alone Damon, was explicitly aware of a multiplicative structure is still ambiguous even though she worked symbolically. The five-card arrangement problem seemed to reveal a limitation in their multiplicative enumeration. Writing down all possible five-card arrangements seemed to be very hard for them. They both could hold the two initial marks constant and systematically and exhaustively vary the elements to place in the three remaining places. But this was nothing other than a modification in the lexicographic orderings that they initially demonstrated. They still needed to "run through" this way of ordering in the case of the last three places. Once that was completed, they could again use their lexicographic method of ordering, but this time they anticipated the number of choices—four and then five. However, they seemed yet to construct the concept of a "slot" [abstracted unit] that anticipation of the number of choices of four and five might have indicated. A slot is an abstraction from the mental process of running through a deck of 52 cards, say, and choosing each one in order when finding how many pairs could be made using the 52 cards. The abstraction follows from unitizing the mental process. The construction of this concept of variable seemingly is critical in recursive multiplicative enumeration. For students' multiplicative enumeration to be recursive means that the students are able to externalize the results of their units-coordinating scheme and operate on these results with operations external or internal to the scheme (Tillema, 2007). When they fixed the first and the second card, counted all possible cases with the two fixed cards and arrived at six, both students simply multiplied six by four and that result by five, which indicated recursive operations. However, because they did not a priori operate in this way, the inference that the students had constructed the concept of a slot that stood in for making five choices, then four choices, etc. was not warranted. Still, both students distributed the six possibilities they generated by holding the two initial marks constant over each element of four possibilities of the second card. Furthermore, the two students took the results of the multiplicative enumeration up to the second card as given and operated on another multiplicative enumeration with the first card position. They could engage in recursive multiplicative enumeration in the process of operating, but they were yet to do so prior to operating. The two students' distinct solving activities with five cards as well as less than five cards leads to the hypothesis that arrangement problems of more than five elements require students to have constructed a program of operations that involves the multiplicative coordination of the operations that are recorded in a sequence of slots if the students are to mentally solve them without engaging in actual coordinating activity.

## Conclusion

This study suggests that (a) the students' enumerative combinatorial counting constructs can be based on their units-coordinating operations, (b) three distinctive levels of enumeration appeared in the students' mathematical behavior: additive enumeration, multiplicative enumeration, and recursive multiplicative enumeration, and (c) permutation problems of more than five elements seem to involve conceptual constructs beyond recursive multiplicative enumeration, that is, the concept of a program of multiplicative operations. These explanations open the way to study students' construction of combinatorial reasoning beyond the formal-operational period in Piaget's works.

# COLLEGE STUDENTS' UNDERSTANDING OF RATIONAL EXPONENTS: A TEACHING EXPERIMENT

Iwan R. Elstak
Georgia State University
matixe@langate.gsu.edu

*Five college students' understanding of exponents was investigated. The students then participated in a teaching experiment to test an alternative route for studying rational and negative exponents. The focus of the study was the role of the laws of exponents in the process of students' understanding of exponents that are not natural numbers. What is the impact of the teaching experiment on the students' understanding of such exponents? Results suggest that students do not base their understanding of non-natural exponents on the laws of exponents and that the teaching method can improve understanding of exponents, depending on their earlier experiences.*

## Introduction

Exponents are basic tools in the arsenal of college students. Functions that model population growth, absorption of light, decay of radioactive material, mortgage rates and interest on capital, all require forms of exponents. Learning exponents starts early in school mathematics. Counting how many times a number is multiplied by itself is probably the main notion in learning exponents. When students move up the mathematical ladder, exponents can be negative, fractions or even irrational numbers. How students construct their notion of such exponents has not been extensively studied. Do students reconcile their early notion of exponents as counting numbers with the new exponents they learn? Do they develop meaningful explanations for rational exponents that make sense to them? What do they think of the zero exponents?

## Research Questions

1. What is the role of the laws of exponents in the students' construction and understanding of rational and negative exponents?
2. How do these college students understand and justify their notions of rational and negative exponents?
3. What is the impact of an alternative route in teaching rational and negative exponents on these students' understanding of exponents?

## The Teaching Conjecture

Postponing formal definitions the idea of rational exponents was built around the notion of relative rates of change. The context was population growth. Rates of change were transformed into factors of multiplication per "time" unit: if a population grows 10 % each year, and the present population is 5000, then the next year the population will be 5000 * 1.1. The factor 1.1 is the factor of multiplication over one year. What could be the population after two years? After three years? After half a year? Each unit of time has its own factor of multiplication.

The emphasis shifted from just following the formal definition to the calculation of factors of multiplication per unit of time or parts of the unit. These factors of multiplication were taken as the intuitive basis for rational and negative exponents. The link between the early definition of

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

exponents and the new factors of multiplication using roots and powers of roots was actively pursued.

A major part of the conjecture was a procedure to solve exponential equations by finding the decimal digits of the exponents. The conjecture was that through this procedure students would create, discuss, and get familiar with decimal exponents and their relations to the laws of exponents for rational numbers, the place value system for decimal exponents and an alternative interpretation of the zero exponent.

## Empirical and Theoretical Background

Many textbooks define $A^N$ as A*A*A*….*A with N factors of the number A. $A^1$ is defined as A and $A^0$ as one (1). Researchers have commented that these definitions together with those for rational and negative exponents represent an inconsistency in terms of presentation, language, and /or meaning of exponents compared with the early definition, in this paper the common definition, of exponents (Lockhead, 1991).

*Empirical Studies on Multiplication and Exponential Forms*

Many problem areas in learning and understanding multiplication have been identified in empirical studies on multiplication and exponential forms. Studies by Bell, Fischbein, & Greer (1984), Ekenstam & Greger (1983), Tirosh & Graeber (1986), have identified misconceptions about multiplications and divisions with decimals and fractions. Students' struggles with word problems involving multiplicative contexts with or without fractions were documented by DeCorte, Verschaffel & Van Collie (1988), Taber (1991). Others, like Boulet (1998), Mulligan & Mitchellmore (1997), have studied ways to conceptualize multiplication and to link it to models of repeated multiplication of smaller and smaller units. An important step was made when Confrey and her colleagues created the splitting model of multiplication to propose an intuitive model for exponential multiplication. Teaching experiments testing the model suggested a strong learning potential of the model for visualizing exponents and multiplication (Confrey & Smith, 1995).

*Students' Understanding of Definitions*

Rational and negative exponents are defined in textbooks by relying completely on a definition. Natural exponents refer to actions that are clear and meaningful to the student. Definitions that have a strong familiar side and tend to be immediately clear to students are classified as "logical" definitions (i.e., logical for the learner!). Definitions that rely on features and characteristics of a concept and rely solely on these properties are classified as "lexical." Students, even in mathematics, seem to have problems with lexical definitions (Edwards, 1997; Edwards & Ward, 2004). What they develop over time is a concept-definition and a concept-image. These are cognitive structures associated with the concept or the definition and constructed based on experience mostly (Tall & Vinner, 1981). Students can also show considerable skill in computations with a concept without being able to explain what the steps mean or how to attach conceptual meaning to the symbols involved in the computation (Owens & Super, 1993).

*Theoretical Framework of Understanding of Mathematical Concepts*

Herscovics, Bergeron and Goldin developed a framework for the concept of mathematical understanding with three components. The first component deals with intuitive (visual, perceptual) understanding, logical-physical and procedural understanding, and logico-physical abstraction. The second component describes the emergence of mathematical concepts through logical and procedural understanding, mathematical abstraction and formalization. At each stage the learner constructs conceptual schemes that involve layers of knowledge for problem solving. The construction of notions of invariance of operations, generalizations, and more abstraction are part of the second component. The more advanced the mathematical concepts, the less physical pre-concepts and more prior mathematical concepts are involved (Goldin & Herscovics, 1991). The third component of the framework is the theory of internal and external representations. External representations are symbols, diagrams, notations, graphs, equations, in general tools for thinking. Internal representations are inferred mental constructions, and cognitive conceptual schemes. Language, including definitions, visual, kinesthetic systems etc., are all part of internal representations. External and internal representations form one system that also includes affect (Goldin, 1998; Goldin & Herscovics, 1991). External systems are sometimes expressions of internal systems, while external systems can be internalized. The learner constructs her/his internal representation through acts interacting with tools and systems. Internal representations can also interact and mediate the working of other internal systems (Goldin, 1998).

*Encapsulation of processes.* In the Goldin-Herscovics-Bergeron model of mathematical understanding (Herscovics & Bergeron, 1988; Goldin & Herscovics, 1991) it is not clear how learners' knowledge evolves from first actions to mature mathematical concepts. APOS theory by Dubinsky (1994) provides a framework. Actions (A) on physical or mental (mathematical) objects are internalized by the learner and (can) become processes (P). When the internalized process has evolved to the point that the learner can reverse or transform such processes and actions mentally, it takes on the form of a mathematical object (O) for the learner. This is the stage of encapsulation. The learner thinks or talks about a process or an operation from a global, structural, point of view. She/He can perform actions on the mental image of the process as if it was an independent object. The whole mental construction becomes part of a new scheme (S).

## Methodology

Five undergraduate students at a large Midwestern university were first selected based on their willingness to be interviewed and to participate afterwards in a four week teaching experiment. One student was a freshman, two were in their second year and had completed pre-calculus classes with the researcher, and two were in the education program in their third year and had completed calculus classes successfully. The students are given fictitious names and are called Ann, Chandra (both female), Bob, Dennis, and Eddy.

The research started with the pre-interview: a semi-structured interview, lasting a little over one hour, conducted by the researcher with each student separately. The interviews were audio taped and then transcribed. The purpose of the pre-interview was to document the knowledge and understanding of rational and negative exponents of each student at the beginning of the teaching experiment.

The five students then participated in a videotaped teaching experiment of four weeks to test the effectiveness and impact of an alternative route to teaching and justifying exponents and improving the understanding of decimal exponents. In the teaching experiment the zero exponent was treated separately in two different contexts. Once as related to smaller and smaller fractional exponents that tended to a factor of multiplication of one. And later, as related to its role as a place holder in the decimal representation of exponents when solving exponential equations. The students were again interviewed separately after the second, the third and the last week of the teaching episodes. These interviews were semi-structured and audio taped. After the conclusion of the teaching experiment the post-interview was conducted separately with each student, using the same questionnaire as the pre-interview.

The video tapes made during the teaching experiment were studied in various cycles to extract as much as possible relevant material for transcription and analysis. The pre- and post-interviews together with the data from the interviews conducted during the teaching experiment provided a basis for studying changes in the students' ideas and their understanding of exponents

## Results

*The Role of the Laws of Exponents*

The Laws of Exponents (LOE) operate for all the students as basic properties for computational purposes. Each student in the study was able to work with positive integer exponents using the LOE "spontaneously." Only one student (Dennis) was aware of the actual name of LOE. All the others just focused on knowing the specific properties that were needed to work with exponents. The first conclusion is that the Laws of Exponents functioned at the computational level for the students.

The notion that the LOE would act as a collection of properties for understanding the invariant patterns or properties for all exponents and thus would provide a strong basis for creating rational and negative exponents was not confirmed. The most powerful concept image of all the students turned out to be the Common Definition of Exponents (CDE). This well established network of ideas states that an exponent represents the number of factors in a repeated multiplication of a certain unit or base number. The concept implies the existence of a base, or a unit, a stage of multiplication, and the presence of a sufficient number of factors to be multiplied.

*Students' Understanding of Rational and Negative Exponents*

The CDE is more powerful than the LOE in forming the notion of students in their efforts to understand what rational exponents or negative exponents are. All the students reported serious conflicts in their learning activity when trying to explain what these rational or negative exponents were. From a learning perspective, the most important activity was the effort of the students for overcoming the notions of the CDE as a basic but conflicting set of ideas for expanding the concept of exponents.

The zero exponent exposed the limitations of the traditional approach to exponents further. All students reported a conflict in trying to apply the CDE to the zero exponent. When asked to explain the zero exponent they all expressed reservations as to the justification for the value one assigned to powers of zero. Only Dennis, the freshman offered an (incorrect) explanation why the value should be one. All students mentioned the authority of the teacher as a basis for accepting the value of one (1) for zero exponents. None invoked the laws of exponents as a basis for their beliefs. Each student expressed the feeling that the value one was either "weird" or that it should be zero, because there were "no factors."

All the students seemed to show attempts to explain their images of exponents of various kinds by trying to fit these new notions of exponents into the definition that they knew and understood fully, the Common Definition of Exponents (CDE). The zero exponents were conceived as finding a multiplication when zero factors are used or as a special case with an explanation that seemed plausible, but avoided answering the question how the CDE is related to the value of 1. The negative exponents also presented challenges, voiced by students as "weird" or "unacceptable," or "you can't have negative exponents," or they referred to the "school teachers" to justify the meaning of negative exponents. The fact that there was no apparent conceptual connection for the students between the CDE and the traditional definition of negative exponents did not stop them from applying the working definition of negative exponents and solving problems. The authority of the teachers, the school and the existence of "answers" probably overruled their concerns. With the rational exponents the basic picture was similar in the sense that the CDE seemed to function as the point of departure for interpreting the given definition. No reference was made to rational actions to be applied to the underlying properties of roots and powers. This notion that all you needed was the value of the exponent seemed to be connected also to the unambiguous world of the CDE where one given exponent fixes the value of the expression.

Each of the five students showed some hesitancy or uncertainty about how one knew if one given number is a power of another given number. The common operations with exponents seemed to go one way only: given a base and a number, find the value when the base had that number as an exponent. The reverse action seemed quite unfamiliar to the students. This problem would re-appear when the chain of multiplications was proposed in the teaching experiment.

The CDE seemed to be the only concept that had a clear operational process and a meaningful interpretation for the concept of exponents for the students. The lack of a meaningful extension and development of the CDE into a broader notion that reconciled the CDE with the new definitions for the zero exponent, the rational exponent and the negative exponent made it unlikely that students like those interviewed would develop on their own, an overarching concept of exponents that was applicable to all types of exponents, from integers, to zero, to rational and negative numbers.

When asked to explain what $5^{1/3}$ meant to them they were able, after some hints, to explain what that symbol stood for. Chandra and Dennis commented that $5^{1/3}$ did not mean 1/3 times the factor 5. Chandra saw the definition as problematic: "How do you multiply the number five 1/3 times? That's impossible." The equality of forms like $5^{1/3}$ and $5^{2/6}$ were not connected to radicals and their properties, but to the fact that 1/3 = 2/6. Only Anna and Chandra were able to explain after some hints, how the decimal digit in $3^{2.1}$ could increase the value of $3^2$ from 9 to 10.045…

The conclusion is that the laws of exponents did not provide the students with sufficient support to build an understanding of rational, negative or the zero exponents. The definition based on counting factors (common definition) was still the lens through which students tried to understand exponents of all kinds. Much more cognitive support was needed to build strong understanding of rational and negative forms of exponents for these students.

*Impact of the Teaching Experiment*

The biggest hurdle for the students was to understand that the model for population growth was not linear in its mechanics. Their initial ideas involved using linear and additive thinking models to find rates of change over multiple periods or over parts of a period. If a population grows by 10% each year then why is it not growing 20% over two years? If a bacterial population grows by 100% each three hours why does it not grow 33% per hour? The central role of factors of multiplication and the multiplicative nature of the process required extensive work and discussion.

A procedure for numerically solving (without the use of logarithms) exponential equations like: find A if $5^{A} = 10$, made students create their own versions of the procedure. This part was internalized by the students with minor problems. The problems were associated with how to handle and explain digits of zero in exponents like $3^{2.0959} = 10$.

Students struggled with the requirement in the teaching to justify the rational properties of fractional exponents from the properties of radicals and powers of radicals. This was most pronounced for Bob, Dennis, and Eddy. They stated never to have been exposed to such knowledge before. All roots had to be checked with numerical examples and calculators by these students to convince them of certain properties of radicals.

Negative exponents were introduced using three perspectives. The first focus was on the graph along the x-axis to find previous population numbers by dividing by the factor of multiplication. This was explained as a “backward” movement of exponents associated with directed numbers in ordinary subtraction. Then the functions $F(x) = a^x$ and $G(x) = (1/a)^x$ were compared and found to be symmetrical with intersections at X = 0. Finally the symmetry was used as a way to solve exponential equations like, find X if $(0.8)^X = 10$. Finding Y in $(1.25)^Y = 10$ first, then using the symmetry to understand that X = -Y provided a solution for the first equation.

All the students accepted the metaphor of backward movement for the exponents. Bob did not fully understand the use of symmetry for solving equations, but accepted the “backward movement” idea associated with the division. He even proposed the term “factor of division” for the number used. Ann and Chandra repeatedly used the metaphor themselves, while Eddy created his own symbolic representation to describe his understanding of negative, positive and zero exponents by what he called “forward, backward and no movement at all in the graph.” Dennis vacillated between using the metaphor and using his high school method of replacing negative exponents by finding the inverse of the base.

The post-interviews revealed that Ann and Chandra were able to formulate a general, single definition of exponents that applied to rational, decimal, zero and negative numbers for exponents. The other students were not able to do that, but none mentioned weirdness or inconsistency again. Their definitions were still the common definition with special cases for rational and negative exponents. Dennis still stuck to his definition of zero from high school, but all the others linked the zero exponents to the fact that higher roots of a number tend to produce numbers like 1.0000… with expanding rows of zeros. This was associated to a final value of 1 for exponent zero.

## Discussion

The teaching experiment did not result in all students being able to voice a generalized notion of exponents that applied to all possible numbers. Two students did reach that stage however. They were the students who had studied calculus and seemed to be more mathematically mature compared to the other students.

There is still more research to be done to find out what is needed beyond what was offered in the teaching experiment that can guide students to understand fully what exponents stand for and how the original laws can be extended to fractions, decimals, negative and even irrational exponents. The method to show how exponential equations can be solved numerically can possibly be used to help students understand intuitively what logarithms are.

*We report results from a larger study using a mixed-methods approach to examine the relationship between changes in attitude and achievement using the connected SimCalc MathWorlds® environment. Aspects of students' anxiety linked to sharing work publicly declined during our curriculum intervention. This was significantly correlated with increases in student knowledge and interpretation of multiple representations of functions. Similarly, positive change in student attitude towards technology was related to increases in knowledge of algebra concepts related to linear functions. After analyzing video data, we believe positive student outcomes result from increased motivation through active and mathematically-meaningful participation in the classroom.*

## Background

SimCalc MathWorlds® software (herein referred to as SimCalc) allows students to create mathematical objects on graphing calculators and see dynamic representations of these functions through the animations of characters whose motion is driven by the defined functions. Students are then able to send their work to a teacher's computer. Calculators are connected to hubs that wirelessly communicate to the teacher's computer via a local access point. The flow of data around a classroom can be very fast allowing large iterations of activities to be executed during one class.

In our intervention, we included activities that allow students to create functions in SimCalc on the TI-83 Plus or TI-84 Plus graphing calculator which can then be collected (or "aggregated") by a teacher into the SimCalc software running in parallel on a computer using TI's Navigator Wireless network. The activities are part of a curriculum, developed and refined over many years, that focuses on core high school Algebra ideas such as linear functions, simultaneity, covariation, and slope-as-rate — rather than slope as $m$ in the equations, $y=mx+b$. The activities utilize Classroom Connectivity (CC) in new ways to supplement or replace existing traditional algebra curriculum (Hegedus & Kaput, 2004).

We report some specific findings from a larger quasi-experimental study where we investigated the implementation of SimCalc—a dynamic software and curriculum package—in regular U.S. high school classrooms. In particular, we focus on the impact of our resources on student motivation and attitude, and its correlation with mathematical performance. Significant learning gains by high school Algebra 1 students were measured across a 3-6 week quasi-experimental intervention conducted in several ninth grade Algebra 1 classrooms across two medium- to low-achieving districts in Massachusetts, U.S., with teachers of varying experience

## Theoretical Perspectives

Our connected approach to classroom learning is reiterated in seminal works that highlight the potential of classroom response systems to achieve a transformation of the classroom-learning environment (Bransford, Brown & Cocking, 1999). Similarly other investigators have expanded their approaches to include devices that allow aggregation of mathematical objects submitted by students (Wilensky & Stroup, 2000). Linking private work in a mathematically meaningful way through networks, and displaying the aggregations of whole class work, potentially enhances students' metacognitive ability to reflect upon their own work in reference to others (Huffaker & Calvert, 2003). These activities create an intrinsic motivation context with a socio-cultural view to "motivation in context" (Hickey, 2003) that is also intrinsically mathematical, accomplishing a much more intimate intertwining of motivation and mathematics that can be typically accomplished in existing classrooms.

## Research Questions

In this paper, we focus on one particular SimCalc class, taught by an experienced SimCalc teacher, with respect to changes in attitude and learning gain. We explore the following questions:

- What relationship(s) exists between student gains in performance on pre- and post content tests and measures of attitude?
- In what ways might attitude influence performance gains?
    - Which classroom behaviors and/or interactions suggest an attitude–performance connection?
- How might the SimCalc environment impact relationships between student performance gains and attitude?

## Methodology

*Sample*

Five teachers in a total of eight classes in two school districts participated in the larger SimCalc study. The remaining Algebra 1 classes in each district, eight in total, were used as comparison classes. Algebra 1 is typically taught in ninth grade where students are 14-15 years old. The teachers involved in the study were not randomly chosen; rather they agreed to be a part of the project for various reasons. We chose the single SimCalc classroom on which to focus our paper based upon the robustness of the relationship between the variables we wished to investigate, i.e., performance gain and attitude.

*Data Collection*

Motivation was measured using pre- and post-intervention attitude surveys. The student survey used to measure attitudes and beliefs about mathematics, school, and technology was comprised of 27 items that participants responded to on a Likert-type scale ranging from "0 – Strongly Disagree" to "4 – Strongly Agree." An example item was, "I think mathematics is important in life."

Video data was collected for each class in the SimCalc group and one class in the comparison group during the intervention. Each class was recorded with two digital cameras. One of the cameras was focused on the teacher and the whiteboard space where connected SimCalc was projected. The other was positioned at the front of the class and was focused on the students using a wide-angled lens to pan out and observe whole class dynamics and small group interactions. Both cameras were used as roaming cameras when the class was involved in small group work. Video data was collected for twenty-six classes, each class lasting approximately fifty-five minutes for the SimCalc class in this case study. A second researcher took detailed field notes of the classes. Selected students were interviewed at the end of the intervention. Classroom video episodes were used as a qualitative component that re-enforced our quantitative findings because surveys and/or structured interview analyses do not always accurately reflect the attitude/affect of a student (Goldin, 2008; Ma & Kishor, 1997; Schorr & Goldin, 2008).

The instrument used to measure learning gains was a mathematics content test compiled from various state high-stakes state tests used to determine school success for No Child Left Behind (NCLB) accountability. The 22 item pre- and post-test included twenty multiple choice items worth 1 point, one short answer question worth a maximum of two points, and one long answer question worth a maximum of four points.

## Results

*Quantitative*

Our initial analysis focused on student gain in specific content areas and on changes in attitude. Our goal was to identify patterns of change and potential relationships between various dimensions of the data.

The content test was broken down into concept categories: graphical interpretation items (41% of the test), proportion and rate items (23%), recognizing and determining a pattern items (9%), and multiple representation items (27%). These groups did not include the long answer open response item, which was omitted due to a low response rate by both treatment and comparison groups. The SimCalc group showed gains on each category of the content test. In particular, the SimCalc students had a significantly greater gain than the comparison group on multiple representation items $t(322)=3.069$, $p<0.01$. These items dealt with generalizing relationships across representations. Conceptual transfer across multiple representations of a mathematical concept or object is an important theme in mathematics education and one of the National Council of Teachers of Mathematics process standards (NCTM, 2000).

We conducted a principle components analysis on items from the student attitude survey, which produced a four-component model that accounted for 48% of the total variance. We categorized these into four broad components that coincided with our theoretical model of attitude: *Deep Affect/Beliefs not subject to casual change (20.8%)*, *Anxiety (11.4%)*, *Preference to work alone (8.5%)*, and the *Perception and Use of Technology (7.3%)*. Based on this analysis we computed weighted composite scores for each dimension on the survey to allow us to measure change in attitude over time. Table 1 below displays descriptive statistics for each subscale used in the analysis from our sample population.

*The SimCalc case study class.* The case study class demonstrated gains in both performance and attitude when compared with the aggregated treatment and comparison groups. This class had a lower score mean score on the pre-content test than the aggregated treatment or comparison groups. However, the case study class demonstrated greater content gains (2.42) from pre to posttest than either the treatment (1.99) or comparison (.96) groups. They also had higher mean scores on the pre-survey for the *Deep Affect* subscale (11.3, compared to 10.6 for treatment and 10.4 for control), and the *Anxiety* subscale (9.0, compared to 8.4 for treatment and 8.3 for control), and recorded a greater gain (.40 and -1.2 respectively) than the other two groups (-.19 and -.27 for treatment and -.48 and -.07 for control).

Table 1
*Descriptive Statistics for Attitude and Content Test Sub-scales on the Pre Survey and Pre Content Test for all Classrooms in the Study*

| | | N | Mean Initial Score | SD | Min | Max |
|---|---|---|---|---|---|---|
| Content Test | Content Test Score (0-26)* | 396 | 10.2 | 3.6 | 1 | 19 |
| | Graphical Interpretation (0-9)* | 396 | 5.1 | 1.6 | 1 | 9 |
| | Proportion and Rate (0-6)* | 380 | 2.9 | 1.8 | 0 | 6 |
| | Recognizing and Determining a Pattern (0-2)* | 396 | .36 | .48 | 0 | 1 |
| | Multiple Representations (0-6)* | 396 | 1.8 | 1.4 | 0 | 6 |
| Student Survey | Deep Affect | 301 | 10.5 | 3.6 | 0 | 18.2 |
| | Anxiety | 296 | 8.3 | 3.4 | 1.1 | 18.7 |
| | Preference to Work Alone | 304 | 3.2 | 2.5 | 0 | 9.3 |
| | Perception and Use of Technology | 301 | 5.7 | 2.1 | 0 | 10.9 |

*The range of scores for the subscale

A larger positive gain on the *Deep Affect* subscale implied that students chose higher agreement responses on items describing math as interesting and important. This gain also suggested a more positive overall attitude toward school at the end of the intervention than at the beginning. Similarly, the case study class had a larger negative gain for the *Anxiety* subscale, which suggests students were less anxious at the end of the intervention then they were at the beginning. The case study class had a lower mean for the *Perception and Use of Technology* subscale on the pre-survey (5.3) but had the highest positive gain among classes (.36). The gain for the aggregated treatment group was negative (-.20) indicating that they enjoyed technology slightly less than they had at the beginning of the intervention.

We explored the relationships between changes in attitude and gain in content knowledge by analyzing a correlation matrix of these dimensions (Table 2). Most notably, changes in anxiety and preference to work alone were correlated to gain on the multiple representations subscale. A regression analysis confirmed that *Anxiety* significantly predicted gain on this subscale, $ß=-.39$, $t(16)=-2.82$, $p=.012$. *Anxiety* also explained a significant portion of variance in gain scores on this factor, $R^2=.33$, $F(1, 16)=7.96$, $p=.012$.

Table 2
*Correlations between Gain on the Content Test Subscales and Changes in Attitude Subscales for the Specific SimCalc Class*

| | Mult. Rep. Gain | Gain in Graph Int. | Change in Deep Affect | Change in Anxiety | Change in Work Preferences | Change in Perception and Use of Technology |
|---|---|---|---|---|---|---|
| Total Gain | .711** | .764** | .327 | -.422$^{\dagger}$ | .370 | .460$^{\dagger}$ |
| Mult. Rep. Gain | | .261 | .214 | -.576* | .515* | -.047 |
| Gain in Graph Int. | | | .336 | .004 | .350 | .535* |
| Change in Deep Affect | | | | -.389 | -.007 | .633** |
| Change in Anxiety | | | | | .065 | -.016 |
| Change in Work Preferences | | | | | | -.004 |

*p<.05, **p<.01, $^{\dagger}$ p<.1

*Qualitative*

In the video data collected in our comparison classrooms, and at the beginning of the SimCalc intervention for this particular class, students were seated in rows, answered teacher questions when called upon, and the Initiation-Reply-Evaluation sequence was the primary discourse method of the class (Wertsch & Toma, 1995).

Towards the end of the SimCalc intervention, the classroom discourse in this specific SimCalc class was quite different. Dialogic function was evident as students actively questioned, reacted to, and transformed the ideas and utterances of their peers, their peers' work and their own work (Wertsch & Toma, 1995). We propose that these illustrate the significant learning and, more importantly, the correlation with attitudinal changes that are evident in our measurements presented above. The particular classroom episode on which we have focused is not an outlier. This episode is a representative sample of the class from the latter portion of the intervention that exemplified the discursive and pedagogical practices that may be attributed to significant changes in our content and motivation sub-scales. In this episode students worked on an activity called *Coming Together*. In this activity students created a motion for a SimCalc actor, B, such that B started at 2 times their group number of feet (each group was assigned a different group number) and ended in a tie with Actor A. Actor A was defined by the function: y=2x on a domain of [0,6]. Students built a function expression to fit the goal of the activity. Once students developed their functions, the teacher collected them. Before any student work was shown the teacher conducted a class discussion. A discussion about the motion began when the teacher asked what would happen when she ran the animation.

(1) S5: We're all gonna go different speeds but we're all gonna end at the same position cause that uh end at
(2) Teacher: Where is everyone going to be at the end of the motion?
S4: Not all different speeds.
S6: 12.
(5) S1: 12.
Teacher: 12 what?
S1: feet.
Teacher: Feet. Right okay... So at the end
S4: They're gonna be at point (6,12).
(10) S5: Group 6 isn't gonna move. {S5 is in group 6}
S8: yes we move. We go like this. {In the air with her pointer finger outstretched, she gestures a horizontal line}
S4: They go sideways.
S1: No they don't move, time goes on.
S9: Cause they start at 12.
(15) S1: Yeah.
S3: It's like they already won.
S4: It's like they're at rest.
S5: Yeah but on the world we don't move.
S4: They're resting for 6 seconds.
(20) Teacher: S5 says in the world Group 6 is not gonna move.
S1: Yeah.
S3: No, they're not gonna move at all.

S3: That's right. They just stay there.
Teacher: Do we agree with that?
(25) *{Multiple students reply with yeah}*
S8: Yeah but time is moving.
Teacher: Time is moving but they aren't.
S1: Yeah cause you'll like see everyone else move but them.

In this excerpt, the teacher repeated what a student said twice, and facilitated the conversation three times: once to ask a question, once to clarify the units, and once to see if the class has come to an agreement. Student agency was evident as they debated their work and the work of their peers (lines 9-19). The students in Group 6 started at 12 feet and must end at 12 feet, therefore their character would not be moving. The students were building their understanding of how time and position co-vary.

In line (9), a student responded with a multiple representational answer. The class was discussing the motion, which is measured in feet, but his answer was in terms of the graph, the line segments would "end" at the point (6,12). Time was implicit in the motion.

Line (2) showed the teacher accepting the first response and then attempting to ask a different question. S4 did not agree with S5 and he initiated a discussion. While his comment was not addressed in this except, S4 followed up a little later in the class again saying, "not all different speeds." S4 then explained that some groups would have the same speed, but different velocities, because they were traveling in a different direction. He also conceptualized the symmetry that was created in the class' set of motions and graphs as evidenced by his discussion of the slopes of the line segments that followed later in the class:

S4: We were the opposite of them. We were their opposite.
S6: And so then the next two...
S4: Cause they were 2 and we were negative 2
Teacher: So the slope. So you think group...you were saying group 4…
S6: 5 and 7 I think
Teacher: So group 5 and group 7 had opposite slopes?
S6: Yeah
S4: And group A and group 4

The SimCalc activities allowed discussions to emerge that were not present prior to the intervention. The students talked to one another about the mathematical objects they created on their calculators and that had been aggregated by the teacher. The networked classroom appeared to have enhanced a rich set of communication events where analysis of mathematical variation was brought to a social plane and where students could understand the core mathematical ideas in focus from a collaborative perspective. (Hegedus, Dalton, Cambridge et al., 2006).

The rich collaborative communication continued as the teacher asked students what the class set of graphs would look like when she displayed them. The students began using metaphors to describe this. A few students mentioned the set of graphs would look like a fan or a rake with the graph of Group 6 as the *handle of the rake* because it was perpendicular to the y-axis. The teacher followed up students' initial response with her own metaphor.

Teacher: How about if I see it as a hand?
S1: Yeah I can see it as a hand.
S2: Kinda, skinny hand.
S: No.
S1: Yeah huh cause look.

S3: A hand with six fingers on it?
S9: Doesn't make sense.
S1: Yeah, a hand.
S4: Yeah a hand with 6 fingers {laughs}.
Teacher: Think about it though. What would be your y-intercept? Where would your y-intercept be?
S9: Your pinky.
S4: At the webbings.
S9: That doesn't make sense.
Teacher: Pretend there's an extra one [an extra finger]
S3: That would be where they end though {See image 2 where S3 is referring to the "webbings" or palm of his hand}
Teacher: That would be where they end—I'm sorry. You're right. So what would my palm be? My palm would be where they?
S3: End. {Referring to the point (6,12)}

Within one activity, students relied on three major representations SimCalc offered them to make deductions on the behavior of the family of functions. They used this knowledge to help them derive a function rule that can be generalized for any group in the class. The group relied heavily on the animation space and graphs to understand which groups would have a negative and positive slope, which was at the heart of their debate.

Throughout this entire classroom episode, the teacher acted as a mediator. She prompted or guided students if they were stuck but provided students an opportunity to make their own discoveries. The students debated and argued about the underlying mathematics. They challenged each other and made conjectures, correct or not, with the goal to derive a general expression and understand its meaning.

## Conclusion

Several aspects of learning in the SimCalc environment may contribute to lower anxiety measures. While this research is in its early stages, we speculate that three effects may be at work: (i) SimCalc provides a malleable environment with which to explore concepts in personally meaningful ways, (ii) students can make numerous conjectures, some of which may be false, before coming to a final answer, and (iii) the use of multiple representations in the curriculum and software provide for the deliberate generalization of concepts.

At this point, there are many potential explanations for motivation/learning performance relationships in SimCalc classrooms. As longitudinal data accumulates, we will investigate the connection between attitudinal changes and gains in performance using larger sample sizes and more refined analyses. We will also explore whether our hypothesized factors—the richness of the SimCalc context, the reduced emphasis on “one right answer”, and the explicit transfer of concepts to a variety of mathematical representations—contribute to such changes.

# A CONCEPTUAL CHANGE LENS ON THE EMERGENCE OF A NOVEL STRATEGY DURING MATHEMATICAL PROBLEM SOLVING

Mariana Levin
University of California, Berkeley
levin@berkeley.edu

*This paper reports on an analytic case study of a pre-algebra student who makes a surprising and significant mathematical discovery over the course of several episodes of problem solving. The research reported in this paper is motivated by the goal of understanding how and why the student's strategies shifted from a simple, yet purposeful, guessing and checking approach to a sophisticated approach based on linear interpolation. The paper illustrates how a conceptual change framework developed in the science education literature can provide useful analytic tools for understanding shifts in problem solving strategies in terms of underlying conceptual refinements and reorganization.*

## Introduction

The phenomenon of interest in this paper is how new strategies emerge during mathematical activities, such as problem solving. Microgenetic analyses of strategy change (See Siegler, 2006 for a review) have focused on developing techniques for tracking shifts in strategy usage at a fine grain level of detail. While we share this attention to fine-grained analyses, our focus in the line of research reported in this paper will ultimately be on the processes by which an individual constructs a novel strategy from existing conceptual resources as opposed to the processes by which individuals come to reliably activate and use one strategy over another competitor strategy. In other words, the approach proposed by this research project is to re-frame analyses of strategy change in terms of underlying conceptual change. We will illustrate how an analytical approach known as "knowledge analysis" (diSessa, 1993; Sherin, 2001) for studying growth and change of conceptual structures can provide useful analytic tools for understanding the shifts in problem solving strategies that come about due to underlying conceptual refinements and reorganization.

To illustrate the potential of this approach, we will explore a case study of a pre-algebra student, Liam, who largely independently re-invents a deterministic and essentially algebraic problem solving strategy, known as linear interpolation, through the activity of solving algebra word problems using a purposeful guessing and checking strategy. Previous research has documented that students use informal problem solving approaches such as guessing and checking prior to instruction with algebraic solving techniques (Johanning, 2004, 2007; Kieran, Boileau & Garançon, 1996; Nathan & Koedinger, 2000; Stacey & MacGregor, 2000). However, the conceptual nature of students' guessing strategies and what kind of mathematical ideas can potentially be developed as a consequence had not previously been objects of extensive study. One reason for this is that the prior studies of students' pre-algebraic problem solving approaches were based primarily on written records and hence did not offer access to the richness and learning potential of students' informal strategies.

The case shared in this paper offers a surprisingly clear demonstration of how important algebraic ideas such as function, co-variation and rate of change can emerge and be developed through the successive refinement of informal problem solving strategies. Such potential for the development of algebraic reasoning is discussed in Levin, 2008. An important contribution of

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

the current research is the explicit identification of key knowledge resources that are activated and used as the student constructs the linear interpolation strategy. Thus, the specifics of the case of Liam are new to the literature on the development of algebraic thinking, but beyond that, the case of Liam is an interesting site to begin elaborating theoretical and analytical tools for studying the growth and change of knowledge (i.e., conceptual change) in mathematics, and is thus of more general interest.

## Theoretical Framework

In this paper, the "knowledge in pieces" epistemological perspective proposed by diSessa, (diSessa, 1993) is adapted to analyze the conceptual underpinnings of an observed strategy shift in the case of Liam. In this theoretical perspective, an important underlying assumption is that individual knowledge can be thought of as a complex system comprised of many knowledge elements of diverse types. As individuals learn and gain in expertise, activation of relevant knowledge elements becomes more appropriately context sensitive and coordinated as ensembles of elements. DiSessa, 1993 and Sherin, 2001 argue that it is fruitful analytically to engage with the complexity of individual knowledge systems by defining a base vocabulary of sub-conceptual primitive knowledge elements. One reason this is argued to be useful analytically is because important features of expertise may manifest themselves only at the level of primitives.

## Data Collection and Methodology

The data corpus for the Liam case study includes video and written work collected over the course of six individual semi-structured tutorial sessions with a researcher, each approximately one hour in length. Liam was one of six pre-algebra students participating in this study aimed at analyzing students' emergent understanding of variable and letter-notation using a curricular tool, a Guess and Check chart, as suggested by a widely-used algebra curriculum (Sallee, Kysh, Kasimatis & Hoey, 2002). The Liam data corpus was selected for extended analysis because of the unexpectedly rich conceptual development that occurred during the sessions. The analysis of video and transcripts of problem solving in this study allowed access to students' real-time reasoning as they solved problems. Video data was transcribed for analysis, annotated with relevant details such as students' gestures, and coordinated with written work artifacts.

## Research Questions

1. How can we characterize Liam's conceptual understanding in a way that will make tracking moment-by-moment shifts in understanding analytically feasible?
2. What conceptual understandings did Liam develop between two contrasting episodes that may have allowed the observed change in problem solving strategy to occur?

## Background and Context

Liam is a pre-algebra student who initially approached solving word problems using a purposeful guessing and checking approach, which he devised (as research shows that many students do) without any previous instruction about how to solve such problems. Over the course of several individual sessions, he refined his purposeful guessing and checking approach, organized in tabular form, to an essentially algebraic algorithm (linear interpolation) for solving word problems. The linear interpolation strategy we will examine in this paper emerged naturally over the course of the sessions with Liam, and was not something that was explicitly designed to be part of the sessions with the tutor/researcher.

Data excerpts illustrating the approach taken by Liam at the beginning and ending of the sessions are given below. One can see that while Liam's initial approach was based on purposeful guessing and checking, his later approach is deterministic, building off the linear structure underlying the problem contexts, and in fact no longer involves "guessing" at all.

**Episode One**: **Systematic and Purposeful Guessing and Checking**

In this first focal episode, one observes that Liam is using a purposeful, systematic guessing and checking approach to solve the given word problem. This problem was the first in the series of sessions where the tutor had suggested that Liam organize his guessing and checking strategy in a Guess and Check chart. Previously, Liam had used the invented strategy of "guessing and checking," (though not arranged in a chart).

*The base of a rectangle is three more than twice the height. If the perimeter of the rectangle is sixty inches, find the height and the base of the rectangle.*

Below is a reproduction of the chart Liam constructed, along with excerpts from the transcript coordinated with his activity with the chart.

| Height | Base | Perimeter | 60 Check |
|---|---|---|---|
| 18 | 2(18)+3=39 | 36+(39+39)=114 | ↑ |
| 10 | 2(10)+3=23 | 20+46=66 | ↑ |
| 8 | 2(8)+3=19 | 8+8+19+19=54 | ↓ |
| 9 | 2(9)+3=21 | 9+9+21+21=60 | = |

"Oh. So it's actually a lot lower. I just realized that."

"This is way too much." … "Almost twice as much. So I'll try with 10."

A little too high…

"It's probably nine."

"Well, it was actually definitely 9 if this [result for guess of 8] was too low and this [result of guess of 10] was too high. Unless it was a decimal number."

*Figure 1.* Transcript from Liam's problem solving approach in episode one in which Liam used "successive approximation" to find the solution to the word problem. The chart is a typed reproduction of Liam's work.

Already in episode one, Liam is already making very purposeful choices about the sequence of trial values he constructs. Certainly, his choices of guesses are far from "random." In fact, he already appears to have an approximate sense for how the input/output pairs he generates co-vary linearly. One can also notice that he is making inferences in terms of both "scalar" judgments ("a little too high") and also "proportional" judgments ("it's a little less than twice" the target value).

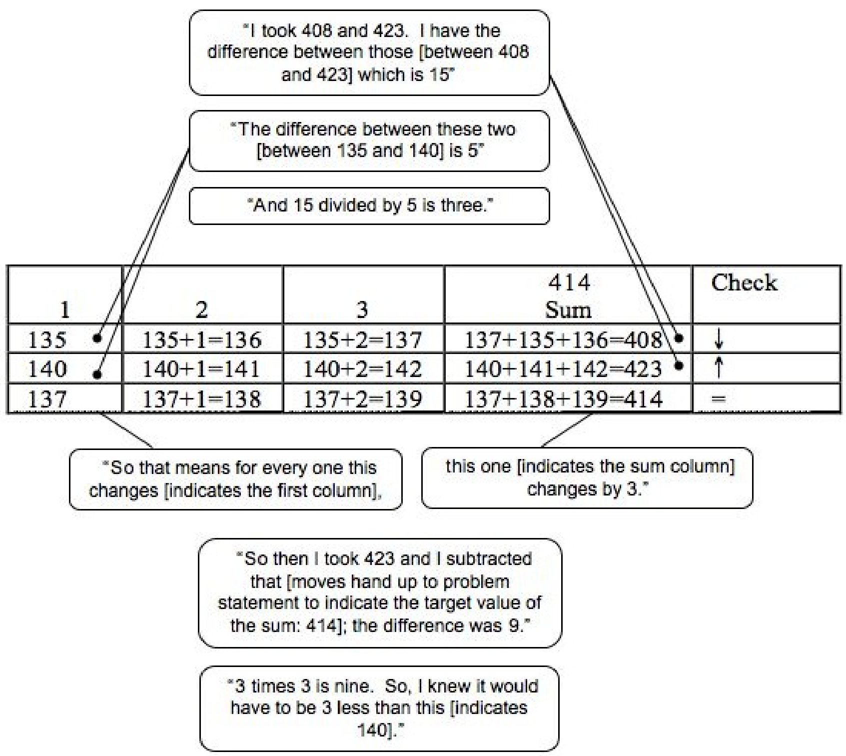
### Episode Two: Leveraging Linearity to Solve Problems

Later in the series of sessions (session 5 out of 6), Liam had refined his strategy from merely "purposeful guessing and checking" to "linear interpolation." In this data excerpt, one can see Liam deploy his newly constructed linear interpolation strategy to solve a problem of a similar underlying (linear) form as in focal episode one. The problem he was working on this episode was:

*The sum of three consecutive integers is 414. Find the three integers.*

In solving this problem, Liam continues to organize his work in a "guess and check" chart (a typed reproduction is pictured below). After having solved the problem and when asked to explain his solution strategy in this later, contrasting episode, Liam says

*"I took 408 and 423 [see chart below]. I have the difference between those [between 408 and 423] which is 15. The difference between these two [between 135 and 140] is 5. And 15 divided by 5 is three. So that means that for every one this changes [indicates the first column], this one [indicates the sum column] changes by 3. So, then I took 423 and I subtracted that [moved hand up to problem statement to indicate the target value of the sum: 414]; the difference was 9. 3 times 3 is nine. So, I knew that it would have to be three less than this [indicates 140]."*



| 1 | 2 | 3 | 414 Sum | Check |
|---|---|---|---|---|
| 135 | 135+1=136 | 135+2=137 | 137+135+136=408 | ↓ |
| 140 | 140+1=141 | 140+2=142 | 140+141+142=423 | ↑ |
| 137 | 137+1=138 | 137+2=139 | 137+138+139=414 | = |

*Figure 2.* Transcript from episode two in which Liam used the "linear interpolation" method he constructed. The chart is a typed reproduction of Liam's work. Though quotations are presented separately (to highlight the multiple steps involved in Liam's strategy), this constitutes one uninterrupted utterance by Liam.

To give a quick recap of Liam's activity in the second episode, we see that after Liam has finished the computations with two trial input values, Liam forms the ratio of the difference between the two outputs to the difference of the two trial inputs. This allows him to figure out the rate of change (in this case the constant of proportionality, or the slope) of the underlying (linear) function. Liam explicitly interprets the ratio he has formed as the unit worth of one guess: the amount the output will change corresponding to a change in one of the input. Liam then takes the output corresponding to one trial input he has selected as a reference and figures out how far that output is away from the target output. He then uses the unit worth of one guess to figure out how much he should change the input by in order to produce the change in output he just computed.

In episode two, Liam has refined his sense of how inputs and outputs co-vary. He has now found a way to quantify and explicitly leverage his intuitions about the underlying linear relationship that all the input-output pairs satisfy. Notice that the idea that a given input is "worth" a fixed amount in terms of its effect on the output is a refinement of the earlier qualitative versions of proportionality Liam used in episode one.

## Discussion of the Two Contrasting Focal Episodes

An important point of contrast between the two focal episodes is that in episode one, Liam's solution method is highly dependent on his inferences about a *particular* guess. However, in episode two, Liam realizes that his solution method is *general*, and depends only on determining the rate of change between *any* two input-output pairs. Further, he purposefully uses two trial values not for the purpose of converging to the solution to the problem, but for the purpose of determining an invariant (the rate of change) of the underlying functional relation which all input/output pairs must satisfy. Once he has determined this invariant, he uses it to deduce the unknown value that solves the problem.

## Analytical Framework

The key analytical move and insight made in this paper involves reframing the "strategy change" observed between episode one and two in terms of "conceptual change." To understand strategy change as conceptual change, we need to go deeper than a top-level description of the contrasting features of strategy one and strategy two. The task before us now is to find a way to describe the relevant shifts in conceptual understanding that allowed the strategy change to take place. Of course, we recognize that Liam has many other forms of resources that could potentially contribute to the construction of a new problem solving strategy (epistemological, meta-representational, etc.) in addition to the conceptual resources we will discuss in this paper. We focus on shifts in the activation and coordination of knowledge resources in this paper because even in this limited arena, there is significant analytical work to be done.

The first strand of analysis in this study involves recognizing that the approaches in the two focal episodes are qualitatively different and giving a characterization of some of the important dimensions of this difference. Some aspects of difference were discussed in the previous sections where it was noted that the move from "qualitative" to "quantitative" formulations of proportionality over the course of the sessions was particularly noteworthy as an underlying conceptual shift.

The focus of a second analytic strand is to give a characterization of and provide an argument for a set of relatively primitive and elemental knowledge resources, which allow will one to track processes of change in fine-grained detail. The underlying assumptions of the knowledge in pieces epistemological framework directly guide how the conceptual resources are identified in our analysis. In this analysis, we seek to identify the knowledge that was relevant to Liam and that he was drawing upon in solving the problems. To do this, one can consider the justifications he makes concerning his choices for trial values. This line of analysis has resulted in the identification of several conceptual resources that Liam activates and uses over the course of the sessions. Examples from the two focal episodes presented in this paper are given below.

| **Candidate knowledge resource** | **Description** | **Examples of resource activation in focal episodes** |
|---|---|---|
| Monotonicity | Larger inputs (in reference to previous inputs) result in larger outputs and smaller inputs result in smaller outputs. | All guesses in focal episode one fit this pattern. If a particular input resulted in an output that was too high, the next input was chosen to be a number lower than the previous input. Likewise, if a particular input resulted in an output that was too low, then next input was chosen to be higher than the previous input. *(Focal episode one)* |
| Sandwiching/In-betweeness | If an input yields an output that is too high and another input yields an output that is too low, then the true input must be in between these two inputs. | "Well it was actually definitely 9 if this [result for 8] was too low and this [result of a guess of 10] was too high. Unless it was a decimal number." *(Focal episode one)* |
| Qualitative formulation of proportionality | Small changes in input correspond to small changes in output. | This was "a little too high." [then he chooses a next guess that is two integer values lower]. (*Focal episode one)* |
| | Medium changes in input correspond to medium changes in output. | N/A in focal episodes one and two. |
| | Large changes in input correspond to large changes in output | "This is way too much" [and he follows up by choosing a guess that is a lot lower than the previous guess] *(Focal episode one)* |
| Half as a reference point | If an input yields an output that is about twice (or exactly twice) as much as the target output, then the next guess should be about half (or exactly half) as much. | This is "almost twice too much." [then he chooses a next guess that is nearly half as much] *(Focal episode one)* |
| Unit worth/Quantitative formulation of proportionality | A change of one in the input corresponds to a fixed change in output. | "So that means that for every one this one changes [notes the input column], this one [notes the corresponding output column] changes by three." *(Focal episode two)* |

*Figure 3.* A summary of "knowledge resources" identified in the analysis of Liam's justifications for choices of next trial values.

## Discussion and Findings

The main goal of this paper has been to illustrate how the emergence of a novel strategy in episodes of problem solving can be productively framed in terms of underlying conceptual reorganization. As we have seen, the landscape of the knowledge resources that students draw upon in employing informal problem solving methods is surprisingly rich. Through a preliminary analysis with the data from the case of Liam, we have seen that something as apparently simple as students solving word problems using informal strategies like guessing and checking actually can yield a striking complexity under analysis. The main contribution of this paper is an analytic framework that re-positions observed strategy changes for solving problems in terms of underlying conceptual reorganization. In the case elaborated in this paper, explicit candidate knowledge resources have been named that should allow one to track the dynamics of change between the two contrasting episodes discussed in this paper.

One of the challenges of tracking strategy change in terms of underlying conceptual reorganization is that the conceptual reorganizations are likely to be of a small scale and highly situated to the task at hand. In the data excerpts, we saw evidence that Liam had “invented linear interpolation” in a tabular context. Without being explicitly taught about functions, Liam implicitly recognized the “guess and check” chart he was generating as he solved problems as a tabular representation of a function. In inventing linear interpolation in this context, he discovered the tabular version of what might be stated in graphical terms as “two points determine a line” and the fact that once you have a point and the slope you can get to any other point on a line.

Since Liam was not familiar with “symbolic” or “graphical” representations of functions at the time of the sessions, one would not expect that he would spontaneously recognize and apply his linear interpolation approach in these other representational contexts. Hence, his understanding of “linear interpolation” is only a projection into the tabular representational context of a mature understanding of “linear interpolation.” Accordingly, the sub-conceptual grain-size posited by the “knowledge in pieces” framework is particularly well adapted to the goals of the analytic work in this line of research. A fine-grained and situated characterization of knowledge will be required to make sense of the emergence of Liam’s strategy in the tabular representational context.

## Future Research

Future analytic work grounded in this case study and other replication case studies will be needed to continue to identify other potentially relevant knowledge resources used by students. Preliminary analyses of a complementary classroom data corpus and data from the interviews with the five other pre-algebra students give evidence that the knowledge resources we have discussed in this paper are sometimes but not always activated in the solution strategies of other students. This certainly does not mean that students don’t “have” such resources. It may only indicate that they do not see them as relevant to the task at hand. One would hypothesize that classroom practices shape in fundamental ways what knowledge a student sees as relevant to activate as they engage with solving problems.

The analytic framework sketched in this paper naturally extends into at least two other additional strands. The work in the first two strands of analysis presented in this paper focused on (1) documenting that there was a change in the organization of Liam’s knowledge and (2) generating a vocabulary with which to describe that change. As suggested throughout this paper, the natural next analysis would focus on giving a genetic account of knowledge growth and change using the specific resources identified in this paper. Certainly, this would involve looking at the episodes *in between* focal episodes. Further, it is natural, both from the perspective of giving accounts of learning processes and from the perspective of designing instruction informed by such accounts, to ask what factors influence the process of conceptual change and by what mechanisms. Accordingly, a fourth analytic strand would focus on going beyond a description of the dynamics of change over the sessions in terms of the resources to proposing likely mechanisms that drove the process of conceptual reorganization forward. There are several potential candidates for significant mediators of the constructive process. Some examples of potential mediators include the role of the representational form in organizing the data obtained from individual trials, social interactions and questioning in the learning setting (both by the researcher and the student), the role of the activity of solving a problem in driving the inquiry, and the role of a students' prior knowledge and understanding. In addition, extending the analysis to other kinds of resources, such as epistemological resources and beliefs (Hammer, 2000), could lead to future insights about how and why strategies emerge in episodes of problem solving.

*In this article, we discuss differences between the mathematics instruction of CMP and non-CMP teachers in the LieCal project. There are three aspects of instruction that 200 6th grade urban classroom observations showed were strongly and differently related to the type of curriculum that teachers were using. These three aspects relate to the teachers' use of (1) group and individual work, (2) written narratives and worked-out examples, and (3) conceptually- and procedurally-focused instruction.*

## Introduction

Historically, curriculum has played a central role in educational reform. In all of the reform movements since the 1960s, curriculum has been used as a means to convey what and how teachers should teach (NCTM, 1989, 2000), and it has also been used to serve as an agent for instructional improvement (Ball & Cohen, 1996). While curriculum does not always dictate the content of instruction (Freeman & Porter, 1989), research has consistently shown that curriculum has a strong influence on the ways mathematics is taught (Remillard, 2005; Robitalle & Travers, 1989; Schmid et al., 2002). In fact, teachers often base their teaching approaches primarily on the ways the curricular materials are presented (Cai, 2005; Robitalle & Travers, 1989; Tarr et al., 2006). However, research has not documented specifically how curriculum materials actually influence classroom instruction.

The current discussion of how curriculum materials actually influence classroom instruction habitually has focused on differences between the use of *Standards*-based curricular materials developed through the support of the National Science Foundation (NSF) and the use of more traditional curricular materials developed through the support of commercial publishers (Hirsch, 2007; Reys, Robinson, Sconiers, & Mark, 1999; Tarr et al., 2006). *Standards*-based NSF-funded curricula claim to build students' understanding of important mathematics through explorations of real-world (or sometimes fanciful) situations and problems. These curricular materials are intended to align with the recommendations in the NCTM *Standards*, with a focus on the importance of thinking, understanding, communicating, representing, making connections, reasoning, and problem solving (e.g., NCTM, 1989, 1991, 2000). This view stands in contrast to a more conventional approach to curriculum that emphasizes the application of well-rehearsed procedures to solve problems, and stresses the memorization, recitation, and use of decontextualized facts, rules, and procedures. In this article, we report initial findings from our investigation of differences between the mathematics instruction of CMP and non-CMP teachers.

## LieCal Project

This research for this article was done as part of our LieCal project. LieCal (Longitudinal Investigation of the Effect of Curriculum on Algebra Learning) is a project that investigates differences between the effectiveness of the Connected Mathematics Program (CMP) and the effectiveness of more traditional middle school curricula (non-CMP) on students' learning of algebra. CMP is one of four *Standards*-based middle school curricula developed with funding from NSF (Lappan et al., 2002). In the LieCal project, we are studying the algebra-related teaching and learning of about 1400 students in 16 urban middle schools as they progress from sixth through ninth grades. Our overall goal for the LieCal project is to provide: (1) A profile of the intended treatment of algebra in the CMP curriculum with a contrasting profile of the intended treatment of algebra in the non-CMP curricula; (2) a profile of classroom experiences that CMP students and teachers have, with a contrasting profile of experiences in non-CMP classrooms; and (3) a profile of student performance resulting from the use of the CMP curriculum, with a contrasting profile of student performance resulting from the use of non-CMP curricula. In order to provide a profile of CMP classroom experiences and a contrasting profile of experiences in non-CMP classrooms, we are collecting data on how teachers use CMP and non-CMP curricula. In this article, we discuss differences in CMP and non-CMP classrooms in the LieCal Project.

## Method

The LieCal Project is being conducted in 16 middle schools in a district serving a diverse student population. When we began the project, 27 of the 51 middle schools in the school district had adopted the CMP curriculum while the remaining 24 middle schools used other more traditional curricula. Eight CMP schools were randomly selected from the 27 schools that had adopted the CMP curriculum. After the eight CMP schools were selected, eight non-CMP schools were chosen based on the comparable ethnicity, family incomes, accessibility of resources, and state and district test results.

An important part of the LieCal Project's examination of the fidelity of curricular implementation is classroom observations. The observations upon which this article is based were conducted in the 6th grade of the 16 middle schools. Subsequent observations in grades 7 and 8 yielded similar results. Using a pre-developed observation instrument[1], two trained research specialists observed each of the 50 participating classes (24 CMP classes and 26 non-CMP classes) 4 times a year, twice in the fall and twice in the spring. Due to space limitations, we have chosen to report only on the data from the 6th grade observations.

The LieCal observation instrument is designed to provide a comprehensive analysis of the instruction that transpires during each class. Two retired, highly experienced mathematics teachers were hired as research specialists to conduct the classroom observations. Over the course of the year, we checked the reliability of the specialists' coding three times. These three sessions revealed that the reliability of the coding done by the two specialists was quite high. The reliability achieved during the three sessions averaged 79% perfect agreement using the criterion that the observers' coded responses were considered equivalent only if they were identical (i.e., perfect match). The reliability averaged 95% using the following criteria: (a) If an item or sub-item was "scored" using an ordinal scale, then the specialists' coded responses were considered equivalent if they differed by at most one unit; (b) If an item or sub-item (e.g. representation) was "scored" by choosing from a list of alternatives all the words/phrases that characterize it, then the specialists' coded responses were considered equivalent if they had at least one choice in common (e.g. symbolic and pictorial vs. pictorial).

## Results

There are three aspects of instruction that our classroom observations showed were strongly and differently related to the type of curriculum that teachers were using. These three aspects relate to the teachers' use of (1) group and individual work, (2) written narratives and worked-out examples, and (3) conceptually- and procedurally-focused instruction. Our findings regarding these three instructional aspects are presented next.

*Teachers' Use of Group and Individual Learning*

The CMP curriculum is composed, to a large extent, of extended contextual tasks, called investigations. The teachers' edition of the CMP curriculum encourages teachers to organize their students in small groups to work on the investigations, which guide the students to explore important mathematical ideas and ways of thinking as they try to understand and make sense of real-world situations. Using the observation instrument of the LieCal Project, we documented ways that teachers organized students to engage in lesson activities. Two of the ways we documented were the use of small-group and individual learning. Nearly half of the CMP lessons (47 out of 100) involved students learning in small groups, but only 7.4% of the non-CMP lessons (7 out of 95) involved group learning (See Table 1). Accordingly, the CMP students also spent a larger percentage of lesson time engaged in group learning than non-CMP students. In particular, on average 15.4% of the total CMP lesson time was used for group learning, but only 2.3% of the total non-CMP lesson time. This means that, overall, CMP students spent about six times longer than non-CMP students on group learning.

What is surprising, however, is that when group learning was used in non-CMP classrooms, the time students spent in small groups was similar to the time spent in CMP classrooms. In fact, in the 47 CMP lessons that used group learning, the average number of minutes students spent in groups was 18.9 minutes, which is very close to that for the seven non-CMP lessons, 16.4 minutes. This result suggests that once teachers decide to use small-group learning, both CMP and non-CMP teachers engage their students in small group learning for about the same amount of time per lesson.

Table 1. *Group and Individual Learning in Both CMP and Non-CMP Lessons*

| | CMP Lessons (n=100) Minutes (n=5724) | Non-CMP Lessons (n=95) Minutes (n=4980) | Z | |
|---|---|---|---|---|
| Group work | | | | |
| % of Lessons | 47.0 | 7.4 | 6.02 | $p < .01$ |
| % of Minutes | 15.5 | 2.3 | 22.75 | $p < .01$ |
| Individual work (not on homework) | | | | |
| % of Lessons | 32.0 | 51.6 | 2.69 | $p < .01$ |
| % of Minutes | 10.7 | 12.6 | 3.15 | $p < .01$ |
| Individual work (on homework) | | | | |
| % of Lessons | 9.0 | 27.4 | 3.09 | $p < .01$ |
| % of Minutes | 1.4 | 6.5 | 16.15 | $p < .01$ |

From the opposite point of view, the relatively little use of group learning in non-CMP lessons implies that individual student work occurred in many more non-CMP lessons than in CMP lessons. There are two types of individual work. One is on homework, and the other is on non-homework activities. About half of the non-CMP lessons included individual learning that was on non-homework activities, but only about one third of the CMP lessons included individual learning that was not on homework.

CMP students worked individually on homework in 9 of the 100 observed lessons (9%), but non-CMP students worked individually on homework in 26 of the 95 observed lessons (27.4%). Both CMP teachers and non-CMP teachers assigned homework in about one third of their lessons. Therefore, in our study non-CMP students worked individually on homework in about 81% (26/32) of the classes in which homework was assigned. However, CMP students worked individually on homework in only about 27% (9/33) of the classes in which homework was assigned. So, non-CMP lessons were three times more likely than non-CMP lessons to have students working individually on homework.

*Teachers' Use of Written Narratives and Worked-Out Examples*

Even a cursory comparison of the CMP mathematics curriculum with non-CMP mathematics curricula reveals major differences between them. Customarily, the sections of non-CMP curricula are organized around worked-out examples of mathematics problems similar to the beginning exercises that appear at the end of the sections, rather than the application problems that appear later. The worked-out examples generally are connected by short narrative paragraphs that explain the worked-out examples, or that provide definitions, generalizations, and formulas that are based on the examples. On the other hand, the CMP curriculum contains very few worked out examples and almost no formulas. Instead, the curriculum is composed of a series of investigations that the students are expected to explore, often in groups. Each investigation comprises multiple paragraphs of written narrative interspersed with diagrams, tables, and unworked problems that the students are asked to analyze, solve, and discuss. In our study, we found that these two types of curricular presentations lead to very different patterns of textbook use by teachers and students.

Table 2. *The Purpose of Textbook Use**

| | % of CMP Lessons (n=100) | % of Non-CMP Lessons (n=95) | Z | |
|---|---|---|---|---|
| Students looked for problems in the text | 63 | 64 | 0 | NS |
| Students reviewed diagrams, charts or pictures | 28 | 1 | 5.10 | p<.01 |
| Students reviewed examples or find formulae | 5 | 16 | 2.30 | p<.05 |
| Students read from text | 49 | 14 | 5.09 | p<.01 |
| Students do not use text | 3 | 16 | 2.89 | p<.01 |
| Teachers drew examples from text | 17 | 47 | 4.34 | p<.01 |

*Student percents total more than 100 because textbooks can be used for multiple purposes in a lesson.

Table 2 shows ways that students used both CMP and non-CMP textbooks. The students' most frequent use of both the CMP and non-CMP texts was to look for problems in the text. These problems generally formed the basis for their instruction or their practice. This type of usage occurred in almost equal frequencies in the CMP lessons (63%) and the non-CMP-lessons (64%). We have shown elsewhere (Cai et al., 2009), however, that the overall cognitive level of the tasks posed by the CMP teachers was significantly higher than that of the tasks posed by non-CMP teachers. Therefore, opportunities to think conceptually and make connections were much different in the CMP classes, even though the frequency of use of problems from the text was the same in both types of mathematics classes.

The investigation of the other three purposes for which students used their textbooks revealed large and significant differences between the CMP and non-CMP classrooms. In particular, the CMP students in our study used their textbooks to review diagrams, charts or pictures in 28% of the CMP lessons we observed, while the non-CMP students used the textbook for this purpose in only 1% of the lessons. However, the percents were reversed when students used their textbooks to review examples or find formulae (5% of the CMP lessons and 16% of the non-CMP lessons). Also, the students read their textbooks in about half of the CMP lessons we observed, but students read textbooks in only about 14% of the non-CMP lessons.

These last three findings may be due, in part, to the fact that the CMP curriculum contains more written text and more diagrams and charts than the non-CMP curricula. It may also be due, in part, to the fact that teachers of non-CMP curricula presented and discussed the textbook's worked-out examples (or ones like it) much more often than teachers of the CMP curriculum (17% of CMP lessons and 47% of non-CMP lessons). This may have helped obviate the need for the non-CMP students to read the text. These two arguments are especially compelling when one considers that the brunt of the learning from non-CMP texts is often based on the worked-out examples and the subsequent practice problems. This is in stark contrast to CMP texts, in which the burden of learning usually resides in the students' own work on un-worked problems in the text, many of which are integrally dependent for their solutions on accompanying diagrams, charts, and pictures. Similar arguments can be made to explain why non-CMP students did not use their textbooks in 16% of the lessons we observed, but CMP students failed to use the their textbooks in only 3% of the lessons.

*Teachers' Use of Conceptually- and Procedurally-Focused Instruction*

CMP can be characterized as a problem-based curriculum. The focus is more on conceptual understanding than on procedural knowledge. It is expected that students will learn algorithms and master basic skills as they engage in explorations of worthwhile problems. On the other hand, the non-CMP curricula in our study include extensive sets of practice exercises, and the focus is more on procedural knowledge and basic skills than on conceptual understanding. Take the introduction to equation solving as an example, in the Non-CMP curriculum, equation solving was introduced symbolically by using additive property (add or subtract the same quantity on both side of the equation, the equality holds) and multiplicative property (multiple or divide a non-zero quantity on both sides of an equation, the equality holds). On the other hand, in the CMP curriculum, real-life contexts are used to help students understand the meaning of each step of the equation solving, as shown in Table 3 below (Nie, Cai, & Moyer, 2009).

Table 3. *Introduction of Equation Solving in CMP*

| Thinking | Manipulating the Symbol |
|---|---|
| "I want to buy a CD-ROM drive that costs $195. To pay for the drive on the installment plan, I must pay $30 down and $15 a month." | 195 = 30 + 15N |
| "After I pay the $30 down payment, I can subtract this from the cost. To keep the sides of the equation equal, I must subtract 30 from both sides | 195 – 30 = 30 – 30 + 15N |
| "I now owe $165 which I will pay in monthly installments of $15." | 165 = 15N |
| "I need to separate $165 into payments of $15. This means I need to divide it by 15. To keep the sides of the equation equal, I must divide both sides by 15." | $\frac{165}{15} = \frac{15N}{15}$ |
| "There are 11 groups of $15 in $165, so it will take 11 months." | 11 = N |

Table 4. *Sample Conceptual and Procedural Scales in the LieCal Observation Instrument*

1. *Example of Measuring Conceptual Understanding*

The teacher's questioning strategies were likely to enhance the development of student conceptual understanding/problem solving (e.g., emphasized higher order questions, appropriately used "wait time," identified prior conceptions and misconceptions).

| 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|
| Does not ask questions | Asks low level questions or answers his/her own questions | Asks low level questions that lead to a dialogue between teacher and students | Asks high level questions but does not pursue the answers | Asks high level questions, and pursues their answers |

2. *Example of Measuring Procedural Knowledge*

The teacher worked out examples to demonstrate the steps of a mathematical procedure or solution process.

| 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|
| Not at all | | Moderate Demonstration | | Extensive Demonstration |

The classroom observation instrument of the LieCal Project includes twenty-one 5-point Likert scale questions, which are designed to rate the nature and quality of instruction in a lesson. A factor analysis of the 21 questions revealed that five of the 21 questions rate the extent to which the lesson fosters students' conceptual understanding of mathematical knowledge, and another five questions rate the extent to which the lesson fosters students' ability to carry out mathematical procedures. The first question in Table 4 is an example of the type of Likert scale that was used to rate the likelihood that the teachers' instruction would help develop students' conceptual understanding of math knowledge. The second question in Table 4 is a detailed example of the type of Likert scale that was used to rate the likelihood that the teachers' instruction would help develop students' procedural knowledge.

The mean of the sum of the scores on the five questions that measure the likelihood that the teachers' instruction would help develop students' conceptual knowledge was 17.99 for CMP classes and 12.33 for non-CMP classes, which is statistically significantly higher for CMP classrooms than for non-CMP classrooms: $t(193)=10.05$, $p<.0001$.

The mean of the sum of the scores on the five questions that measure the likelihood that the teachers' instruction would help develop students' procedural knowledge was 14.70 for CMP classes and 17.16 for non-CMP classes, which is statistically significantly higher for CMP classrooms than for non-CMP classrooms: $t(193)=4.25$, $p<.0001$.

## Conclusion

In this article, we discuss differences between the mathematics instruction of CMP and non-CMP teachers in the LieCal project. There are three aspects of instruction that our classroom observations showed were strongly and differently related to the type of curriculum that teachers were using. These three aspects relate to the teachers' use of: (1) group and individual work, (2) written narratives and worked-out examples, and (3) conceptually- and procedurally-focused instruction. This article shows that the use of different types of curriculum materials in the LieCal project corresponds to major differences in teachers' classroom practice as it relates to these three aspects of instruction.

Based on findings from the LieCal Project, this article shows that the use of CMP and non-CMP curriculum materials can impact teachers' classroom practice in very different ways. Regarding group versus individual learning in classroom instruction, CMP teachers dedicate more time to group learning than non-CMP teachers, while non-CMP teachers use more individual learning. Because students in CMP classrooms more often work in small groups to perform cognitively demanding tasks, it is likely that CMP students are given more opportunities to interact and digest math concepts and ideas than non-CMP students. On the other hand, students in non-CMP classrooms have more opportunities to practice basic mathematical skills individually. Our classroom observations also revealed that teachers who use the CMP curriculum provide more opportunities for students to use diagrams, charts, and pictures than non-CMP teachers. For non-CMP lessons, both students and teachers are much more likely to use the curriculum materials to study worked-out examples. Finally, CMP classroom instruction is more likely to enhance students' conceptual understanding of mathematical knowledge while non-CMP classroom instruction focuses more frequently on mathematical procedures.

The data in our study do not establish a causal relationship between the different instructional practices we analyzed and the use of CMP and non-CMP curricula. Nonetheless, the differences that we highlighted between CMP and non-CMP teachers' classroom practices are closely related to the nature of CMP and non-CMP curriculum materials. Thus, there is good reason to believe that the choice of curriculum materials by a school or district is an important decision that should be made with the utmost care. When all is said and done, our study confirms that teachers tend to teach their lessons in ways that are compatible with the nature of the texts they use. Therefore, deliberate and close attention should be paid to the compatibility of potential curricula with the teachers' beliefs about the nature of mathematics instruction, and with the goals they have for their students.

## Endnotes

Authors' Note: The research reported in this paper is part of a large project, Longitudinal Investigation of the Effect of Curriculum on Algebra Learning (LieCal Project). LieCal Project is supported by a grant from the National Science Foundation (ESI-0454739). Any opinions expressed herein are those of the authors and do not necessarily represent the views of the National Science Foundation. Assistance provided by Tony Freedman and Bikai Nie is greatly appreciated.

# EXPLORING PROCEDURAL FLEXIBILITY IN STRUGGLING ALGEBRA STUDENTS

Kristie J. Newton
Temple University
kjnewton@temple.edu

Jon R. Star
Harvard University
jon_star@harvard.edu

*Recent studies of procedural flexibility have identified promising instructional techniques can be effective in promoting flexibility with solving equations, but they have done so within controlled environments and using brief interventions. We describe results from a three-week course in algebra, in which these techniques were regularly employed as part of daily instruction. Written assessments and interviews of students who struggle with algebra suggest accuracy, rather than efficiency, is often a driving force when choosing solution methods. Prior instruction emphasizing one method appeared to inhibit flexibility when accuracy was not a concern, but students demonstrated flexibility for less familiar problems.*

## Introduction

For decades, researchers in the fields of mathematics education and cognitive psychology have been interested in the relationship between procedural and conceptual knowledge (e.g., Byrnes & Wasik, 1991; Hiebert & Lefevre, 1986; Rittle-Johnson, Siegler, & Alibali, 2001). A number of questions have been asked about how these two types of knowledge are linked, including which develops first and whether one is necessary for the other. However, recent arguments have emerged that challenge how the two types are defined and measured (Baroody, Feil, & Johnson, 2007; Newton, 2008; Star, 2005, 2007). In particular, Star (2005, 2007) argued that procedural knowledge is often conceived of and measured in ways that that are consistent with rote memorization. Yet, procedural knowledge can also be deep, as it must be in order to flexibly apply solution methods. The current study adds to the literature on procedural flexibility by exploring its development in a real classroom, with students who struggle with algebra.

### *Flexibility*

Verschaffel, Luwel, Torbeyns, and Van Dooren (2007) suggest that researchers have conceptualized flexibility in a variety of ways. Some use the term to refer to a person's ease in switching between solution methods, whereas others also include a person's tendency to select the most appropriate method in a given situation. In the current study we take the latter perspective, suggesting that flexibility develops slowly from knowledge of multiple procedures to the adaptive use of them (Blöte, Van der Burg, & Klein, 2001; Star & Seifert, 2006).

A number of recent studies support the notion of flexibility developing on such a continuum (e.g. Blöte et al., 2001; Star & Rittle-Johnson, 2008). Blöte and colleagues showed that second grade students can learn multiple ways of solving addition and subtraction problems, but the tendency to use alternative methods lags behind their knowledge and preference for them (Blöte et al., 2001). On the other end of the continuum, Star and Newton (under review) demonstrated that experts show knowledge of, frequent use of, and strong preferences for elegant and efficient solutions. The experts were in surprising agreement about which methods were better, even if they did not originally choose the method. When explaining why, they consistently pointed to structural characteristics of the problem (e.g., a certain number is divisible by another) and preferred methods that were more efficient, made use of important mathematical ideas, and reduced the chance for error.

Research by Rittle-Johnson and Star (2007) demonstrated that students who are first learning algebra can gain conceptual knowledge, procedural knowledge, and flexibility simultaneously. By comparing and contrasting two different solutions to the same problem, students in a treatment group (n = 36) gained more on measures of flexibility and procedural knowledge compared to a control group (n = 34) that examined the same two methods but with isomorphic problems. Given the brief intervention used by Rittle-Johnson and Star (4 instructional days), the significant gains in favor of the treatment group in flexibility are encouraging, but it is less clear whether this intervention can yield similar results over more extended periods of instructional time.

Klein, Beishuizen, and Treffers (1998) demonstrated positive effects of flexibility instruction over time in their study of 275 second graders. These researchers compared the impact of arithmetic instruction that promoted flexibility from the beginning, to instruction that emphasized procedural skill prior to promoting flexibility. Both groups of students demonstrated flexibility at posttest; however, promoting flexibility from the beginning of instruction seemed to be more effective. Students who learned flexibility and skill simultaneously outperformed those who focused first on skill alone. Furthermore, their findings suggest that early exposure to multiple solution methods does not hinder procedural competence; the groups performed similarly on a skills assessment.

Star and Rittle-Johnson (2008) also demonstrated that students can learn both skill and flexibility when they compared direct instruction to a more discovery-oriented approach. In their study of 132 rising seventh graders learning to solve linear equations, they found that the different types of instruction had similar effects on accuracy of equation solving but differential effects on flexibility. Namely, prompting students to solve problems in more than one way was most effective for increasing students' use of multiple methods, whereas direct demonstration of efficient methods was most effective at increasing students' use of efficient methods. Although the treatments impacted flexibility differently in terms of *use*, they were similarly effective in increasing flexibility in terms of *knowledge* (i.e., knowing that multiple methods exist and that some are more efficient than others.) This distinction is important and lends support to the notion that flexibility develops on a continuum.

*Current Study*

The current study builds on prior research on flexibility while addressing some of the limitations of that research. First of all, few studies at the secondary level have examined flexibility in real classroom settings, which often include pressures to cover large amounts of material in a limited amount of time, grading systems that emphasize accuracy over efficiency, and a wide range of student abilities. Second, few studies have examined how flexibility might develop for students who struggle with mathematics. Klein et al. (1998) reported that weaker second grade students were not confused by being introduced to multiple ways of solving problems, but it is unclear whether or not this finding would hold for weak algebra students, who may have struggled for years and built up a number of misconceptions that could impede learning. Finally, most studies have relied exclusively on written assessments to understand flexibility. Research suggests that knowledge of efficient procedures sometimes precedes the use of them (Blöte et al., 2001; Star & Rittle-Johnson, 2008), and interviewing students may help researchers understand why. The current study addresses each of these limitations.

Three research questions guide the current study. How do knowledge and use of multiple methods change during an algebra course focused on promoting flexibility? How does prior instruction in algebra impact students' flexible use of solution methods? How does prior knowledge of mathematics impact students' flexible use of solution methods in algebra? These questions are explored in the context of a three-week remedial/review algebra course offered in the summer.

## Method

### *Participants*

Two boys and four girls from a private school participated in the study. Xavier, Ricardo, and Nicole were all new to the school and were entering the ninth grade. A placement exam in algebra determined their need for this course. Annemarie and Naomi were entering tenth grade, and Yvonne was entering eleventh grade; these three students enrolled in the summer course at the recommendation of their prior math teacher. Performance during the course indicated that Nicole and Annemarie struggled most with the content, whereas Yvonne and Naomi struggled least. All students had previously taken a first course in algebra.

### *Measures*

*Algebra exam.* The final exam for the course served as both a pre-test and a post-test. It included 55 items, including linear and quadratic equations, systems of equations, graphing, and pre-requisite skills for quadratics such as factoring and simplifying with exponents and roots. Some of the items were designed such that the traditional approach might not be the easiest or most efficient.

*Intermediate assessments.* Intermediate assessments included homework, quizzes, and tests. Unlike the final exam, intermediate assessments sometimes prompted students to solve problems in more than one way, in order to determine whether or not they had knowledge of solution methods that were different than the ones they chose to use on their own, without being prompted. When prompted, the students were asked to indicate which method they thought was better by placing a star by that method.

*Interviews.* Students were interviewed three times during the course to assess their flexibility and attitudes about flexibility. The pre-interview and post-interview were identical, and they prompted students to solve problems in more than one way or to evaluate two methods of solving or graphing. The students were also asked about their views on learning more than one way of solving problems. An intermediate interview asked about the students' particular solutions from the first algebra test in the course. It also asked about their views on learning to solve problems in more than one way.

### *Procedure*

The three-week summer course included 14 instructional days plus one day devoted to the final exam. The class met Monday through Friday each week for two hours in the afternoon. The first week focused primarily on solving and graphing linear equations and systems of equations. The second week focused primarily on simplifying with exponents and radicals, as well as factoring. The final week continued with factoring and then focused on solving and graphing quadratic equations. A quiz and a test were administered for each of these units, and homework was assigned nearly every evening. Students were interviewed before the course began, immediately following the first test, and after the final exam. The pretest was administered on the first day of class, and the posttest was administered after the last day of class.

A typical lesson involved comparing and contrasting pre-worked examples of problems relevant to the day's topic. Having students contrast cases before discussing them may serve to deepen conceptual understanding by illuminating important features (Schwartz & Bransford, 1998). The features of the compared problems varied in such a way that one method might be preferred in some cases, but another method might be preferred in other cases. For example, when solving equations with parentheses, students might prefer to distribute the number in front of the parentheses when it is a whole number but they might prefer to multiply by the reciprocal first when the number is a fraction. These types of variations were meant to draw students' attentions to the structure of the equations rather than the superficial characteristics (e.g., the equation includes parentheses). However, students were not pressed to use a particular method. Instead, they discussed which methods they preferred, why they preferred them, and under what circumstances.

## Results

*Knowledge and Use of Multiple Methods*

When students were familiar with a particular solution method for a problem type, knowledge of alternate methods preceded use, confirming the findings of prior studies (Blöte et al., 2001; Star & Rittle-Johnson, 2008). However, students were more likely to use alternatives to the general approach with problems that posed difficulty, such as those containing fractions. As an illustration, on Test I all six students solved 7(n + 2) = 49 by distributing the 7 as a first step. On the same test, students were asked to solve -5(7x – 16) = 45 in two different ways, and all six showed knowledge of how to divide by -5 as a first step. Alternatively, three of the students solved $\frac{1}{2}(x - 15) = -4$ by distributing first, and the other three multiplied both sides of the equation by 2. As Xavier noted for this problem, "I think since there is a fraction, it would be easier just to use the reciprocal, in this case, instead of just working out the whole distributive property" (Xavier, intermediate interview).

When students were equally familiar with two different methods, two common reasons were cited for choosing a particular method in a given situation: efficiency and problem structure. With respect to the former, when graphing linear equations on Test I, Naomi and Yvonne both successfully used the slope-intercept method rather than plotting points. Although Naomi's intermediate interview revealed she had knowledge of both methods, she said she used the slope-intercept method "because it's faster." Likewise, Yvonne said her reason for not choosing to plot points was that "there is more involved, and it takes longer." On the other hand, it was quite typical that students noted the structure of the equation when providing a rationale for their graphing method. Although Ricardo chose to plot points when "the problem is really easy", such as for x + y = 10, he switched methods when the structure of the equation was more conducive to a different method. For $y = \frac{1}{2}x + 3$, he said, "Since it already had the slope and the y-intercept, I just found the y-intercept and went up from there, using the slope" (Ricardo, intermediate interview). Similarly, Xavier's rationale for the slope-intercept method was that "you know where to start, and from there you just to use the rise over run….it is ready to go" (Xavier, intermediate interview). And Nicole, who admittedly struggled with all graphing methods, successfully used the slope-intercept method for the same problem "because it was basically in that form" (Nicole, intermediate interview).

When solving systems of equations, students also attended to the structure of the problem in selecting strategies. At pretest, none of the six students attempted to solve the systems of equations, indicating weak or no knowledge of them. On Test I the students demonstrated both knowledge and use of two methods for solving linear systems, and their reason for switching between methods was often focused on the structure of the equations. For example, when one of the equations was already solved for *y*, students generally chose to substitute its equivalent expression into the remaining equation. As Xavier stated in his intermediate interview, "it's right there, what *y* equals, so you just substitute." Yvonne, Ricardo, and Naomi gave similar reasons for using substitution for this same problem. Focusing on characteristics of the equations was consistent with the experts for these types of problems (Star & Newton, under review).

For solving quadratic equations, students concentrated on a mix of efficiency and problem structure at posttest but not at pretest. At pretest, the students showed weak or moderate knowledge of quadratics, and only Naomi alluded to efficiency as a reason for choosing a particular method. During the course, students demonstrated knowledge of all three instructed methods for solving quadratics, but only Yvonne, Nicole, and Naomi attempted to *use* all three on the posttest. Most students cited efficiency as a rationale for a particular method, but some students mentioned structure. For example, Xavier stated in his post interview that one equation had a "perfect square" and another was "pretty easy to factor, it's already in a factorable form." Presumably, Xavier was referring to the fact that the equation was already set equal to zero. Nicole, who often preferred the quadratic formula because she admittedly struggled with factoring, said in her post-interview that her reason for preferring factoring for a particular problem was "because there's no coefficient."

*Impact of Prior Instruction*

At times, prior instruction seemed to limit the development of flexibility. It seemed students were less likely to use alternate methods when they were familiar with one that worked for a particular problem type, especially if they were comfortable with it. The most prominent example concerned linear equations of the type $a(x+b) = c$ where $a$ was a whole number. The course attempted to help students develop flexibility for solving problems of this type, presenting them with an alternate to "distribute first" when $c$ was divisible by $a$ (e.g., use the "divide first" method). Several students began the study having already developed automaticity with the "distribute first" method, and it appeared the exposure was so extensive that it negatively influenced flexibility for these problems.

Students' interview responses provide insight as to why knowledge of the "divide first" method did not lead consistently to its use. In her intermediate interview, Yvonne indicated that she still used the familiar "distribute first" method because "it was like instinct." Annemarie's and Ricardo's interview responses show a similar pattern. At the intermediate interview, Annemarie explained that while she knew how to use the alternative "divide first" method, she had still distributed first because "It's just the way I was taught." Similarly, Ricardo indicated that he still preferred to use "distribute first" because he was "used to it."

Unlike the other students, Naomi had prior instruction that promoted alternate methods for solving linear equations, at least for those involving fractions. In particular, she stated that one of her teachers taught her to "clear the denominator" when solving equations with fractions. In some cases, this strategy led to more efficient methods than the general approach, but not always. For example, at pretest she solved $\frac{2}{3}w + 3 = 10$ by first multiplying all terms by 3, obtaining $2w + 9 = 30$ as the next step. For the same problem at posttest, Naomi used the more traditional first step of subtracting 3 from both sides but then again cleared the denominator by multiplying by 3. In both cases, her methods were less efficient than the typical method of subtracting 3 and multiplying by the reciprocal. Although she did demonstrate knowledge and use of efficient algorithms during the course, her methods were clearly influenced by prior instruction that did not seem to emphasize efficiency. Instead, it seemed to be focused on minimizing error.

*Impact of Prior Knowledge*

Weak knowledge of algebra in some students interfered with their ability to implement and attend to efficient methods for certain problem types. For example, students in the class learned two ways to simplify multiplied exponential expressions with the same base (e.g., $a^3 \times a^4 = a^7$). One method was to expand all the terms and then find a single term that was equivalent to the expansion (i.e., $a \times a \times a \times a \times a \times a \times a = a^7$). The second method was to add exponents and keep the base the same. In this case the general algorithm, adding exponents, is also the more efficient one. However, some students were not comfortable with that method and chose to expand the terms in order to simplify the expression. When simplifying more complicated expressions, some students still used the expansion method. For example, Annemarie seemed to use the method to verify that exponents could be multiplied when raising a power to a power. Although Annemarie's method was inefficient, it did allow her to solve the problem correctly.

Although weak knowledge sometimes led students to use inefficient methods, other times it led to efficient ones. For example, when choosing to not to distribute on equations with fractions, Annemarie said, "Distributing fractions kind of scare me. Distributing them, I'm not good with fractions so I was afraid that if I distributed it, I would distribute the fractions wrong" (Annemarie, intermediate interview).

In fact, many of the students changed their methods when fractions were involved. For example, Ricardo expressed a preference for distributing in most cases but felt differently when 6/5 was in front of the parentheses. In this case, he preferred to multiply by the reciprocal of 6/5 "because this one was totally confusing….it was getting confusing multiplying 6/5 by this. It was easier just to get rid of it" (Ricardo, intermediate interview). Experts who took the same test were also concerned with avoiding fractions or any other arithmetic that may lead to errors. However, accuracy was not the dominant reason for choosing solution methods. For the experts, efficiency seemed to be the driving force (Star & Newton, under review).

Post-interviews support the notion that students who struggle with algebra are often more concerned with accuracy rather than efficiency. This focus may partially explain why knowledge of efficient methods sometimes preceded the use of them; if the method first learned by students was not problematic, they seemed less likely to try a different method. But despite not always choosing to use alternate methods, students in this study still viewed their knowledge of them as advantageous. Nicole suggested that knowing an alternate method was good "because in case you get stuck doing one way, you can always have a backup" (Nicole, post-interview). Ricardo, Xavier, and Yvonne had similar responses. Xavier and Yvonne added that being able to check your work was another advantage of having an alternate way to solve a problem. Only Naomi alluded to efficiency as an advantage. She said in her post interview, "Well knowing more than one way makes it easier to solve an equation just because one way might make solving it a lot harder, so if you know a different way, you could do it faster."

When asked about disadvantages, the students were again concerned with accuracy. In their post-interviews, the same possible disadvantage was offered by all six students. As Xavier stated, "Sometimes you could get the two methods mixed up." However, it was somewhat surprising that five of the six students insisted this was simply a possibility for someone else. As illustrated by Naomi, "People could do that, but I don't tend to get methods confused. Either I get it completely right, or I forget the method all together." Only Annemarie admitted that she might personally "mix up different methods." At the same time, however, she also expressed that the first method she learned did not always make sense to her. In those cases, learning a new method was particularly helpful. In the case of radicals, she stated that the one method her teacher taught was one she "really didn't understand and when you showed me the other method I was like, wow this is easier….I could understand it more and I always hated radicals, but now I am starting to get them" (Annemarie, post-interview).

## Discussion

Being able to flexibly solve problems is one of the hallmarks of procedural fluency (Kilpatrick, Swafford, & Findell, 2001), and recent attention to flexibility in the research literature has revealed some interesting findings about its development. The current study confirms and adds to those findings in several ways. The purpose of the study was to explore the development of flexibility with algebra within a real classroom setting and with students who struggle with algebra.

Findings confirm that students tend to acquire knowledge of alternate methods before they tend to use them (Blöte et al., 2001; Star & Rittle-Johnson, 2008), particularly if they have gained automaticity with one particular method. These results are consistent with Klein et al. (1998), who found that second graders who focused on skill before flexibility were less flexible that ones who focused on both at the same time.

When students encountered problems that were especially difficult or confusing for them (such as those containing fractions), they were more likely to use a new method for that problem. This finding is somewhat counter-intuitive, since one might expect students who are confused to prefer using one method only in order to minimize confusion. Yet, students in this study seemed grateful to have a "backup" method. In general, accuracy was often a driving force for deciding how to solve problems. This finding differs from experts who were asked to solve the same problems (Star & Newton, under review). For experts, efficiency (e.g., being fast, less complicated, easier to compute mentally) was a driving force, and salient features of the problem were cited as reasons for choosing one method over another.

When two methods were equally familiar and comfortable to students, they were more likely to cite efficiency and/or structure as reasons for choosing a method. Most students demonstrated little or no knowledge of graphing, solving systems of equations, and solving quadratic equations at pretest but, during interviews, consistently suggested they used a particular method because of the way the problem was posed to them or because a particular method was faster/more efficient. When students were not concerned with accuracy, their rationales for choosing methods were reminiscent of experts.

Taken together, findings of this study have implications for algebra classrooms. Comparing and contrasting methods for solving algebra problems seems to enable struggling students to solve problems they may not otherwise be able to. Furthermore, prolonged focus on one particular method for a problem type may inhibit flexibility with that type (Klein et al., 1998). The number of cases is limited in this study, but assessments and interviews suggest positive outcomes of instruction focused on flexibility. Although three weeks of instruction extends the time of prior studies, research is needed on how flexibility can be developed in a semester or year-long algebra course.

# THE ROLE OF TASK IN EXPLORING ALGEBRAIC LINEARITY EPISTEMOLOGICAL OBSTACLE IN TECHNOLOGICAL ENVIRONMENT

José Guzmán
Cinvestav-IPN
jguzman@cinvestav.mx

Cesar Martínez
Cinvestav-IPN
libcesar@hotmail.com

*This is a report of a study on high school Mexican students aged 16 and 17. The study seeks to unravel the role tasks when solved by CAS. Algebraic linearity epistemological obstacle features prominently in the tasks that were given to the students. The results showed that students were able to overcome the obstacle relating through the well designed task using CAS.*

## Introduction

For almost 3 decades, Researchers in mathematics education have reported that many secondary school students make algebraic syntax errors when solving problems in a pencil and paper environment. The reasons when students make such mistakes has been well documented such as (Matz, 1980; Booth, 1984).

Recent studies, (e.g., Kieran and Drijvers, 2006), on the use of technology, especially CAS, on the teaching and learning of algebra has indicated that students not only learn the syntax of algebra, but also reflect upon the underlying concepts involved in the symbolic manipulation. The use of technology in teaching change the kind of students-teacher interaction in the class so interesting tasks that students would enjoy solving has to be given (Kieran, 2007, p. 728). Technology on its own does not impact knowledge on the students, rather tasks whose solutions are interesting to students and rich in mathematics concepts should be designed and given to students. What then are the types of tasks that should be given to students when they are allowed to use technology to solve them? High school students achieve to overcome the algebraic linearity epistemological obstacle using technology in teaching? (Adapted from Monaghan & Pierce, 2004, p. 179.)

The role of solving tasks with the help of technology by the students of high school in Mexico is hereby documented. The aim of the study is to answer the question: “What is the influence of carefully drawn tasks such that students overcome the algebraic linearity epistemological obstacles when the tasks are solved with CAS?”

## Conceptual Framework

*Epistemological Obstacle*

The notion of epistemological obstacle arose in Bachelard (1948/2007) when he states: “When a scientific progress is being researched upon the scientific knowledge must be formulated in terms of obstacles, which are neither external nor due to the weakness of the senses, but rather in the very act of knowing “(p. 15). In education there have been many theoretical contributions to shed lights on the various types of obstacles. For example, Cornu (1991) affirmed that an epistemological obstacle is of the same nature as knowledge itself, while Brousseau (2002) notes that the origin of epistemological obstacles are intrinsic difficulties inherent in knowledge (p. 87).

According to Brousseau, an epistemological obstacle is an element of knowledge, which enables students to solve correctly mathematical problems of certain context. In this way the obstacle is established in the person but stops to be effective in solving problems of different context.

In mathematics education, overcoming an epistemological obstacle necessarily implies the occurrence of various interactions between a student and a medium (le milieu, which in the opinion of Brousseau), aims at giving students a task that eliminates any knowledge which acts as an obstacle (Brousseau, 2002). In this sense, Kieran, Guzmán, Boileau, Tanguay and Drijvers (2008) argue that technology can act as an agent that destabilizes some kind of knowledge in students, which acts as an obstacle.

*The Role of Task and Learning in Technology Environments*

Tasks are primarily problems. In the process of solving them, it is important that the people (students and the teacher) focus attention on the underlying mathematical concepts in the tasks. Franke, Kazemi, and Battey, (2007, p. 234) highlights the design of relevant mathematical problems which allow an exchange of ideas that lead to conjecture which are easily verified by students using technological tools in solve the problems.

The instrumentalist approach is one conceptual framework rich in theoretical elements to analyze processes of teaching and learning in technological environments (Drijvers and Trouche, 2008). Under this approach, the integration of technological tools in the classroom is seen as complex because it affects different aspects of education (Drijvers, Doorman, and Boon Gisbergen, 2008b) such as what didactic settings should be used in the classroom, How it should be used and the kind of tasks that should be posed to students to arise their interest in solving them.

To Drijvers and Trouche (2008, p. 368) an artifact is useless when a potential user does not know what kind of tasks that can be solved with it. The artifact suffers from a cognitive processing in the user when he is aware that the use of the devise can be extended (mental scheme) to solve other problems. When a user has developed various ways of using an artifact, an artifact becomes part of a useful and valuable instrument that mediate his mathematical activity. According to Drijvers and Trouche, before an artifact can becomes an instrument (instrumental genesis), a user needs to develop mental schemes which involve the ability to use the artifact properly and the knowledge of the circumstances under which the device is useful. More precisely, in the instrumentalist approach an artifact is an object (physical or symbolic), while an instrument is both the object and the mental scheme.

The instrumentalist approach in education led researchers to define three (closely related) concepts to explain how students learn meaningfully through solving tasks by technological tools. The concepts are: task, technique and theory, known in research as TTT (Artigue, 2002; Lagrange, 2002 & 2003). Technical means the manner in which tasks are solved. This manner does not have to necessarily be quasi-type algorithm or algorithm (Chevallard, 1999) since the use of a technique involves the conceptual knowledge of it; that is know why it is effective or not in solving tasks. Technique is a complex set of reasoning and routine work (Artigue, 2002). Lagrange (2002, p.163) states that tasks are after all, problems. Techniques play a pragmatic role in that the allow results to be generated. They also play an epistemic role, helping users of technology to understand the concepts involved in the task; they help in the generation of theory and serve as a source of further or emergent questions. Thus, resolution of tasks by students involves the development of theory related to the tasks.

## The Study

*Methodology*

The research focuses on nine students (aged 16 to 17) of a Mexican high school. Given their academic background having studied three courses of algebra in the second, third grade of secondary and in the first degree of high school in line with the existing Mexican syllabus, although in the traditional environments using paper and pencil, we can guess that they have imbibed algebraic epistemological obstacle of linearity. The students worked in groups each of which was made up of three students. Each of the students was given a printed copy of the tasks and a TI-voyage 200 calculator.

The applied tasks were designed taking into account persistent and recurring algebraic errors common to students of this educational level. The classical error, $\sqrt{a^2+b^2}=\sqrt{a^2}+\sqrt{b^2}$, due to the linear extrapolation from the rule $\sqrt{a^2\times b^2}=\sqrt{a^2}\times\sqrt{b^2}$. In general, each of the tasks given to the students has two possible solutions. Two errors or mistakes are committed in solving them: one of them is obvious (e.g. substitution error), while the other results from linear extrapolation from an algebraic rule.

The activities were designed to allow students reflect on algebraic errors related with linear extrapolation before and after using CAS. Thus, the purpose of the activities was to inquire what arguments students give in defense of their responses, before and after the use of CAS (calculator TI-voyage 200), to solve the tasks.

*Structure of the Activities*

a) Formulation of the problem;
b) Possible solutions to the problem;
c) Question about what the correct solution is;
d) Justifying their answer;
e) Use of the calculator and implementation of some its specific commands;
f) Reflection on the results given by the calculator;
g) Explanation on the results given by the calculator;
h) Reflections on the processes of the proposed solutions and student's initial response; and
i) Questions about what the correct solution to the problem proposed is.

The activity used in the study is herby reported. Due to space, only part of the data is discussed.

**Actividad 1**

En el zoológico de Morelia se construyó una nueva zona de alimentos. Los techos de los nuevos comedores tienen forma de cono, como se muestra en la Figura 4.

Figura 4

Para terminar con la construcción de la nueva zona de alimentos, sólo falta pintar por fuera cada uno de los techos. Los pintores encargados de realizar el trabajo, por experiencia, saben cuanta pintura se necesita por metro cuadrado de superficie. Ellos han encontrado en un libro de matemáticas una formula que les permite calcular el área superficial de un cono, lo que les ayuda para saber cuanta pintura necesitaran. La formula que encontraron es:

$s = \pi r^2 + \pi r\sqrt{r^2 + l^2}$, donde *s*, *r* y *l* son, el área superficial, el radio de la base circular del cono y la altura del mismo, respectivamente.

Dos de los pintores realizaron los siguientes cálculos, sabiendo que el radio es de 2 metros, la altura mide 3 metros, y $\pi$ lo aproximan a 3.1416.

| Cálculo A: | Cálculo B |
|---|---|
| $s = 3.1416(2)^2 + 3.1416(2)\sqrt{2^2+3^2}$ | $s = 3.1416(2)^2 + 3.1416\sqrt{2^2+3^2}$ |
| $= 3.1416(4) + 6.2832(\sqrt{2^2} + \sqrt{3^2})$ | $= 3.1416(4) + 3.1416\sqrt{4+9}$ |
| $= 12.5664 + 6.2832(2+3)$ | $= 12.5664 + 3.1416\sqrt{13}$ |
| $= 12.5664 + 6.2832(5)$ | $= 12.5664 + 3.1416(3.6055)$ |
| $= 12.5664 + 31.416$ | $= 12.5664 + 11.3270$ |
| $= 43.9824$ | $= 23.8934$ |

*Figure 1*. Exploration of the linearity epistemological obstacle ($\sqrt{a^2+b^2} = \sqrt{a^2} + \sqrt{b^2}$).

## Data Analysis and Discussion of Results

*Before Using CAS Technology*

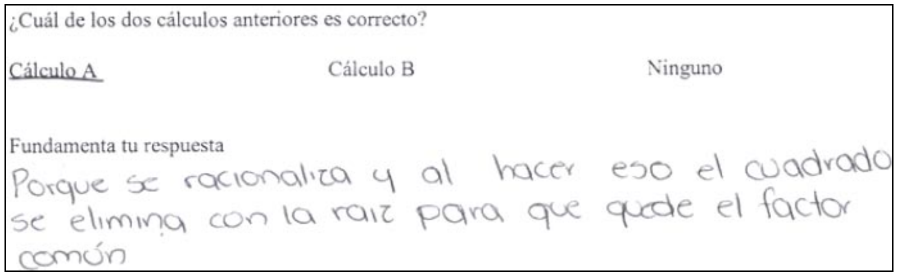
According to the students' justifications before using the calculator to answer the first question of the activity (Figure 2), it is noted that they considered $\sqrt{a+b} = \sqrt{a} + \sqrt{b}$ a valid equality. While all students identified the error or omission in calculating B, this did not lead them to automatically choose A as correct. Importantly, it was the separation of the square root $\sqrt{2^2+3^2} = \sqrt{2^2} + \sqrt{3^2}$ of A which led to the discussion as to whether such separation was correct or not. Below is part of the discussion among team 2, with regard to this separation of the square root.

S1: But here *[referring to the separation of the square root* $\sqrt{2^2+3^2} = \sqrt{2^2} + \sqrt{3^2}$]. Is it separable? I can remember it should not be separated. It goes with everything.

S2: It can be in two forms.

S1: Well yes. It's the same result.

At the end of first part of the activity (paper and pencil environment), all the three groups agreed that the correct solution was A. They argued that separating the sum of the square root simplifies the calculations. In particular, group 1 said that this allows them to rationalize (Figure 2).



¿Cuál de los dos cálculos anteriores es correcto?

Cálculo A Cálculo B Ninguno

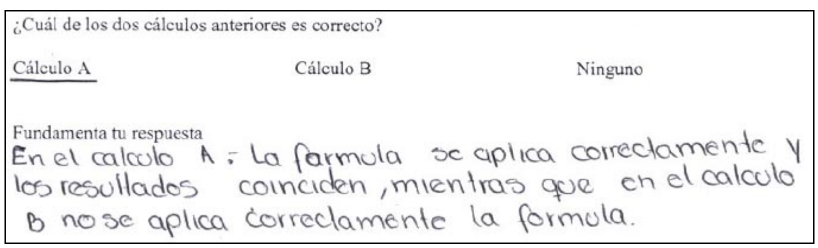
Fundamenta tu respuesta

Porque se racionaliza y al hacer eso el cuadrado se elimina con la raiz para que quede el factor común

*Figure 2*. The response of the group 1 to the first question of the activity before using the calculator.

Figure 3 shows the written record of the response of group 3 to the first question. It notes that the team identified the error or omission in calculating B, not the error in calculating A. In their discussion, it appears that they justified the separation of the square root, arguing that this will simplify the calculations. Here's part of their discussion:

S1: I would say no to this [*referring to the separation of the square root*]. This is not done when a formula is applied [*showing the error*] [...] It is not separable. Not in this kind.
S2: This can be [*referring to A*]. As you said [*pointing to student S1*] here the square root is separated [...] It is not altered.
S1: Just a little [...]
S3: One more step.
S1: Less
S2: Avoid a step.



¿Cuál de los dos cálculos anteriores es correcto?

Cálculo A Cálculo B Ninguno

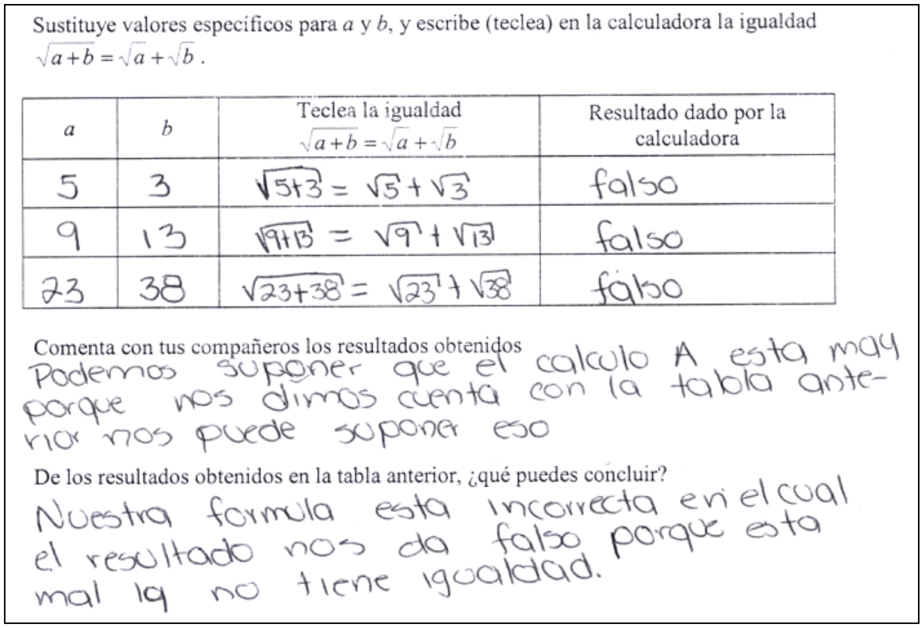
Fundamenta tu respuesta

En el calculo A : La formula se aplica correctamente y los resultados coinciden, mientras que en el calculo B no se aplica correctamente la formula.

*Figure 3*. The answer of group 3 before using the calculator.

*After Using CAS Technology*

After exploring equality $\sqrt{a+b}=\sqrt{a}+\sqrt{b}$ (Figure 4) using the calculator substituting with some specific numerical values for *a* and *b* as chosen by the students. The results obtained by the students, allowed them to reflect on their initial response and thus change their mind.



Sustituye valores específicos para *a* y *b*, y escribe (teclea) en la calculadora la igualdad $\sqrt{a+b}=\sqrt{a}+\sqrt{b}$ .

| *a* | *b* | Teclea la igualdad $\sqrt{a+b}=\sqrt{a}+\sqrt{b}$ | Resultado dado por la calculadora |
|---|---|---|---|
| 5 | 3 | $\sqrt{5+3}=\sqrt{5}+\sqrt{3}$ | falso |
| 9 | 13 | $\sqrt{9+13}=\sqrt{9}+\sqrt{13}$ | falso |
| 23 | 38 | $\sqrt{23+38}=\sqrt{23}+\sqrt{38}$ | falso |

Comenta con tus compañeros los resultados obtenidos

Podemos suponer que el calculo A esta muy porque nos dimos cuenta con la tabla ante-rior nos puede suponer eso

De los resultados obtenidos en la tabla anterior, ¿qué puedes concluir?

Nuestra formula esta incorrecta en el cual el resultado nos da falso porque esta mal ya no tiene igualdad.

*Figure 4*. Part of the activity where calculator was asked to be used.

The exploration of $\sqrt{a+b}=\sqrt{a}+\sqrt{b}$ by students, enabled most of them develop techniques that led to choose the correct answer to the problem (Group 3). This group developed strategies of solving the tasks, which are unlikely to have been developed in the paper and pencil environment. Although these students continued to use only natural numbers, they explored the equality using whole numbers (Figure 5).

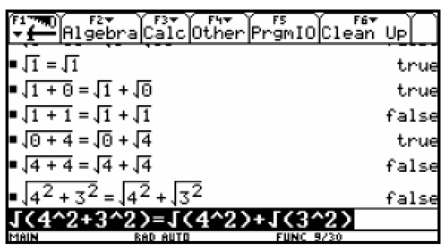


*Figure 5*. Exploration of equality by group 3.

After the equality $\sqrt{a+b}=\sqrt{a}+\sqrt{b}$ has been explored using CAS, most students were able to solve the problem correctly. Some of them were even able to affirmed that the equality is true only when *a* or *b* is zero. Affirmations as the above are unlikely to be made by students of this level if they solve tasks in the paper and pencil environments.

## Conclusions and Final Reflections

It can be noted, in the study, that tasks designed allowed students to reflect on their solutions. Their reflection can be located on three crucial moments in the process of their solution: a) in paper and pencil environment, b) using CAS technology to verify their conjectures and c) in their answer to the questions under each task. Interestingly, the results given by the calculator motivated the students to discuss the veracity of their first sets answers which were based on prior their knowledge in the paper and pencil learning environments. The exploration of equality

$\sqrt{a+b}=\sqrt{a}+\sqrt{b}$ substituting *a* and *b* with certain numbers helped students to raise conjectures which are later validated using CAS.

The model proposed here is useful for activities in two settings (paper and pencil, technology) to solve tasks. The results show that the use of technology, and through the model used in the study, helped students to overcome the *algebraic linearity* errors. The results of the study however raise another question: Is the epistemological obstacle overcome by the students when using CAS technology to solve tasks permanent or temporal? This question will be addressed in a subsequent research under normal classroom environments using technology.

## Acknowledgments

This research was made possible thanks to the funding from "Consejo Nacional de Ciencia y Tecnología" (CONACYT), file # 80 454. Our sincere appreciation goes to the students who participated in this research and their teacher and school authorities who gave us their facilities to carry out the tasks.

# THE EFFECT OF DGS ON STUDENTS' CONCEPTION OF SLOPE

Shiva Gol Tabaghi
Simon Fraser University
shiva_gol_tabaghi@sfu.ca

Ami Mamolo
York University
amamolo@yorku.ca

Nathalie Sinclair
Simon Fraser University
nathsinc@sfu.ca

*This report is the first instalment of a broader study which investigates university students' conceptualisations of static and dynamic geometric entities. In this part we offer a refined look at the conceptualisations of two groups of students – one group which was taught using Dynamic Geometric Software and the other in a 'traditional' fashion. We use both APOS Theory (Dubinsky & McDonald, 2001) and Sfard (2008) to interpret learners' understanding of the slope of lines. Our data reveal that students using DGS developed a strong proceptual understanding of slope, which enabled them to solve problems in which slope could be seen a conceptual object. This report sets the stage for a look forward to how DGS may influence learners' process-object conceptualisation of other geometric representations of algebraic equations.*

## Background

Dynamic geometry software (DGS) offers the possibility for modeling mathematical concepts and processes related to topics across the curriculum (Scher, 2000; Sinclair & Jackiw, 2007). As many researchers have pointed out DGS also enables students to perform multiple actions and generate a large number of examples effortlessly (Hollebrands, 2007; Laborde, 1992; Mariotti, 2000). Although more widely used, and studied, in the context of the geometry curriculum, the dynamic and interactive features of DGS enable the designing of models appropriate for representing algebraic concepts. Such models are built using the geometric language of DGS such as *The Geometer's Sketchpad* (Jackiw, 1989), and thus offer geometric representations of algebraic concepts.

Additionally, these representations are fundamentally dynamic, representing relationships and behaviours over time; students are invited to explore these relationships through the dragging capacity of the software. For example, a model of an affine function might be represented both geometrically (as a line on a Cartesian coordinate system) and algebraically. If the line itself is draggable, students can investigate the relationship between the position of the line on the graph and the resulting algebraic equation, thus emphasizing the invariance of the slope as well as the changing value of the intercept.

While DGS research has mostly been conducted in the contexts of teaching and learning geometry, recent studies have focused attention on the possible benefits that the dynamic manipulation paradigm might have for other school topics (as well as for tertiary-level mathematics). For example, Falcade, Laborde, and Mariotti (2007) have shown that the use of *Cabri-géomètre* (Baulac et al., 1988) can support a covariational approach to functions. Similarly, Sinclair, Healy, and Sales (to appear) report on the use of dynamic functions within both *Sketchpad* and *Cabri*, and the way in which, compared to static functions, dynamic ones elicit more attention to mathematical aspects such as domain and range, the relationship between the dependent and independent variables, and the effect of asymptotes.

In this study, which draws on a wider investigation of the use of DGS in non-geometric areas of the curriculum, we focus on a much more specific element of the school algebra curriculum—that of slope. Given the importance of the notion of slope in early algebra, as well as in higher-level studies, as well as its convenient and widely-used geometric representation, we chose to study the effect of dynamic representations of slope on student learning. Prior research on slope has focused on the notion of slope as a ratio, and on the difficulty students have in constructing the concept of slope using the typical representation of the slope formula (Lobato & Seibert, 2002). Given the dynamic representation available in *Sketchpad*, and, in particular, the ability to drag a line (either by rotation or translation) and observe the dynamically-linked slope measurement, we decided to investigate whether such a representation might help students gain a better understanding of the slope concept as an object (and not just the end point of a calculation involving the rise and the run).

## Theoretical Perspectives

Prior research suggests that learners' engagement with computer software can facilitate certain mental constructions, particularly with respect to the process-object tension (e.g. Weller et al., 2003). Process and object understandings of mathematical entities lie at the centre of the inter-related theoretical perspectives which informed our study: the APOS Theory (Dubinsky & McDonald, 2001), Sfard's *reification* (1991), and the *percept-procept* distinction (Tall et al., 2000).

The APOS (Action, Process, Object, Schema) Theory postulates that learners' understanding of mathematical entities can develop from a *process* conception to an *object* conception through the mechanism of *encapsulation*. In the view of Dubinsky and McDonald (2001), an individual who imagines a mathematical entity, such as multiplication, as an action to be performed internally is said to conceive of that entity as a process. Accordingly, a process conception is recognised by qualitative descriptions which may describe actions though not execute them. For example, with respect to multiplication, imagining an action of collecting three groups of two objects to yield six objects would correspond to a process conception. If that process can be realised as a completed totality – three groups of two objects *as* six, rather than *to yield* six – then *encapsulation* of that process to an *object* is said to have occurred. Encapsulation of a process is a sophisticated step in an individual's conceptualisation. It requires appreciating the mathematical entity as a completed totality upon which transformations or arithmetic operations may be applied.

In a similar vein, Sfard (1991) describes the "quantum leap" that must occur in order that "a process solidifies into object, into a static structure" (p.20) in a learner's conceptualisation. Sfard refers to this leap as *reification*: "an ontological shift – a sudden ability to see something familiar in a totally new light" (1991, p.19). Further, Sfard (2008) identifies reification as a discursive process and describes it as "the act of replacing sentences about processes and actions with propositions about states and objects" (p.44). Relating the process-object distinction made both by Sfard and the APOS Theory to the idea of slope, we suggest that a process conception of slope might be recognised by an individual's description of a line that "goes up" by so much. In contrast, an object conception of slope could correspond to the description of an angle that may be scaled by any number.

Tall et al. (2000) offer a close look at the nature of mathematical objects and the intricacies of encapsulation or reification, and suggest that there is no "universal answer" to the question "how are [objects] constructed" (p.223). In particular, Tall et al. echo Sfard's (1991) observation that a structural (object) conception need not follow directly from an operational (process) conception, particularly in the case of geometric presentations. Tall et al. identify a distinction in how geometric 'objects' may be conceived: as "perceived objects" – *percepts* – or as "conceived objects" – *procepts*. In Tall et al.'s perspective, a perceptual understanding is recognised by an individual's attention to the "specific physical manifestations" (2000, p.228) of the geometric image. For example, a learner might conceive of a circle first as a percept – as a round, symmetric object – rather than as the process of finding all the points equidistant to the centre point.

Eventually, through *reflective abstraction*, a geometric *percept* may be constructed by an individual as a *procept*. Tall et al. (2000) suggest that procepts "are constructed as imaginary manifestations of the perfection of the definition, for instance, lines with no thickness that can be extended arbitrarily in either direction" (p.236). Further, they observe that "the construction of *perceived* geometric objects leads later to *conceived* geometric objects, which, though imagined in the mind's eye, and discussed verbally between individuals, are perfect entities that have no real-world equivalent" (ibid). With respect to the circle, a proceptual conception might correspond to the idea of the set of points which are equidistant from a centre point, and which necessarily form a round shape with infinitely many lines of symmetry.

We contend, in accord with Denis (1996) and Sfard (2008), that an object conception corresponds to 'descriptive' rather than 'narrative' discourse and suggest further that a pedagogical approach which connects algebraic representations with the percept of geometric entities may trigger a shift from narrative to descriptive discourse, and as such, promote encapsulation of that entity to a conceived object. Extending on prior research, we examine how DGS, which allows learners to act directly on objects such as circles and lines, may facilitate the leap toward the descriptive, from process to object conceptualisation of entities with both a geometric and algebraic representation, in particular with respect to *slope*.

## Setting and Methodology

### *Participants*

Participants were undergraduate liberal arts and social science students enrolled in a foundations course in quantitative reasoning. The course was designed as an up-grade to secondary school mathematics courses and focused on topics such as percentages, single variable equations, graphing lines, and problem solving. Two different sections of this course, Class A and Class B, respectively, which were taught by the first and second authors, were engaged in our study.

### *Comparing Instructional Representations*

Class A students were introduced to the notion of slope using dynamic representations of lines. These students used dynamic interactive sketches to visualize the change of slope measurement and the resulting geometric representation of the line. They were introduced to the notion of slope as a measurement to find out the steepness of a straight line, and discussed the relationship of numerical value of slope with its steepness. *Sketchpad* was employed to support the introduction and discussion with providing dynamic sketches of lines. Students interacted with the sketch shown in Figure 1. Specifically, they were asked to drag points A and/or B to find lines with slopes of -10, -4/5, -1/4 and 0. Dragging these points has the effect of tilting the line and generating several different examples of lines and their slopes.

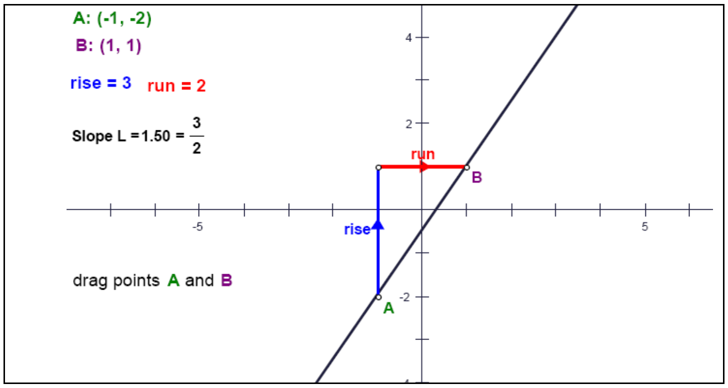

*Figure 1.* A snapshot of the sketch used by Class A.

Class B students were introduced to the notion of slope using a more traditional approach. These students saw static images of the typical triangle construction exemplifying ‘rise over run’ and the associated calculations. Students were exposed to a collection of different examples, including lines with different steepness as well as lines with negative slopes. Analogies and problems that reinforced the concepts of slope and steepness were also discussed. Students were also asked to reflect on and compare lines of different slopes, as in the task demonstrated in Figure 2 below.

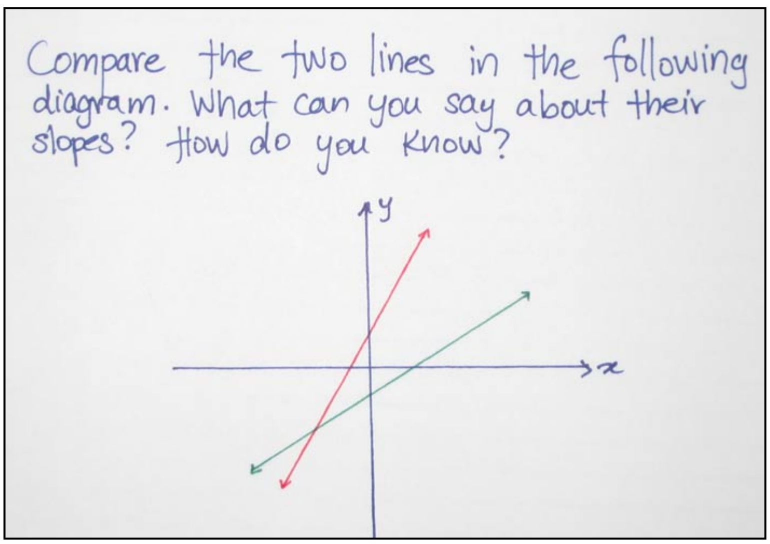

*Figure 2.* A snapshot of the sketch used by Class B.

Each class spent approximately 30 minutes on these slope tasks, and then moved on to investigations of linear equations and intercepts.

*Data Collection*

Data were collected from in-class pre- and post-tests. Pre-tests were given two weeks prior to the lessons on slope, and post-tests were given the week following instruction. Participants’ results on the pre-test informed the design of the post-test items. Pre-test items included questions relating to positive and negative slopes, as shown in Figure 3. It also included a question on identifying parallel lines given a list of equations, interpreting a story problem, and comparing the graphs of $y = x$, $y = 2x$ and $y = 2x+3$.

2. Circle the graph(s) that represent(s) a line with negative slope.

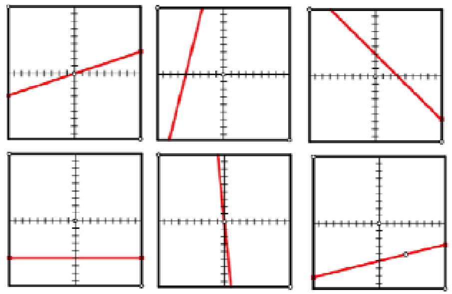

*Figure 3.* Shows positive negative slopes question of the pre-test.

Our intent in designing the post-test was to probe participants' conceptions about the notion of slope. In addition to repeating the question shown in Figure 3 above (with modifications of the actual order and shape of the graphs), we also included three additional questions shown in Figure 4 below: (1) A non-graphical question about the steepness of the slopes of different linear questions; (2) an example generating task; and, (3) a story problem where participants were asked to identify with justification whether the graph matched the story. This line of questioning was intended to present participants with non-routine problems relating to slope and to identify key features in participants' discourse that might indicate how they were conceptualising slope.

1. Consider the equations (a) $y = 3x+2$ (b) $y = 3x+10$ (c) $y = 2x+1000$ (d) $y = 2x-50$.
i. Which is/are steepest? Why?
**ii.** Which is/are less steep? Why?
2. The equation of a line is given as $y = 5x -3$. Provide three different examples of linear equations that pass through (0, -3). [An empty Cartesian graph was also provided].
4. Read the story below and discuss whether the story fits the graph.
*John was walking with his wife along the seaside. After about 5 minutes, he stopped to chat with his friend for a few minutes. He then began to run, to catch up with his wife.*

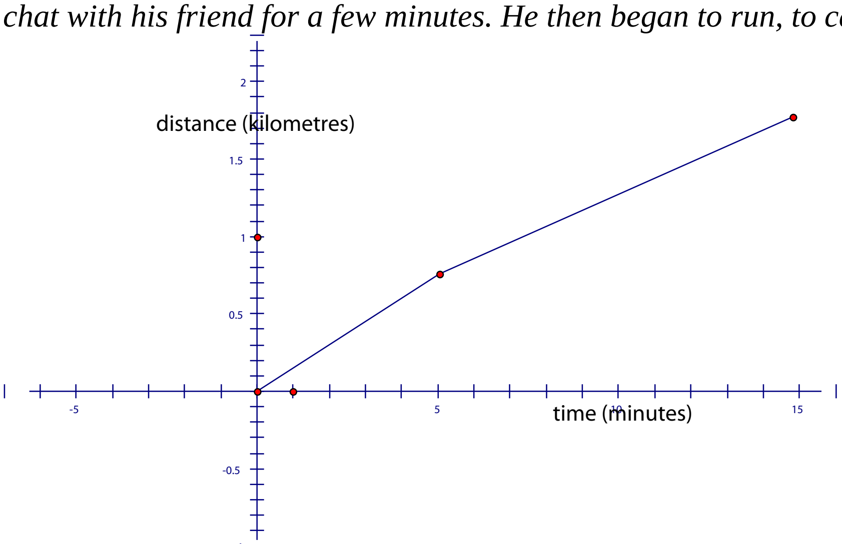

*Figure 4.* Three additional post-test problems.

## Results and Analysis

We present our results in two sections, first in terms of descriptive statistics on the pre- and post-tests, and second, on more qualitative interpretations of the patterns of student answers.

*Analysis of Pre- and Post-test*

Given that only the negative/positive slope question was repeated from pre-test to post-test, we limit our descriptive statistics to the comparison between the two classes on that item. The results are shown in the table below. Class A scores significantly lower on the pre-test compared with Class B, but then outscores Class B on the post-test.

Table 1. *Comparing Class A and Class B: Identifying Lines with Negative Slope*

| | Pre-test % | Post-test % |
|---|---|---|
| Class A | 36.36 | 87.5 |
| Class B | 77.59 | 83.87 |

These results indicate that Class B was already quite strong on the pre-test, and improved only slightly on the post-test. On the other hand, Class A was very weak at identifying lines of negative slope, and improved significantly after their instructional session in which they interacted with the dynamic sketch shown in Figure 1. On this sketch, the values of the rise and the run are shown, as was the value of the slope. Students were asked to drag the line continuously on the screen, so that they created a wide number of examples of lines along with their corresponding slopes. Given that the task asked them to create lines of given slope, they probably focussed more on the value of the slope, than on the values of the rise and the run. Therefore, these students did not need to coordinate the two numbers rise and run, and would have conceptualized the slope in terms of either bending forward or backward.

The lower pre-test scores on this item for Class A are consistent with their scores on other items in the pre-test; in other words, they were weaker than Class B on all items of the pre-test, and were also judged to be relatively weak by their classroom instructor. Given the significant difference in scores on this item from pre- to post-test, we decided to further investigate the students' understanding of slopes in contexts other than identifying positive or negative slope.

While comparative statistics on the remaining three items of the post-test are less useful, we include them here in Table 2 for completeness. We note that question 2, in which students were asked to generate equations having the same *y*-intercept, showed the only significant difference in favour of Class B. We found this result surprising, and will discuss it further in the following section.

Table 2. *Comparing Class A and Class B: Identifying Lines with Negative Slope*

| | Post-test question 1 | Post-test question 2 | Post-test question 4 |
|---|---|---|---|
| Class A | 64.29 | 48.81 | 69.64 |
| Class B | 75.81 | 79.57 | 59.68 |

*Participants' Discourse on Slope*

Tall et al. (2000) identify two distinct descriptive narratives relating to individuals' conceptualisation of geometric entities. On one hand, an individual may attend to visual cues elicited by the physical presentation of the entity – indicating a perceptual understanding. On the other hand, an individual may abstract from the visual cues to describe "the perfection of the definition" (Tall, et al., 2000, p.236) of the entity – indicating a proceptual understanding. Based on our analysis of participants' discourse relating to slope, students in Class A seemed to have developed a strong perceptual understanding of slope. Participants in Class A were able to reason visually, distinguishing negative from positive slopes visually, without relying on the rise over run formula.

Contrary to Class A's results, no change in participants' reference to perceptual aspects of slope or lines were observed in responses to post-test items from Class B. Rather, in support of our hypothesis, Class B participants seemed to rely more on narrative discourse, indicating a process conception of slope, in terms of the APOS Theory. For instance, in response to the "steepness" question on the post-test, the majority of students in Class B who answered correctly justified their response by saying that rise/run = 3/1 was greater than rise/run = 2/1. In contrast, the Class A participants who correctly answered did not make use of 'rise over run' narrative descriptions, and simply stated that 3 was greater than 2. In both classes, incorrect answers involved making comparisons between the values of the intercepts. This suggests that students were not so much confused about slope itself, but about the expression of slope within a linear equation.

Similarly, for the example-generating task illustrated in Figure 4, many participants in Class B superfluously introduced rise over run calculations, relying on manipulating the equation of a line to generate examples of lines with different slopes. Very few participants in Class B realised they could just change the value of the slope to generate a new example. Class B's reliance on manipulating equations is indicative of an operational, or process, understanding of slope. Rather than appreciating slope as an object that could be scaled or acted upon, many seemed to view slope as something which *needed* to be calculated – indicating a process understanding, in APOS terminology, or operational understanding in Sfard's (1991) perspective. Students in Class A who correctly answered this question did seem to generate equations without using the rise over run narrative (we infer this from the absence of the words 'rise' and 'run' in their responses). However, a larger proportion of Class A students simply left this question blank. Once again, we hypothesise that their inability to respond relates to a lack of coordination between the values of slope and intercept in the linear equation. In this case, having a procedural way of solving the problem seems to have benefited Class B.

Similar features were identified in participants' responses to the story problem illustrated in Figure 4. Again, participants in Class B were observed introducing slope calculations to justify whether or not the graph matched with the story. In contrast, participants in Class A were more likely to attend to the visual aspects of the graph, such as identifying stoppage time with a horizontal line segment (slope equal to 0). Participants in Class B were also more likely than participants in Class A to describe lines which "start at" a particular point, suggesting they viewed lines, as well as slopes, as entities which needed to be constructed – processes which needed to be carried out. The relatively strong performance of Class A supports the hypothesis that these students had built a strong perceptual understanding of slope, which they were able to use to interpret the visual graph accompanying the story.

## Conclusion

Based on our analysis of the students' responses to post-test questions, we suggest that the use of *Sketchpad* can help students develop a strong proceptual understanding of slope that emerges somewhat independently from the process-oriented conception inherent in the rise over run formulation of slope. This proceptual understanding corresponds to a descriptive narrative about the conceptual object of slope. The students in Class A, who had interacted with a dynamic graph, were able to use a descriptive narrative to distinguish positive and negative slope, to evaluate the steepness of lines, and to solve story-based problems. We argue that they were able to solve these problems because of their ability to see slope as an object, an ability that they had developed in their interactions with *Sketchpad* in which they directly acted on the graph to create different slopes (rather than acting on, say, the rise or run values of the line). The students in Class A solved these problems very differently than students in Class B, who depended far more strongly—and sometimes superfluously—on process-based conceptions.

Additional questions on the pre- and post-test that involved only algebraic manipulation (and not evaluation of visual graphs) indicated that the students in Class A were less successful in using their descriptive discourse in solving problems in which they had to coordinate between the slope and intercept values of a linear equation. Such problems may in fact require a more narrative discourse. However, we are pursuing further research to determine whether students can also develop an effective descriptive conception of slope within a linear equation, and coordinated with the role of the intercept, in order to be able to solve problems involving both slope and intercept concepts.

# FROM CONCRETE MODELING TO ALGEBRAIC SYNTAX: LEARNING TO SOLVE LINEAR EQUATIONS WITH A VIRTUAL BALANCE

Teresa Rojano
Center for Research and Advanced Studies
trojano@cinvestav.mx

Minerva Martínez
Center for Research and Advanced Studies
minemartinez2008@hotmail.com

*We are reporting on the results of a study undertaken with secondary school students in which a virtual version of a balance model is used to teach the students how to solve linear equations. The model is dynamic and enables the solution of term subtraction equations. We are studying the passage from the model to algebraic syntax and have adopted the perspective of mathematical sign systems (Filloy, Rojano & Puig, 2008), which incorporates student signic productions into the analysis as part of the interaction among the sign systems of algebra, arithmetic and the model.*

## Introduction

A good number of studies have focused on analysing the difficulties faced by students when learning algebraic syntax in order to solve linear equations. Some of the studies highlight the importance of reconceptualizing equalization as a sign of equivalence (Kieran, 1981; Kieran & Sfard, 1999). While others, underscore the need to learn how to operate with unknowns (Filloy & Rojano, 1989; Filloy, Rojano, & Puig, 2008; Herscovics & Linchevsky, 1991; Stacey & MacGregor, 1997; Vlassis, 2001). Some of the latter authors have specifically analyzed the role played by concrete modeling with a balance in the processes of building said syntax. Filloy & Rojano (1989) identified extreme cognitive tendencies in secondary school students, who at the beginning of their work with a balance showed, in some cases, a deep attachment to the model or, in other cases, a very quick detachment from the model going on to carry out the actions solely at the level of symbolic algebra. Vlassis observed in her study that use of the balance model helped students to learn the formal method of applying the same operation to both sides of the equation and that the main difficulties arose when it became a matter of having the subjects generalize the method to equations containing negative integers (Vlassis, 2002). Whereas Radford & Grenier (1996) found that a balance helps students to understand the rule for elimination of like terms.

One common element in several of the previously mentioned studies is that extending the numerical domain of equations to the set of integers represents a factor that obstructs generalization of the equation solution method. Gallardo (2002), Bruno and Martinón (1997) and Glaeser (1981) have analyzed the nature of the difficulty of incorporating negative numbers and their operativity into algebraic syntax. And in more particular terms, Filloy and Rojano have done so with respect to negative numbers and their relation to concrete modelling; they report the case of a student who spontaneously adapted the concrete model so as to solve equations with negative coefficients, which in principle was unexpected (that is to say that the ability to use the model to solve equations with negative coefficients was unexpected). These authors indicate that the foregoing is a manifestation of a cognitive tendency that consists of a deep-seated attachment to the concrete model, even in cases in which the modelling may be even more complex than the operativity itself at the symbolic level (Filloy & Rojano, 1989, pages 22 and 23; Filloy, 1991) that this may represent an obstacle to abstraction and generalization of the algebraic method. By the same token, Vlassis found in her research that the effect of having given students a concrete

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

meaning for manipulation of the equation terms lasted for several months after they had worked with the balance –considered a positive effect. This author admits however that the students will later on have to overcome obstacles related to the processes of abstraction, for instance such as in the case of solving equations that involve negative numbers and for which the balance model was not designed (Vlassis, 2002, pages 356-357).

The study reported here incorporates usage of an applets-based virtual balance model that differs from the traditional model (concrete or diagrammatic) in that it is dynamic and interactive and in that its expanded version (pulley balance) includes representation and solution of equations with term subtraction (SEP-ILCE, 2007) [1]. Another trait of this interactive unit is that it includes a section in which the balance is fixed and the user must choose the operation to be carried out with the terms of the equation (application of inverse operation so as to eliminate terms), which has the effect of helping the student to "abstract" the model's actions to the algebraic syntactic level. The results obtained suggest that after working on tasks with the interactive unit and worksheets that indicate a didactic route for mastering the syntax, the students are able to abstract the model's actions and recover them at the level of symbolic manipulation. The foregoing is achieved for broad families of linear equations, including those that contain terms with negative coefficients.

## Aim of the Study

The main purpose of the study is to research the extent to which work with the dynamic version of the balance referred to above helps subjects to abstract the actions undertaken with the balance at the level of the algebraic syntax associated with the solution of linear equations. In other words we are interested in investigating whether subjects are able to generalize the method of "doing the same thing on both sides of the equation" to increasingly more complex equation modes, including equations that contain term subtractions with positive coefficients. We have included arithmetic ($Ax = B$; $Ax \pm B = C$; A if a specific positive integer, B, C, and D are particular non-negative integers) and non arithmetic equation modes ($Ax \pm B = Cx \pm D$), in keeping with the classification of Filloy & Rojano (1989).

## The Virtual Balance and the Didactic Circuit

As previously mentioned the concrete model used consists of a virtual version of the traditional diagrammatic model. In the first part of the interactive unit, students work with the **basic balance** (see Figure 1).

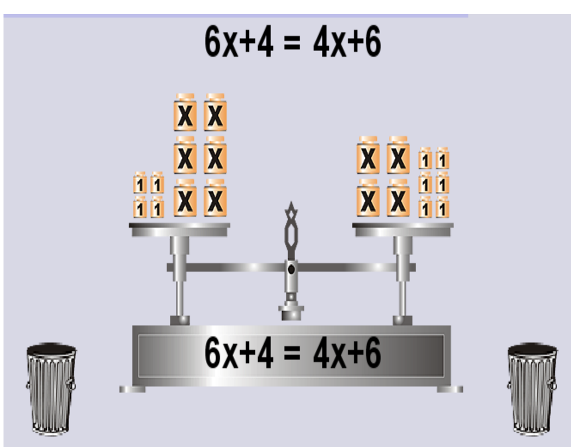

*Figure 1.* Basic balance.

Users can drag objects to add them onto either side of the balance (taking them from the piles in the middle) or to drop them. The objects available have either known weights (unit weight) or unknown weights (x). The idea is for students to understand the principles guiding the actions that maintain or re-establish equilibrium at each step. The sequence of scenes includes the following sections: a) *weigh objects*; b) *represent a given equation*; c) *find the value of the unknown weight*. The bottom section displays the equation that is to be solved, as well as the changes to the equation that result from the actions carried out on the balance, thus acting as feedback. Equations to be solved appear randomly, however the *level* button makes it possible to gain access to exercises containing increasingly more complex equations.

In the second part of the interactive unit, students work with **pulley balance** (see Figure 2). With the extended balance model one can represent and solve equations that include subtraction of positive coefficient terms, that is to say it is possible to remove and subtract weights. The terms that are subtracted are represented by weights that are placed in the upper pans. Objects can be dragged from the upper pans to the lower pans –be that the right or left pan– and vice versa. One can see that when going from an upper pan to a lower pan (or the other way around) or from the left to the right pan (or the other way around), the operation sign preceding the corresponding term in the equation changes (this can be observed in the equation that is displayed in the bottom section of the balance).

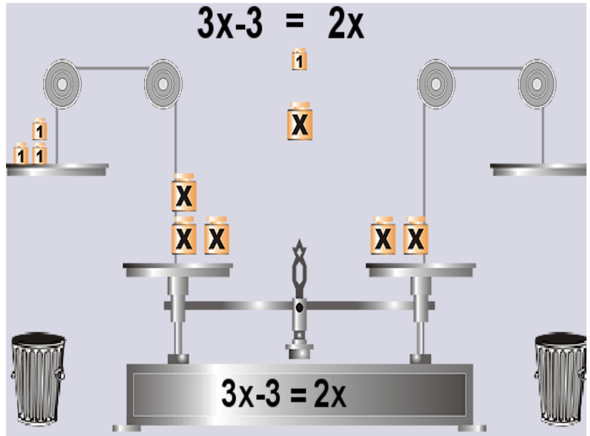

*Figure 2.* Pulley balance.

In the basic balance model, the didactic circuit consists of the following: 1) Familiarization with the balance (weighing objects); 2) representation of equations on the balance (correspondence between the elements of the equation and those of the model); 3) solution of equations with the dynamic balance, finding the unknown weight by eliminating objects from the pans (principles of manipulation that maintain the equilibrium); 4) solution of equations with the fixed balance, by choosing the inverse operation that is applied to the terms of the equation (recovery of the principles that maintain the equilibrium at the syntactic level: notion of algebraic equivalence) see Figure 3; and 5) solution of equations without the balance, transforming and re-establishing equalization at the symbolic level of algebra (automatization of actions at the syntactic level).

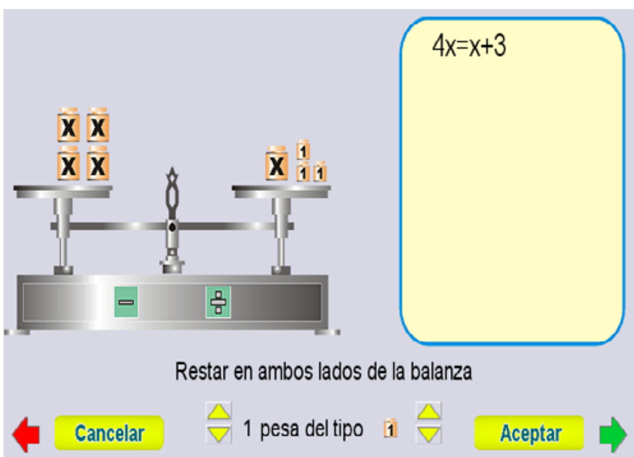

*Figure 3.* Fixed balance.

Steps 1-5 are repeated when using the pulley balance, thus extending the method to equations with term subtraction.

## Mathematical Sign Systems and Abstraction to Syntax

In the theoretical approach proposed by E. Filloy (Filloy, Rojano, & Puig, 2008; Kieran & Filloy, 1989; Puig, 2004) the notion of text is introduced to be used in the analysis of any sense production practice, for example when the learner interacts with a teaching model. From this standpoint essentially based on the semiotics of Pierce (1931-58), a distinction is made between *text* and *textual space,* a distinction that corresponds to that between *meaning* and *sense*. A text is the result of a reading/transformation labor made with a textual space, the aim of which is not to extract a meaning inherent in the textual space, but to produce sense (Filloy, Rojano, & Puig, 2008, page 125). The textual space is a system that imposes a semantic restriction on the person who reads it; the text is a new articulation of that space, individual and unrepeatable, made by a person as a result of an act of reading. Thus a teaching model is a succession of texts that are taken as a textual space to be read/transformed into another textual space as the learners create sense in their readings.

The interactive virtual balance unit is a teaching model and a textual space in terms of the afore-described theoretical perspective. When students interact with that textual space reading / transformation processes are unleashed, and sense is produced in those processes: the sense of the actions in the model and the corresponding actions at the symbolic level of algebraic syntax with the elements of the equation.

At the same time in this theoretical model symbolic algebra is considered a mathematical sign system (MSS), understood as a sign system (with its corresponding code) in which there is a socially conventionalized possibility of generating signic functions (Filloy, Rojano, & Puig, 2008, page 7). Attached to the MSS are the sign systems or strata of sign systems that learners produce in order to give sense to what is presented to them in a teaching model. According to Filloy the texts produced by readings that use different strata can be described in an MSS, but when that does not take place only the creation of a new MSS will make it possible. The process of creating new MSSs for that purpose is a process of abstraction and the new sign system is more abstract than those preceding it. In the case at hand, the new sign system is that of algebra and it is more abstract than the sign system of arithmetic. It is also more abstract than that of the intermediate strata constituted by the productions of the students themselves based on their interaction with the virtual balance model. Examples of that type of production will be showed in a subsequent section.

## Methodology and Data Collection: Sessions With and Without the Balance

The study was carried out with a group of eight secondary school students, 12 to 14 year olds, who had not received any instruction on the algebraic method for solving linear equations. Worksheets were prepared in keeping with the didactic circuit of the interactive balance unit, as were a pre and post questionnaire aimed at finding out what strategies the students used to solve the equations prior to and after their work with the balance. The items of both questionnaires correspond to arithmetic and non arithmetic equations.

The six class sessions in which the balance was used were undertaken in a computer lab during one and the same school term. The large screen display of the interactive unit was used for teacher explanations, pupils' individual participation, and collective discussions. Additionally, the students worked in pairs on the computers to solve the tasks proposed on the worksheets. The following section is a discussion of the outcomes obtained during the class sessions.

## Analysis of Outcomes

### *Sessions Using the Basic Balance*

In the first session, students worked with the scenes *"finding the weight of "x" and representation of linear equations on the balance"*. They manipulated the virtual dynamic model and were able to relate the meaning of balance –pertaining to the sign system of the model– with the meaning of the equality sign in the equation –pertaining to the sign system of algebra. However not all of the students were able to attain said level of understanding; when doing the tasks with paper and pencil, two of the students continued to write the equation transformations as chains of equalization (their own productions that are located within an intermediate stratus between the sign system of arithmetic and that of algebra).

During the *equation solution* session (second scene) the students demonstrated self confidence, navigating through the five complexity levels: from solution of equations with a single occurrence of an unknown (arithmetic equations), through to solution of equations in which the unknown appears on both sides of the equalization (algebraic equations). The worksheets, which students solved with paper and pencil, show how the subjects adapted the model and used it in solving equations containing coefficients greater than those supported by the virtual model. In this stage, we observed diagrammatic reproductions (drawings) of the model and the symbology used is a mixture of those diagrams with arithmetic operation signs (personal productions generated due to the interaction with the sign system of the model and incorporation of elements of the sign system of arithmetic).

In the third session, where students must *solve equations choosing the inverse operation*, we observed significant progress in algebraic syntax. The students were able to solve the equations, eliminating terms by applying the corresponding inverse operation and in the majority of cases there were no indications that the students had resorted to the balance model, not even diagrammatically. As of that point, we observed recovery processes of the actions undertaken in the model, at a more abstract level, producing sense related to the actions carried out with the elements of the equation. This more abstract level is the sign system of algebra, which enabled the students to carry out the reading/transformation of the texts constituted of the more complex linear equation modes (for instance, non arithmetic equations with negative coefficients that did not have meaningful referents in the balance). The foregoing was not possible for them when they remained at intermediate (more concrete) strata related to the model and/or to arithmetic. At this stage the solution characteristics were the following: use of the inverse operation; progressive usage of algebraic signs (students no longer use the model drawing, they rather make use of algebraic symbols), although in some cases we still observed certain reluctance to operating unknowns and a return to arithmetic strategies. The progress achieved in algebraic syntax as of the third session can be seen in Figure 4, which depicts part of two students' worksheets produced throughout several sessions.

*Sessions with the Pulley Balance*

In addition to progressing toward solution of a more extensive family of linear equations, working with the pulley balance enabled students to identify and learn the term transposition method. As such at the end of the study, participants could indistinctly apply that method, as well as that of “doing the same thing on both sides” or “using the inverse operation” method. Toward the second to last session, students solved all of the exercises and any reluctance for operating unknowns in non arithmetic equations had disappeared. At the same time, students had left behind usage of the model, and equations were solved in the sign system of algebra, although in some cases use of arithmetic operation signs persisted (for instance, ÷). At the syntactic level, the difficulty of applying the methods learned to a more extensive family of equations with negative numbers reappeared, especially in cases of signed numbers that are not suitable to modeling with the balance or in the case of negative solutions (such as, for example: $5x + 7 = -3x – 9$). The latter confirms the outcomes of Vlassis (2002), in the sense that the presence of negative numbers represents an obstacle for generalization of the method.

During the last session, which dealt with *solution of equations containing terms with negative coefficients, choosing the correct operation*, the virtual model made it possible to reinforce the way of working that the students had previously acquired; that is to say, transposition of terms. The foregoing can be attributed to the fact that in this section the model displays, on the left hand side of the scene, a representation of the actions that are carried out.

As mentioned before, the worksheet for this scene contains both arithmetic and non arithmetic equations, with additive structure and with term subtraction. We observed that the final work of the students contained both solutions attained using the “doing the same thing on both sides” method (for single-step equations), as well as the “term transposition” method (for equations with occurrences of “x” on both sides) (See Figure 4, session 6).

*Pre and Post Questionnaires*

Figure 5 is a synthesis of the outcomes of the pre and post questionnaires, while Figure 6 depicts some examples of the answers given by the students to items contained in both questionnaires. These outcomes confirm our classroom session observations, through the worksheets, dealing with the evolution of subjects on their road to mastering algebraic syntax in order to solve linear, arithmetic and non arithmetic, additive and term subtraction equations. In some cases, children could extend the method to equations of the form $Ax + B = - Cx + D$. However, there is no evidence to suggest a complete generalization of the method, for example to linear equations with a negative solution.

| PRE-QUESTIONNAIRE | POST-QUESTIONNAIRE |
|---|---|
| • Students apply arithmetic strategies to solve both arithmetic and non-arithmetic equations.<br>• They avoid operating on the unknown when solving non-arithmetic equations.<br>• Trial and error strategies predominated in the solution of non-arithmetic equations. | • Use of algebraic syntax predominates.<br>• Verification of solutions by numeric substitution.<br>• Special writings appear. For example, when solving the equation $5x+2 = -3x-6$, 3 out of 8 students operate on constant terms and terms with ‘x’, separately, as follows:<br>$5x+3x = 8x$<br>$-6-2 = -8$<br>$x = -8/8$<br>• Many still use the sign ÷: $10x=2$, $x=2÷10 = 5$ |

## Final Discussion

According to Filloy when teaching is begun with a concrete model it is important to understand the actions executed, as well as to discover the syntax elements implicit in those actions. This process leads to abstraction of operations; that is to say recovery processes at the syntactic level. In the study reported on here, manipulation of the dynamic virtual balance model in the initial scenes made it possible to produce sense related to those actions in the model. Work with the scenes of the fixed balance and choosing the inverse operation favored production of sense at the level of algebraic syntax. In other words the fact that it was not possible to manipulate the balance fostered abstraction toward the sign system of algebra by way of discovering the implicit principles of preserving equality (balance). The foregoing became crystal clear in the post-questionnaire when the students solved the equations solely with paper and pencil and with no access to the interactive model. These outcomes serve to ratify those of other authors (Vlassis, 2002; Filloy & Rojano, 1989; Radford & Grenier (1996) who used a diagrammatic version of the balance in their research. The outcomes from the pulley balance section suggests that working simultaneously with addition and subtraction of weights also leads students to discover and abstract the rules of term transposition. That discovery broadened the students' level of algebraic competence with respect to solving linear equations, from the "doing the same thing on both sides" method to the vietic "term transposition" method, as well as to the rule for grouping like terms. The expansion also applied to the type of linear equations, given that the students ended up solving equations with negative coefficients, although several cases demonstrated the classic difficulties that students of that age group have in understanding and operating negative numbers.

## Endnote

[1] The pulley balance allows for modeling of equations that have an additive structure and of term subtraction equations. This means that only terms with positive coefficients that are added or subtracted can be modelled, while terms that include signed numbers, such as in 7 – (-2x) or 5x + (-3) cannot, unless the students are familiar with the syntax of negative integers that enables them to reduce the previous cases to 7 + 2x & 5x – 3, respectively. The foregoing is due to the fact that objects on the balance always have a positive weight. This applet-based interactive unit

was developed by the programming group “Descartes” at the Latin American Institute of Educational Communication (ILCE) in Mexico and is part of the interactive materials that the Ministry of Education (SEP) has distributed in the public secondary schools across the country. The experimental work was funded by CONACYT, Mexico (Project Ref. No. 80359).

*Interpreting Global allows to explore the contents of the algebraic expression in order to identify visuals variables in the graphic, giving a categorical variable in the algebraic expression. However, developing the global interpretation in polynomials of degree higher than two seems to be a complex task, because the trace, to identify and interpret the correspondents visual variables. To overcome this problem, an alternative to explore qualitative and quantitative traces is reviewed here based upon "visual characteristics". This is enriched through the use of numeric representation analyzing the graph relations of deep-figure from the numerical point of view.*

## General Background

Duval (1999), mentions that mathematic visualization is not simultaneous in the field of perception; it is an intentional cognitive activity that produces a representation in two-dimensions (screen, paper, etc.). It shows the relationship between representational units that make up the figure, meaning that mathematical visualization presents only a mathematical object. These are "seen" through the organization of relationships between figures. In the case of the graph, it has two figures: deep-figure (meaning the Cartesian Plane) and the figure-form representing the trace.

In this regard, global interpretation (Duval, 1999) identifies the visual values to establish the relationships with categorical values of the algebraic expression. The treatment is essentially qualitative, leaving the deep-figure as a stable frame. This is an important issue in order to explore the contents of the representation, since the modification of deep-figure, dividing locally the unit of graduation, produces a change in figure-form. This activity modifies the unit of graduation, a change identification of the values.

Duval (1994), emphasizes the common principle of the visual organization for the numerical representation, in learning, which has two apprehension levels:

- "an apprehension resulting of a simple exposition cognitive of control.
- and an apprehension that result of the interpretation global". (pp. 6)

The first level is the most helpful in teaching, because it focuses exclusively on one approach to control, i.e. …, while the second level is ignored, it is required to expose the contents of the representation to identify the representational units, establishing connections with others, in particular the algebraic.

The objective of this paper is to establish a numerical analysis of the graph through the numerical table to enhance the algebraic construction. To pursue such a goal it is necessary to explore the contents of the numerical table (numerical representation) from a global interpretation requiring the use of treatments, thus benefiting the identification of numeric variables to establish connections with the categorical variables (from the algebraic representation).

## Enhancement of Global Interpretation

The global interpretation (Duval, 1988) stresses the changes in the algebraic expression corresponding to visual variables pertinent to interpret the graph, allowing the association of a visual variable with a categorical variable within the algebraic expression. It contributes to the identification and establishment of relations between the two representations.

Duval analyzes the behaviour of the straight line through the global interpretation, mentioning the possibility of a similar analysis for the case of the parabola. This paper has identified and reviewed the visual and categorical variables (algebraic expression) for second order polynomials. The study reveals the difficulty in discriminating the visual variables that characterize the polynomial, since the behaviour of the trace presents more variation than the straight line, increasing the number of numerical variables to be identified. With respect to the study of the cubic polynomial, the interpretation of its content through the analysis in the algebraic expression is performed. This task tends to be exhaustive due to modifications of the trace, obstructing the interpretation of the visual variables suffering many variations. However, these are identified for the cube term$(y = \pm ax^3)$. The analysis is complicated when involving linear and quadratic terms, except from the independent term that does not modify the behaviour of trace. An alternative is designed based upon qualitative information, for instance, the cubic polynomial around the origin in a vicinity small enough, whereby the term $a_3x^3$ is neglected in magnitude to the rest $(a_2x^2 + a_1x^1)$. This induces behaviour similar to $a_2x^2 + a_1x^1$ facilitating the visual identification of the visual variables with respect to the modifications of algebraic expressions, whereas the term independent is null.

Since the conditions used to discriminate the visual variables in the cubic polynomial, specifically for the terms $a_2x^2 + a_1x^1$ are different from those developed by Duval (1994), these are named "visual characteristics". The analysis to identify the "visual characteristics" of linear and quadratic terms is carried out through the selection of a small vicinity around the origin, where the term $ax^3$ is neglected in magnitude compared to the rest ($bx^2 + cx$), including the behaviour of a cubic polynomial, it is very "similar" to $bx^2 + cx$, i.e. the reader may reviews the cubic polynomial $Y(x) = ax^3 + bx^2 + cx$ , considering the functions $y(x) = ax^3$ and $h(x) = bx^2 + cx$ in order to identify the visual variables of the cubic term, as the "visual characteristics". (see Figure 1)

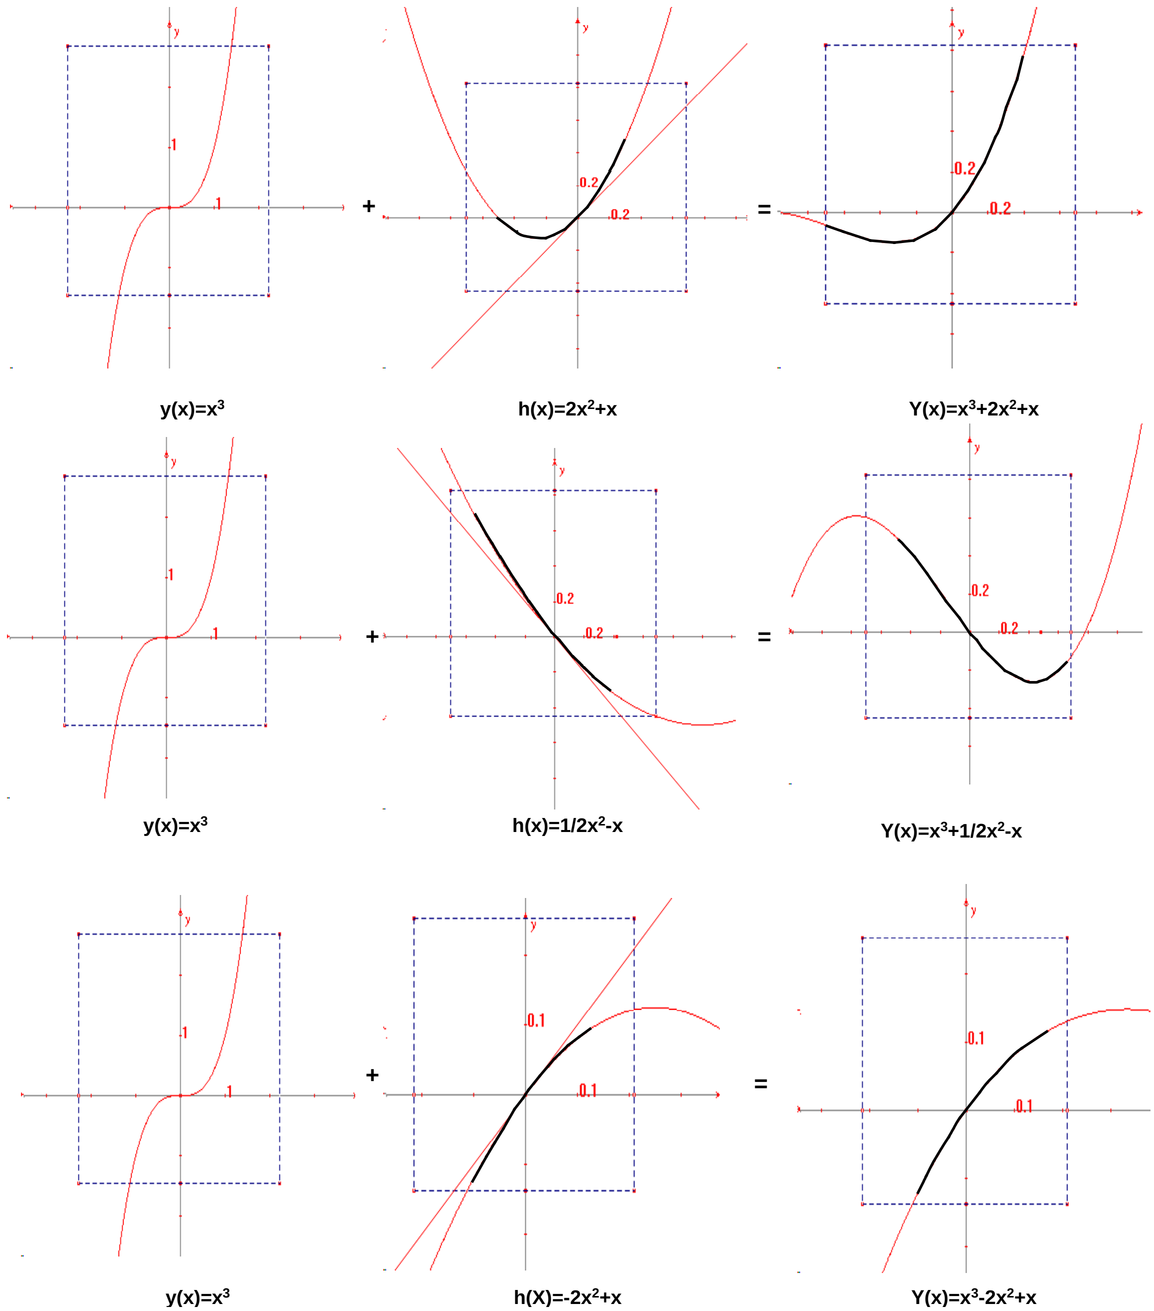

*Figure 1*. Examples of the behaviour of linear and quadratic terms for the polynomial ($Y(x) = ax^3 + bx^2 + cx$).

The "visual characteristics" identified in the vicinity of the origin are:

| Features Visual | Categorical Variables ($bx^2$) |
|---|---|
| **The line opened up** | **b>0** |
| **The line opens down** | **b<0** |
| **The stroke is close to its axis of symmetry** | **b≥1** |
| **The line moves away from its axis of symmetry** | **b<1** |

Moreover, in the behaviour of the linear term the trace is the tangent line to the parabola at the origin. This line is displaced to the right or left of the vertical axis with respect to the parabolic behaviour. For that analyzed behaviour, the line around the origin benefits the global interpretation through qualitative treatment to identify the "visual characteristics". It interprets the information from the global perspective, allowing the relations based on the changes of the categorical variables from the algebraic.

This approach strengthens the exploration of the trace within a region of the plane, identifying the information for the recognition of "visual characteristics", as well as the relation with the algebraic representation (categorical variables). Based upon this information it is suggested a global study in one region of the plane, whose information helps to identify relationships in the graph and the algebraic expression according to the modifications set out in this by using other representations from the identified information.

### Exposition of the Reason to Explore the Content Numeric in the Graphic, as well as the Need for Numeric Representation (table value), to Enrich the Information Identified in the Graphical Representation

Until now, the information has been analyzed using qualitative treatments in the graphical representation, however, the task to construct the algebraic expression of a graphic requires information of the numerical type, raising the possibility of analyzing the graphic through quantitative treatment, i.e., analyzing the relationship between deep figure and figure form from a numerical point of view. This led to exploration of the information contained in the deep-figure to establish relationships with the behavior of trace, requiring the use of treatments that contributes to the identification of numerical values, and thus establishing relations with the characteristics and visual variables. In this sense, the discrimination of the numerical values are closely related to the scale, since the characteristic and visual variables depend directly of the scale. Therefore is necessary to consider the same graduation in both axes. This is a global condition to identify the characteristics of visual variables. Based upon this premise, the variable and visual characteristics of the polynomial of degree two and three explore the deep-figure, allowing the identification of specific numerical values.

The quantitative treatment developed in the deep-figure generates numerical sequences, which are identified globally. Discrimination is performed through the "covariance". That consists of a displacement of $y_r$ to $y_{m+1}$ in coordinated movements $x_r$ to $x_{m+1}$, while maintaining the same graduation in both axes. This favours a particular behaviour of the numerical values, which are obtained through the movements in the x-axis (Figure 2).

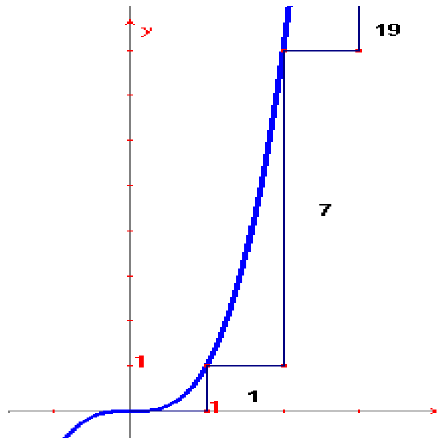

*Figure 2*. Treatment of the quantitative polynomial y = x $^3$.

The displacement takes place on the y-axis, generating the following sequence: 1, 7, 19, . . . , 3n $^2$ +3 n +1 (called a basic sequence). This sequence has an important role in the study of the cubic polynomic cubic, which is identified in global representation. To discriminate the visual value of the cubic term, depends on the number of repetitions that present the numerical sequence, so its algebraic representation is y = 1x $^3$.

To identify the sequence number in the numerical representation (numeric values) explores the coordinated behavior of the "x" values and the "y" values, i.e. for the composite column with "x" values is carried a subtraction operation of consecutive terms. Typically the increase in x is the unit, while the column's "y" values are implemented in terms of the consecutive subtraction of values (finite difference).

The exploration is performed with the information generated by finite difference. Table 1 shows the treatment to identify the quantitative information contained in the polynomial of degree three.

Table 1. *Treatment for the Global Quantitative Numeric Representation*

| x | $y = a x^3 + bx^2 + cx + d$ | $\Delta y$ 1° Diferencia | $\Delta(\Delta y)$ 2° Diferencia | $\Delta(\Delta(\Delta y))$ 3° Diferencia |
|---|---|---|---|---|
| 0 | d | | | |
| | | a + b + c | | |
| 1 | a + b + c + d | | 6a + 2b | |
| | | 7a + 3b + c | | 6a |
| 2 | 8a + 4b + 2c + d | | 12a + 2b | |
| | | 19a + 5b + c | | 6a |
| 3 | 27a + 9b + 3c + d | | 18a + 2b | |
| | | 37a + 7b + c | | |
| 4 | 64a + 16b + 4c + d | | | |

Diferencia Común

In the case of the cubic polynomial ($y = ax^3 + bx^2 + cx + d$), the quantitative analysis of the numerical representation generates three columns corresponding to the first, second and third difference (Table 1), These provide information to discriminate the numerical values of the visual variables, therefore the numerical values of the categorical values for the algebraic expression. For example in the third difference ($\Delta(\Delta(\Delta y))$) (Table 1, column 5), a common variance allows the identification of the numerical value for the coefficient of cubic term (a) using the general rule for the common difference "6a"

## Third Difference

| Constant | Categoric Value |
|---|---|
| 6 | a |

The second difference ($\Delta(\Delta y)$) (Table 1, column 4) allows discrimination between the numerical value for the categorical value of the coefficient of the quadratic term (b). The second difference consists of two digital sequences, the first of which is multiplied by the value of the categorical coefficient cubic term, while the second is multiplied by the value of the categorical coefficient quadratic term.

## Second Difference

| Categoric Value | Numerical Value |
|---|---|
| a | (6,12, 18,..., 6n) |
| b | (2,2,2,..., 2) |

Referring to column 3, which corresponds to the first difference ($\Delta y$) provides information to identify the categorical value of the coefficient of the linear term (c), consisting of three numerical sequences: the first one is multiplied by the value categorical coefficient of cubic term (a), the second sequence is multiplied by the value of the categorical coefficient of quadratic term (b), and finally the last sequence is multiplied by the value of the categorical coefficient of linear term (c), i.e. ;

**First Difference**

| Categoric Value | Numeric Squence |
|---|---|
| a | (1,7,19,37,..., $3n^2$+3n+1) |
| b | (1, 3, 5, 7,...,2n+1) |
| c | (1, 1, 1,..., 1) |

The use of finite differences allows identifying the numerical values of the visual variables and characteristics. These values are also present in the algebraic and graphic representations, which allow connections between the three representations from the interpretation global under the focus numeric.

## Conclusions

The global interpretation is a way to identify relevant information in the graphical representation in the numerical representation, to explore its implications in the algebraic representation, since the modification of a variable visual (graphic) or numeric sequence (numerical representation) involves a change in the categorical variables of the algebraic representation. In this sense, the numerical representation provides relevant information that benefits the identification of the numerical values of the coefficients to the algebraic expression.

The scale is a determining factor for constructing the expression of a curve and the visual identification of variables and the numerical sequence, i.e. if the scale is the same for both axes, visual variables are kept while the numerical sequences are altered, however, if the change of scale is only one axis then both variables are altered visual and numeric sequences. Therefore the study of the background figure-fund is an important aspect to be considered seriously when exploring the graphical representation and numerical representation.

The identification of the visual variables, as mentioned by Duval (1988), is an important activity to explore and interpret the contents of the representation, however, when scanning polynomials of degree greater than two, the task becomes difficult due to the complexity of the curves. Therefore, we discussed the need to explore qualitatively the trace at vicinity to evaluate its content. This vicinity is around the origin where the polynomial $f(x) = a_0x^n + a_1x^{n-1} + ... + a_n$ behaves as a polynomial of the degree n-1 such as $a_1x^{n-1} + ... + a_n$. In other words the polynomial $f(x) = a_0x^n + a_1x^{n-1} + ... + a_n$ tends to lose the term $a_0x^r$.

The analysis of the behavior of some trace of the origin allows the qualitative approach of identifying the "visual characteristics", and interpreting information from a global perspective, which allows connections to the categorical variables in the algebraic representation.

*A three-week teaching experiment employed qualitative analysis to determine the growth of algebraic reasoning. Learning trajectories were determined across individuals and tasks. Results indicated that subjects increased their abilities to symbolically generalize and justify rules.*

## The Study

The focus of this study is to consider the effects of a three-week teaching experiment designed to introduce pre-service teachers [PSTs] in an elementary mathematics methods course to algebraic reasoning. The question of study relates to 12 PSTs' growth of algebraic reasoning over time, through a study of their learning trajectories when engaged in pattern finding activities. The conceptual framework is derived from the work of Powell, Francisco, and Maher (2003) and a previous analysis of the critical events that occurred during this teaching experiment (Richardson, Berenson, & Staley, 2008). Five critical events were noted beginning with the generalization of a recursive rule (level 1) and concluding with the generalization of an implicit rule with justification of the y-intercept and coefficient (level 5). The 12 Caucasian, female subjects were first semester, senior undergraduates in elementary education at a large state university in the Southeastern US. The related tasks asked PSTs to determine rules and justifications related to the perimeter of n-block trains made from pattern block shapes. Audio data were collected and transcribed for each diad and whole class discussions; artifacts and field notes provided additional data. Cross case analysis was used to analyze the data. The analysis of pre-service teachers' learning trajectories tends to indicate individual growth of algebraic reasoning over time while reminding the researchers that learning is not linear and that time is needed with related tasks for quality learning to occur. Using each week's result as a case informs the researchers of the varied knowledge bases and learning time lines of pre-service teachers including tasks that proved more or less difficult. Analyzing the second case of individual PSTs we capture the extent to which the tasks contributed to growth of reasoning over time. We conclude that it is important to find a series of related tasks that are geometric in nature and engage the PSTs in a community where ideas flow freely in written and verbal form. These are features of the teaching experiment that we attribute to its success in promoting algebraic reasoning among a methods class of elementary pre-service teachers.

# YOUNG CHILDREN'S INFERENCE AND GENERALIZATION OF FUNCTIONAL RULES USING CUBE TOWERS: INITIAL FINDINGS

Janet Eisenband Sorkin
Teachers College, Columbia University
jge2004@columbia.edu

## Introduction

Although there has been increasing emphasis on algebra in early grades in the past several years, we are still only beginning to appreciate young children's abilities to reason algebraically. In this study I investigated young children's understanding of functions. The central task was a variation on activities previously used to assess children's function abilities—numeric function machine game and visual growing patterns (see Carraher & Schliemann (2007) for a review)—in which cube towers serve as inputs and outputs in a function machine game. In this way students should be able to "see" relationships clearly without needing to calculate total amounts and thus be able to explore relatively complex rules.

## Method

Seventy-two second grade children were shown a series of input/output tables in the context of the activity described above. Students were also assessed with more traditional and/or non-visually based function tasks, for example finding the appropriate number of paddles for a given number of canoes, or inferring a $f(x) = 2x+1$ rule from a table of numeric data. Finally, students were administered standardized mathematics and language ability measures.

## Findings

Preliminary analysis indicates that the majority of the children could infer multiplicative (e.g., $f(x) = 3x$) and composite multiplicative and additive or subtractive (e.g., $f(x) =3x + 2$; $f(x) = 2x-1$) rules. Further, many children could also understand more complicated rules such as $f(x) = x(x+1)$ or $f(x) = x(x-1)$. Even children achieving relatively low mathematics ability scores and who performed poorly on other function tasks could identify mathematical functions using the activity. Many children could coherently express generalizations for rules; however this piece was challenging for others, particularly those with lower mathematics and language abilities.

## Conclusion & Implications

Data collected thus far suggest that in the context of this activity, young children are able to infer functional rules before a) they learn about those functions' corresponding operations formally, and b) they can succeed on other types of function tasks. More analysis is needed to understand correlations among performance on this task, performance on other function tasks, and mathematics and language ability scores. The results have implications both for curriculum development for young children and for approaches to algebra instruction in general.

# EFFECTS OF THE CALCULATOR ON STUDENTS SOLUTIONS TO A PROPORTIONAL REASONING ASSESSMENT: IMPLICATIONS ON DIAGNOSING STUDENTS THINKING

Axelle P. Faughn
Western Carolina University
afaughn@email.wcu.edu

*This paper describes research conducted on a group of 38 college students entering a College Trigonometry course. A quantitative literacy test aimed at tapping into these students' proportional reasoning skills suggests that when permitted to use the calculator, students tend to more readily use a multiplicative mode of reasoning, whereas additive reasoning is favored when operations are performed by hand. These results have potential applications on making technology-embedded assessment decisions.*

## Introduction – Perspective and Framework

"*Proportional Reasoning* refers to detecting, expressing, analyzing, explaining, and providing evidence in support of assertions about, proportional relationships" (Lamon, 2005, p. 4). Students' thinking when faced with proportionality situations has been extensively researched over the past two decades (Behr, Harel, Post & Lesh, 1992; Clark & Kamii, 1996; Lamon, 1993, 2005; Longest, 2002; Steffe, 1994). Researchers have designed assessment instruments to evaluate students' proportional reasoning skills and raise teachers' awareness of children's thinking about ratios and fractions (Allain, 2000; Misailidou & Williams, 2003). The middle school curriculum relies heavily on proportional reasoning. Students' error patterns, misconceptions and intuitive reasoning about proportionality are particularly interesting for educators in middle grades and beyond (Cramer & Post, 1993; Sowder, Armstrong, Lamon, Simon, Sowder, & Thompson, 1998). Indeed, research shows that students' ability to reason proportionally is a strong predictor of how well they thrive in algebra and geometry (Person, Longest, & Berenson, 2003). Of particular interest is the differentiation between two types of mathematical thinking when dealing with numbers: additive, and multiplicative thinking, which translate into absolute versus relative terms when dealing with a comparison setting (Lamon, 2005, p.29). Having to choose between these two reasoning is the ground for many students' mistakes in answering problems that involve ratios and proportions.

With the widespread use of calculators in the mathematics classroom, it is crucial to study the effect of such technology on students' thinking. Research focusing on students' learning mathematics with technology is already extensive (Penglase & Arnold, 1996; Forster, 2006; Heid & Blume, 2007). The 2008 Educational Technology Standards for Teachers clearly address the issue of assessing students' thinking while using technology by encouraging teachers to "provide students with multiple and varied formative and summative assessments aligned with content and technology standards and use resulting data to inform learning and teaching" (ISTE's Educational Technology Standards for Teachers, 2008). To align assessment designs with the technology standards, one needs to gain insight on how using technology affects students' responses on various forms of assessments.

*Research Focus/Questions:* This article contributes to raising awareness on how the calculator might affect students' answers within the scope of proportionality situations. This in turn will hopefully help teachers design thoughtful technology-embedded assessment strategies

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

when trying to diagnose students' reasoning. In particular we consider the following questions: Does using the calculator affect students' choice of reasoning patterns when solving proportionality problems? And if so, what does the calculator allow students to do differently?

## Methodology

The initial setup for the project was to assess a group of college students' quantitative literacy skills upon entering an introductory college math course. "Quantitative literate citizens […] are capable of interpreting and using information presented quantitatively" (Hastings, 2006, p. 56). These issues are currently highly in focus for higher education curriculum changes (Madison & Steen, 2003). A group of 38 college students entering a college trigonometry course were assigned a Proportional Reasoning test on the first day of class. This decision was based on the researcher's belief that acquiring proportional reasoning fluency is a major requirement to becoming quantitatively literate (Lamon, 2005, p.10). Quantitative literacy being especially at stake for students in courses below calculus (Hastings, 2006), it was important for this project to rely on comprehensive evidence of these students' ability to reason proportionally. Even though the test was initially designed to assess rising $8^{th}$ graders' proportional reasoning skills (Allain, 2000), it was selected over other proportional reasoning assessment instruments for its comprehensive approach to proportional reasoning, including comparison problems as well as missing value items. Indeed, reducing proportional reasoning to missing value problems would have provided only limited insight on quantitative literacy (Lamon, 2005).

The majority of college students will not encounter mathematics beyond pre-calculus, and the courses below calculus hold a population of students that calls for increased focus by the Mathematics Education Community due to its variety of backgrounds and ability levels (Hastings, 2006). However, the results described in this article are striking enough that they also might raise questions at the middle school and secondary school level.

The test, developed by Allain (2000), is comprised of ten questions from various sources that assess a variety of skills related to proportional reasoning. Half of the students were allowed to use the graphing calculator when taking the test, and half were not. The test was graded using the following rubric and students' answers were analyzed individually in random order, and then grouped according to the calculator split after individual grades had been assigned. The list below shows the categories of Allain's rubric, with Longest's (2002) additional category of a zero score for no response or a response that shows no mathematical effort, designed in combination with the test:

- 4 - Correct answer with evidence of appropriate strategy;
- 3 - Incorrect answer due to computational error with evidence of appropriate strategy;
- 2 - Correct answer without evidence of strategy or evidence of inappropriate strategy;
- 1 - Incorrect answer with evidence of inappropriate strategy;
- 0 - No mathematical response.

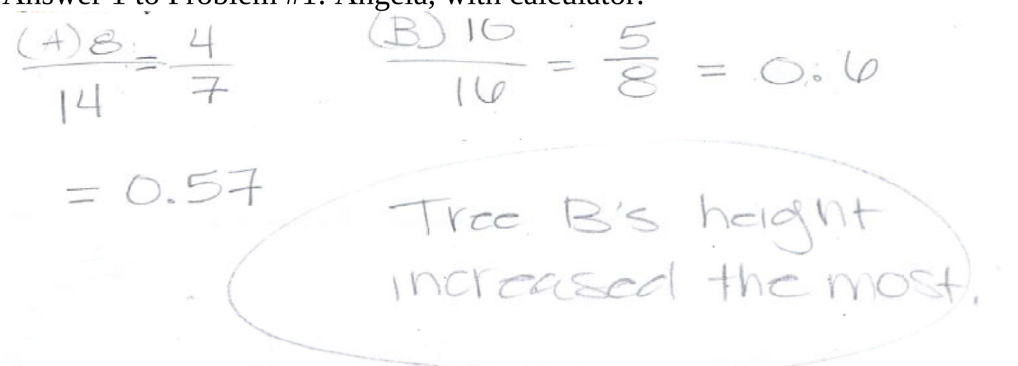
## Analysis of the Results

Examination of students' solutions shows that students tend to translate a problem into percentages or decimals when allowed to use the calculator, therefore adopting a multiplicative behavior, whereas students without the calculator more often resort to additive thinking patterns. For example, students were asked to solve the problem below:

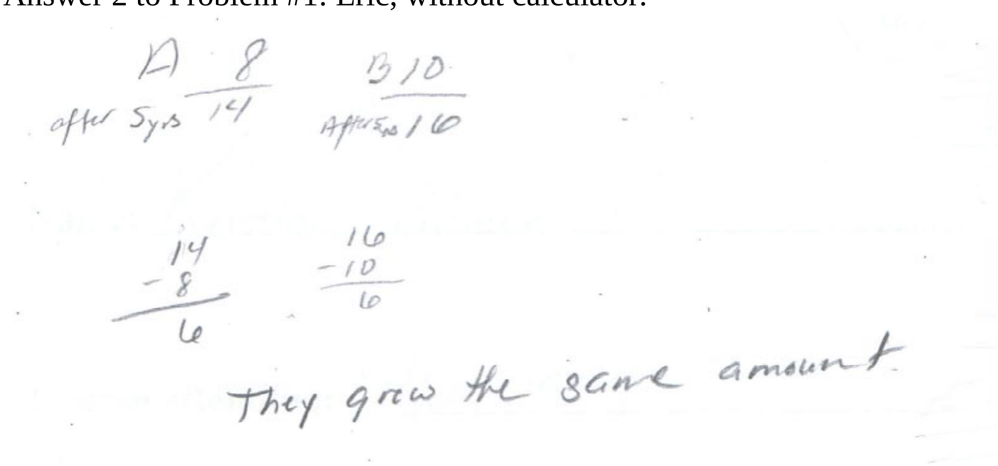
> <u>Problem #1</u>: *Two trees were measured five years ago. Tree A was 8 feet high and tree B was 10 feet high. Today, tree A is 14 feet high and tree B is 16 feet high. Over the last five years, which tree's height increased the most relative to its initial height?*

A typical answer using additive thinking is that both trees increased the same, by 6 feet. When using multiplicative thinking, a student is likely to compare the relative growth ratios of both trees and may conclude that either tree A or tree B grew the most relative to its initial height depending on how the ratios were compared. An example of both reasonings by students is given below:

Answer 1 to Problem #1: Angela, with calculator.



Answer 2 to Problem #1: Eric, without calculator.

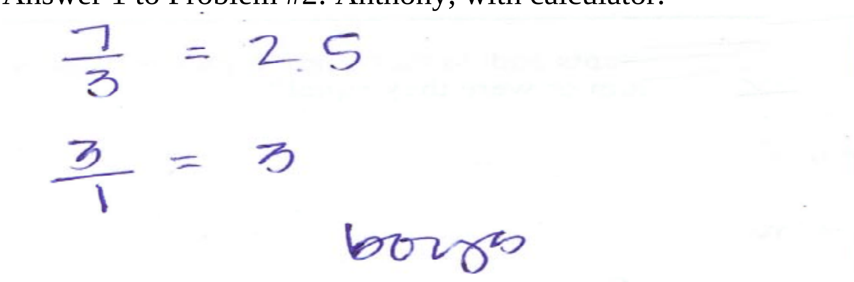


Eric's and Angela's answers were chosen here for their commonality in the group's responses to Problem #1. Among the students who were not allowed to use the calculator, 48% resorted to absolute thinking similar to Eric's in trying to answer the problem, and 48% chose relative reasoning. Within that group, 75% of the students who arrived at the right answer using relative thinking opted for an additive type of reasoning first (both trees increase the same amount of 6ft), and then a relative comparison to the initial heights of the trees (comparing 6:10 versus 6:8). Of the group with the calculator, only 31.5% chose additive thinking while 68.5% opted for multiplicative comparisons, none of which involved an initial additive step; others did not provide appropriate explanations for their answers to decide.

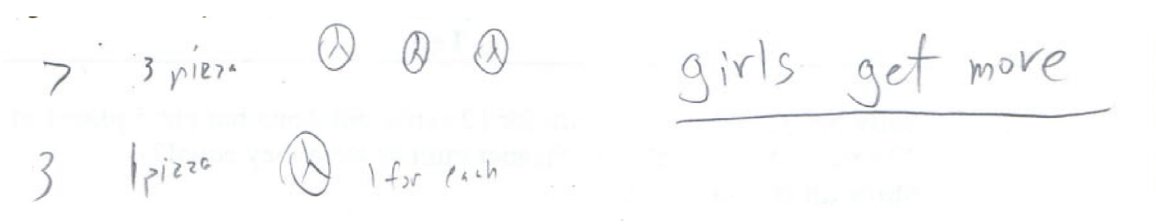
Choosing multiplicative reasoning over additive reasoning did not necessarily lead to the right answer. Indeed, students who used a ratio comparison often misinterpreted the final results when providing an answer, the same way Angela did. A further analysis shows that among the students who opted for multiplicative reasoning, 50% from the calculator group arrived at the correct solution, whereas 60% of those not using the calculator got the correct answer. This type of error due to numerical misinterpretation reflects another clear indicator of deficient quantitative literacy when the connections and transfers between numerical and contextual worlds are overlooked. This inability to interpret a result is better illustrated by students' most common answer to the following problem, probably one of the most difficult in the set assigned:

> *Problem #2: There are 7 girls with 3 pizzas and 3 boys with 1 pizza. Who gets more pizza, the girls or the boys?*

Answer 1 to Problem #2: Anthony, with calculator.



Answer 2 to Problem #2: Erika, without calculator.



For problem #2, 39% of the group with the calculator followed Anthony's path and answered that the boys were getting more pizza, whereas only 28% of the group without the calculator made that mistake. In this case, not having access to a calculating device forced the students to carefully think about the relationships among quantities, often in terms of sharing slices as Erika did. On the other hand, students with the calculator often simply plugged in the numbers in order of appearance in the text and compared decimals without thinking further about their contextual meaning. This type of error has been previously documented (Clark, Berenson, & Cavey, 2003; Person, 2004) and shows a disconnection between the contextual world of ratio and the numerical world of fractions. An important step to adequate proportional reasoning, thus improved quantitative literacy, involves the ability to go back and forth between these two worlds. This seemed more instinctive for the students when the calculator was not available. Like Erika, students without the calculator had a tendency to use drawings in their solutions, whereas no student using the calculator felt compelled to do so throughout the whole test.

## Discussion

The results above lead us to think that allowing the calculator on the proportional reasoning test had an effect on students' reasoning patterns. In particular the multiplicative reasoning patterns necessary to solve most proportional reasoning problems were encouraged by the use of the calculator. One should not conclude however that allowing the use of technology on such assessment will necessarily improve students' results. On average, the students from the group with calculators did not perform better than the group without, but the types of inappropriate strategies used were different. The absence of a calculator forced the students to think more carefully about the relationships between quantities. They often designed strategies that showed evidence of an elaborate thinking process and involved heuristics other than numerical manipulations. On the other hand, the students with the calculator more often misinterpreted the results they were finding even though their initial computations were correct. Students who did not use the calculator also provided more written explanations which we could use as a more transparent window into their thinking processes.

The tendency to choose multiplicative reasoning when using a calculating device has major consequences on designing assessments where the calculator will be available. Indeed, if the purpose of the assessment is to diagnose students’ ability to reason through a given problem, and choose an appropriate sequence of operations that will lead to a correct answer, one must be aware that the calculator is likely to condition students into adopting a multiplicative behavior, which may flaw the interpretation of the results in terms of students cognitive abilities: in such cases, opting for a multiplicative type of thinking would not necessarily show evidence of understanding why this particular thinking is appropriate in the given situation. Nevertheless, knowing the advantages that technology brings to the classroom, especially with the greater availability of visual representations and greater access to self-monitoring, one should not suppress it from the assessment process the way it has often been advocated in college courses. Rather, these results call for the development of technology embedded instruction where assessments are carefully designed to reflect its daily use in the classroom culture. It is important for teachers to learn how to use technology efficiently and know when to introduce it in the classroom for higher conceptual understanding: more studies like this one will help accomplish that goal so that technology may also be selectively part of assessing students’ skills, rather than banning it altogether from college courses for what it might “help” students accomplish. A diversity of modes of assessment is highly necessary to get a glimpse of students’ reasoning complexity. Due to the pervasive nature of technology in our society, quantitative literacy assessments should be highly informed by studies on cognitive technology.

## Conclusion

It is important to call for caution when trying to generalize the results described here. The pool of participants being small, the author wishes to encourage further research designs that may confirm or refute the validity of such findings. Of particular concern would be the tendency to generalize them to lower grades at which students’ developmental stages might affect their attitude towards the calculator, as well as their quantitative literacy skills and choices of reasoning. In other words, this paper is intended as a call for a larger scale study, be it to inform the higher education community on effects the calculator might have on students’ answers to assessments, or to raise questions on how one might be able to incorporate technology in assessment designs while still tapping into students’ cognitive skills.

# TEACHERS' ESTIMATION OF ITEM DIFFICULTY: WHAT CONTRIBUTES TO THEIR ACCURACY?

Wenyan Zhou
Vanderbilt University
wenyan.zhou@vanderbilt.edu

*This study used assessment items as a tool to assess teachers' understanding of student learning progression. We asked ten teachers to rank the difficulties of eleven items about the concept of linear measurement for elementary and middle school students. We compared teacher's rankings to the empirical order found in a field administration of the eleven items. Results indicated that only three teachers' ranking reflected the empirical order. Neither the amount of training teachers had on mathematics nor did the mere length of their teaching experience predict their accuracy. We discussed the relation among pedagogical knowledge, content knowledge, and teaching experience.*

## Background

This study is situated in a large, multi-year, multi-site project that focuses on teaching and assessing student knowledge of data modeling and statistical reasoning at elementary and middle school levels (e.g., Lehrer, 2007, Lehrer, Kim, & Schauble, 2007, Seeratan, et al, 2008). We conceptualize data modeling and statistics as encompassing knowledge of seven dimensions, and have developed construct maps (Wilson, 2005) to describe the hypothetical trajectory of learning progression along each of those dimensions. We used those construct maps not only as models for developing assessment items, but also as professional development tools to stimulate discussions about student performance. This paper focuses on one of the seven construct maps, namely, the theory of measurement construct that focuses on children's understanding of principles underlying (linear) measurement. Specifically, we suggest that evaluating item difficulty is a useful activity to learn about teachers' understanding of student learning progression, in this case, progression with regard to the concept of linear measurement.

## Perspective

The importance of understanding children's learning progressions is well-established and is clearly articulated, for example, by Davydov (2008) in his theory of developmental instruction. We consider this understanding a part of teachers' pedagogical content knowledge (Shulman, 1986). Understanding the learning progressions is a complex task. Teacher knowledge of the structure of a domain and of child development has been postulated as contributors to a sophisticated understanding of the learning progressions. Before we test the relation between teacher understanding of a learning progression and the other knowledge preparations of teachers, however, we need to have tools to assess their understanding of a learning progression. This study uses an assessment-based tool to probe into teachers' understanding of learning progression on the topic of linear measurement.

## Method

### *Participants*

Ten teachers were recruited from participants of our monthly professional development workshops during the year 2007-2008, held in a major city in the southwestern US. We sent out requests to the entire group of 26 teachers, and ten of them responded. Among these ten teachers, one was male. This male teachers and one of the female teachers were the only teachers having a degree in mathematics. One female teacher had prior training and experience in accounting. These three teachers were the only teachers among the ten who had teaching experience in mathematics only ($7^{th}$-$9^{th}$ grade mathematics). The remaining seven teachers all had training in educations and had taught all subjects. At the time of interviews, one of the seven teachers was a $7^{th}$ grade mathematics teacher; one was a coach for mathematics and science in an elementary school. All teachers had teaching experience of at least four years.

*Instrument*

A series of items assessing student understanding of linear measurement had been developed in the large project about assessing data modeling and statistical reasoning. We used eleven items in the research described here. The measurement topics covered by the items include the following: direct reading of a ruler, reading a ruler from starting positions other than zero, unit iteration, constant units, unit conversions, and unit partition in different fractions.

In addition to the eleven items, we prepared student responses for two of the items, one item on constant units and another on reading a ruler from starting position of one. We prepared four types of student responses for each of the items.

The theory of measurement construct map was also used during the interview.

*Procedure*

In December 2007 and February 2008, we interviewed the teachers individually on days not having the workshops. Prior to the interview, teachers filled out a questionnaire asking for information about their academic training and teaching experience. In the beginning of the interview, we asked teachers to reflect on their theories of how children developed concepts of linear measurement. We then presented them the eleven items, in random order. We asked teachers what understanding each of those items assessed. Following this question, we asked teachers to order the items according to their relative difficulty. We used prompts such as "Which item do you think students are able to complete successfully earlier than the others? Which item do you think would be the hardest for the students?" We asked teachers to try to put the items to distinct levels, but ties were also permitted. Teachers were also asked to justify their ordering.

After teachers order the items, we asked them to locate the items on the theory of measurement construct map. We asked that, if a student were completely correct on an item, what level on the construct map his/her performance would correspond to. Following this activity, we asked teachers to examine the selected student responses for two of the items, one at a time. Teachers were asked to explain student strategy indicated in each response, to locate the responses on the construct map, and to order them according to their sophistication levels.

*Administration of the Items*

We asked teachers of our existing professional development partnership in another site to help collect responses from their students to the same eleven items. Those teachers located in school districts in south central US. They administered the items in their classrooms during December 2007 to January 2008. Individual teachers determined exam time and duration for their classes. A field coordinator collected completed tests from participating teachers and mailed them to us. A total of 360 students responded to our tests. Student responses were coded and analyzed with a partial credit model to determine the relative difficulties of the items. The analysis was run using the ConQuest software (Wu, Adams, Wilson, & Haldane, 2007). The resulting order was the empirical order of item difficulty.

## Preliminary Results

We calculated Spearman rank-correlations between each teacher's ordering of the items and the items' empirical order. Three teachers' orderings were significantly correlated with the empirical order at the level of .05 (Spearman's rho > 0.648, n=11), indicating high accuracy. Among these three teachers, two taught all subjects and one taught middle school mathematics. The one who taught middle school mathematics was also the teacher with the least teaching experience (four years teaching 7th and 8th grade mathematics). Another one of these three teachers initially erred on a problem involving improper fraction, indicating that mathematics competence might not be directly related to knowledge of learning progression.

Moreover, mathematics training did not seem to be a significant contributor to teachers' accuracy. Between the two teachers with degree in mathematics, one tended to underestimate the more difficult items, but was relatively more accurate with the easier ones; the other tended to overestimate the easier items, but was more accurate with the more difficult ones. The mathematics coach had the lowest accuracy among the ten teachers, followed by another teacher who had teaching experience only at grade five and above.

Furthermore, teachers who were more accurate (i.e., having a larger Spearman's rho) were often more accurate with the easier items (e.g., between the two teachers with mathematics degree, the one who was more accurate with the easier items was also more accurate in general). Therefore, it appeared that teachers' difficulty with these set of items focused on ordering the easier items. Teachers appeared to have better sense of the difficulty for items that were more difficulty. The mathematics coach, however, was the only anomaly among the ten, because she overestimated the easier items and underestimated the more difficult ones, resulting in a negative rank correlation between her ordering and the empirical order.

Examining teachers' justification of their ordering indicated that many related their answers to their personal experience, i.e., what they personally found more challenging. This might explain why the teacher who initially erred on the problem involving a simple improper fraction could be accurate in her estimations – although she might not be good at mathematics, she might be a reflective learner/practitioner.

## Discussion

This study shows how assessment items of student knowledge can also be used to assess teachers' understanding of learning progression, which we consider to be a component of teachers' pedagogical content knowledge. We note that the pattern emerged out of our finding is consistent with the notion that pedagogical content knowledge and domain content knowledge are different. Our study also indicates teaching experience may not be directly related to teachers' pedagogical content knowledge, which in this case is in the form of understanding student learning progression.

As we are completing the analyses of the remaining interview data, which include a detail look at teachers' justifications of their orderings and their interpretations of the construct map, we hypothesize that teachers who are more accurate in their ordering would also tend to have better understanding of our construct map, which describe the learning progression of students about the concept of linear measurement.

We realize that, however, our study is exploratory, and future research will need to establish the validity of our tasks as an assessment tool for teachers' understanding of learning progression.

# ASSESSMENT AS AN OPPORTUNITY TO LEARN: USING COLLABORATIVE TESTS TO IMPROVE STUDENTS' MATHEMATICAL UNDERSTANDING

Joan Kwako
University of Minnesota Duluth
jkwako@d.umn.edu

*Using the framework that assessment can provide an opportunity to learn, this study investigated the impact of collaborative testing on college students' understanding of statistics. In addition, because collaborative tests have the potential to mitigate test anxiety, students' attitude toward the treatment was studied. Results of the tests demonstrated that those students who tested collaboratively scored higher than students who tested individually. Moreover, students who tested collaboratively and were rated as low ability (based on a standardized entrance exam) outscored high ability students who tested individually. Additionally, results of the attitude survey showed an overwhelmingly positive view of using collaborative tests.*

## Theoretical Framework

Assessment, referred to broadly by Shepard (2001) as an emergent paradigm, can also be referred to as a framework to study students' understanding of mathematics. Assessment as an emergent paradigm refers to a conception of assessment that is more aligned with a constructivist perspective on teaching and learning. A focus on reform teaching in the 1980s and 1990s led to a gap between contemporary mathematics teaching and traditional assessment practices. Whereas the teaching and learning of mathematics had entered a reform paradigm that was determined by constructivist ideals, the assessment of mathematics remained in a traditional paradigm more closely aligned with behaviorist ideals (Greeno, Collins, & Resnick, 1996; Shepard, 2001).

One way to shift assessment into the constructivist paradigm is to provide students the opportunity learn by communicating with each other while completing an assessment task. Communication is a critical component of learning mathematics; in particular, communication is an essential component for learning mathematics with understanding (Fennema, Sowder, & Carpenter, 1999). In fact, NCTM highlighted communication as a necessary component when defining communication as one of the five Process Standards (2000). According to the communication standard, students must be able to—

- organize and consolidate their mathematical thinking through communication;
- communicate their mathematical thinking coherently and clearly to peers, teachers, and others;
- analyze and evaluate the mathematical thinking and strategies of others;
- use the language of mathematics to express mathematical ideas precisely (p. 60).

Discussing others' ideas while defending one's own, can expose misconceptions, misinterpretations, and holes in one's thinking, leading to expanded understanding by all. "Through communication, ideas become objects of reflection, refinement, discussion, and amendment" (NCTM, p. 60). Communication in learning mathematics and the importance of assessment in determining the amount of learning that occurred are central features in learning with understanding. As such, they provide a solid foundation by which to frame a study of students' understanding of mathematics through the use of collaborative tests.

## Literature Review

Although assessment has many purposes, its use as a summative tool to evaluate, rank, and quantify student understanding is its most common purpose. Currently, researchers in K–12 (de Lange, 1999; Romberg, Zarinnia, & Collis, 1990) and higher education alike (Gold, Keith, & Marion, 1999; Shepard, 2001) agree that how students are assessed needs improvement. According to Shepard, "the purpose of assessment in classrooms must…be changed fundamentally so it is used to help students learn and to improve instruction, not just to rank students or to certify the end products of learning" (p. 1080).

A focus on assessment is grounded in the prominent role assessment takes in the learning process—prominent because one can only determine the degree to which learning has occurred if one assesses that learning. This role is also appropriate due to the fundamental nature of assessment on student performance not only in K–12 education (Chappuis & Stiggins, 2002; Shepard, 2000; Stiggins, 2002), but in higher education as well (Adams & Hsu, 1998; Ritter, 2000). Especially when assessment is used to *support* learning in addition to being used as a measure *of* learning, it is fundamental to the whole teaching/learning process. When assessment is used to support learning, teachers adapt the process and flow of information about student achievement in order to advance, not merely check on, student learning (Stiggins, 2002). This act of assessing can provide students with an opportunity to learn, and specifically, learn important mathematics (Steen, 1999; van den Heuvel-Panhuizen & Fosnot, 2001). When envisioned as such, assessment is an integral part of instruction (Black & Wiliam, 1998; Schoenfeld, 1997; Shepard, 2001; D. C. Webb, 2001).

While the main goal for using collaborative tests in this study was to provide students with an opportunity to learn, research has confirmed many other reasons for implementing collaborative testing. For example, taking tests in groups can reduce anxiety in testing situations. It is possible that anxiety surrounding test taking can serve to motivate students to rise to the challenge. However, it is much more likely that this kind of anxiety will interfere with thinking and eventually compel students to give up. According to Helmericks (1993), "[C]ollaborative testing operates to alleviate, or at least mitigate, examination anxiety, a major source of the debilitating math anxiety that …students endure" (p. 287). Thus the use of collaborative tests can allow students who normally might "freeze" to not only complete the test, but actually learn in the process.

Research has also shown that collaborative test taking promotes continued learning in that once students have the opportunity to learn, they can continue learning (Ittigson, 2002; Lehman, 1995; N. M. Webb, 1995). According to Webb, "[e]ven a small amount of collaboration may influence a student's understanding and performance" (p. 247). In addition, developing new understanding by building on other students' ideas is a form of learning as is giving explanations which encourage the explainer to justify, reorganize, and clarify his/her thoughts (Webb, 1995). Learning is not accomplished when students have given up. In a group testing situation, it is not acceptable to give up; "students put a lot of pressure on their group members and get very irritated if another member is not holding up his/her end" (Lehman, p. 4). So while peers do not allow each other to slack, it is because they hold their group members responsible for ensuring all group members understand the material.

In addition, collaborative tests require communication, which many agree is of the utmost importance not only in teaching and learning, but also in assessment (McConnell, 2002; NCTM, 2000). In fact, in NCTM's Assessment Standards for School Mathematics (1995), the authors state that assessment should enhance learning, and learning involves being able to reason and communicate mathematically. Communication such as this encourages support for each other's learning as opposed to competition. Traditional testing methods involve students working alone and are characterized by individual competition, primarily for grades. In contrast, collaborative testing engenders an “all for one, one for all” atmosphere conducive to learning, especially with the peer pressure for everyone to hold their own.

Based on the framework presented above, the author chose to investigate the effectiveness of using collaborative tests to improve students’ understanding of statistics and their perceptions of the treatment in general. In particular, the present study is guided by two overarching research questions: 1) In what ways does taking tests collaboratively increase students’ understanding of the material, and 2) What aspects of the treatment did students find especially helpful in terms of helping them understand?

## Methods

This study was designed to provide data sources that would document the influence of using collaborative tests as compared to individual tests. The primary source of data that was used was a series of three initial tests and three similar, but different retake tests measuring students’ understanding of basic statistics concepts. A secondary data source, an attitude survey, required students to rate ten statements on a five-point Likert scale and answer five open-ended questions regarding their perceptions of the treatment. Using a very simple two-by-two experimental design, this study compared initial test scores (taken either collaborative or individual) to retake scores (all taken individually) in both groups (reading horizontally) and compared scores on both tests between groups (reading vertically) (see Figure 1).

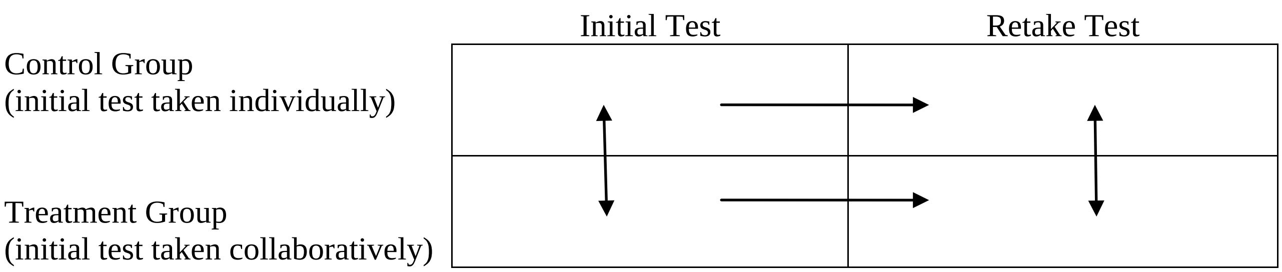

*Figure 1.* Two-by-two design to compare test scores between groups and between tests.

Forty-eight students enrolled in two sections of Quantitative Literacy at a two-year Arts College in the Midwest participated in the study. The median age of the students was 19, almost 70% were male, and the majority of the students were Caucasian. Both classes met twice a week for one hour and forty minutes, one class in the morning (the control group) and the other in the afternoon (the treatment group). The classes covered the same material each day and were taught by the same instructor.

The groups were deliberately assigned so that each group had at least one high ability student and to the extent possible, similar numbers of high and low ability students as measured by a median split of the scores received on an Asset test (ACT Incorporated, 2003) taken upon admission to the college. The Asset test is a national standardized test designed to “[obtain] academic and background data about advisees,…[place]-students in courses that match their interests and abilities,…[and help] students explore their educational and career options” (ACT Incorporated, 2009). The students remained in the same groups throughout the study except for occasions when more than one student was absent from a group.

Through the discussion of a reading based on Johnson, Johnson, and Holubec (1993) which highlighted the purposes, goals and methods of cooperative learning and collaborative test taking, the treatment group learned about the key features of cooperative learning and collaborative testing. In addition, the treatment group practiced, in their prescribed groups, the cooperative techniques by solving an in-class problem which involved multiple solution strategies and multiple answers. The students in the control section had no cooperative training and completed the same in-class problem individually. The students in the control section had no cooperative training and completed the same in-class problem individually.

All students took an initial test measuring their understanding of basic statistics concepts and then two days later, at the start of the next class period, they took a similar, but different, retake test on the same material. Each test contained two or three open-ended problem-solving questions that required students to explain, describe, or demonstrate how the problems were solved, and one or two procedural questions. The tests were all graded by giving partial credit if either (a) the answer was wrong but the process was correct or (b) the answer was wrong but the student was on the right track. Tests from both sections were graded together by the instructor with care being taken neither to look at the names nor to note in which section the student was enrolled. The students in the treatment group took all of the initial tests in their prescribed groups of three, while the students in the control group took the initial tests individually. Both groups took the retake test on the same material individually.

## Results

Table 1 lists the relative scores all for students on both the initial and retake tests. Reading vertically, the table shows the difference in students' understanding of basic statistics concepts between original scores and retake scores. Surprisingly, in only one case (control group, test 2) did students score better on the retake than on the original. In fact, students who tested collaboratively scored as much as almost 37% lower on all retake tests, whereas students who tested individually scored higher on two out of three retake tests, although at most only 5% higher.

Reading horizontally, in all but one comparison between the control group and treatment group, the treatment group scored higher, not only on all the initial tests, but also on two out of three retake tests. In particular, students testing collaboratively scored as much as 31% higher on an initial test and 12.5% higher on a retake test.

Table 1

*Mean Percents of Tests and Percent Differences between Control and Treatment Scores*

| Tests | Control group (Individual initial, individual retake) Mean | Treatment group (Collaborative initial, individual retake Mean | Percent of increase ↑ or (decrease ↓) between control and treatment scores |
|---|---|---|---|
| Test 1 | 78.0% | 86.8% | 8.8% ↑ |
| Test 1 Retake | 71.5 | 77.3 | 5.8↑ |
| Percent of ↑ or (↓) initial to retake | (6.5) ↓ | (9.5) ↓ | |
| | | | |
| Test 2 | 58.4 | 89.8 | 31.4↑ |
| Test 2 Retake | 62.8 | 75.3 | 12.5↑ |

| | | | |
|---|---|---|---|
| Percent of ↑ or (↓) initial to retake | 4.4 ↑ | (14.5) ↓ | |
| | | | |
| Test 3 | 56.0 | 84.9 | 28.9↑ |
| Test 3 Retake | 58.3 | 54.2 | (4.1) ↓ |
| Percent of ↑ or (↓) initial to retake | 2.3↑ | (30.7) ↓ | |

The results of the breakdown between high and low ability groups are shown in Table 2. The mean scores of and the mean difference (high minus low) between the high and low ability groups are represented. As might be expected, the high ability students scored higher on all tests taken individually. However, the low ability students who tested collaboratively actually outperformed the high-ability students in two out of three initial collaborative tests. And although the low-ability students scored lower than the high-ability students on the individual retake tests, they only scored on average, 3.6% lower. This is contrasted with low-ability students who tested individually and scored an average of 17.1% lower than the high-ability students.

Table 2
*Mean Test Percentages for High and Low Ability Students and Mean Differences between Abilities*

| | Individual | | | Collaborative | | |
|---|---|---|---|---|---|---|
| | Test 1 | Test 1 Retake | T1R-T1 | Test 1 | Test 1 Retake | T1R-T1 |
| High ability | 81.0% | 82.7% | 1.7% ↑ | 82.9% | 79.3% | (3.6↓) |
| Low ability | 75.0 | 62.1 | 12.9 ↑ | 90.7 | 75.6 | (15.1↓) |
| Mean difference | 6.0 | 20.6 | | (7.8) | 3.7 | |
| | | | | | | |
| | Test 2 | Test 2 Retake | T2R-T2 | Test2 | Test 2 Retake | T2R-T2 |
| High ability | 67.0% | 70.0% | 3.0 ↑ | 75.5% | 76.1% | 0.6% ↑ |
| Low ability | 51.0 | 50.0 | (1.0) ↓ | 88.8 | 74.3 | (14.5) ↓ |
| Mean difference | 16.0 | 20.0 | | (13.3) ↓ | 1.8 | |
| | | | | | | |
| | Test 3 | Test 3 Retake | T3R-T3 | Test 3 | Test 3 Retake | T3R-T3 |
| High ability | 68.2% | 63.7% | (4.5) ↓ | 93.2% | 56.4% | (36.8) ↓ |
| Low ability | 43.8 | 53.0 | 9.2↑ | 75.9 | 51.0 | (24.9) ↓ |
| Mean difference | 24.4 | 10.7 | | 17.3 | 5.4 | |

The secondary data source, the results of the attitude survey, showed that with only a few exceptions, students expressed very positive feelings about the treatment. The answers to both the Likert scale section and the open-ended question section strongly supported testing in collaborative groups. In particular, 93% of the students agreed or strongly agreed that they felt much less stressed when taking the tests in groups; 92 % of the students stated that working in groups made it easier to learn; and 70% agreed or strongly agreed that they have a better understanding of the material because of working in groups. The only suggestion students had to improve the collaborative testing process that was mentioned by numerous students referred to group composition. Forty-one percent of the students commented on the size, make-up, or consistency of the groups, but with no *one* suggestion standing out as agreed-upon by a majority of students.

## Discussion

In five out of six tests, students who had the chance to test collaboratively performed better than those students taking the tests individually. It is no surprise that students testing in collaborative groups during the initial test would score higher; the fact that they scored higher on two of the three individual retake tests strongly suggests that collaborative testing has merit. However, if collaborative testing really improves understanding it would be expected that the scores were higher on all three individual retake tests. Since all retake tests were taken individually, one could speculate that (a) students were not using the collaborative testing situation to help them learn and instead simply solved the problems by relying on the expertise of the high ability student in the group, or (b) the lower scores were due to the retake tests themselves, a possible limitation of the study.

However, the results of the high and low ability analysis were consistent with other research (N. Webb, Nemer, Chizhik, & Sugrue, 1998) in that the low ability students who tested collaboratively benefited the most from the testing treatment. They scored, on average, 11.9% higher on the individual retake tests than the low ability students who tested individually. An interesting result is that the high ability students who tested collaboratively scored an average of 14.3% lower on their individual retest. One could speculate that this was due to their perception that working in a group was not going to be beneficial to them; often high ability students prefer to work alone or only with other high ability students, and feel burdened when working with lower ability students. This is in contrast to low ability students who might perceive immediate value to testing collaboratively; due to their lower ability they often are much less confident about their answers and benefit greatly by the feedback they receive while testing collaboratively.

## Limitations

Some limitations exist within this study that could minimize the amount of strong evidence of the effectiveness of collaborative testing. One such limitation is the small sample size. Classes consist generally of at least thirty students, but student withdrawals resulted in class sizes of approximately 23 students. Another limitation is the limited time invested on training students how to learn cooperatively and test collaboratively. Training for these skills occurred at the same time as the study itself, thus the effectiveness of students testing collaboratively was compromised by the fact they were at the same time learning *how* to work together.

However, as can be seen by the scores, the students did improve over time; the scores of the second and third collaborative tests were approximately 30% higher than the scores on the individual tests, and 6% higher on the initial test taken collaboratively. This is consistent with the research that states that students need specific training over time in the skills required to work effectively in groups (Johnson et al., 1993).

The tests themselves also may have decreased the effectiveness of the study. For a test to accurately measure a group's understanding, it needs to include open-ended questions that require all group members to participate and contribute to the solutions. Otherwise, if there is only one right answer, the brightest student will often simply take the test and allow the others to copy. These types of tests, although effective when testing collaboratively, are extremely difficult to take individually. This would explain the lower scores on the retakes (which were taken individually), as all tests were written with collaborative testing in mind to maintain consistency.

However, two other limitations—if they could be accounted for in future studies —might actually strengthen the case for collaborative tests. A major limitation in this study was the transient student population. The multiple absences of numerous students made the consistency of groups nearly impossible in some cases. According to the research, for cooperative learning (or collaborative testing, in this situation) to work, students must be invested in the group; the group sinks or swims together (Johnson and Johnson, 1993). With so many students repeatedly absent, building this type of commitment was nearly impossible, as groups were constantly changing. Also, the absences meant that those students were behind when they did show up since almost no students returned to class with the current homework done. Thus, simply by improved student attendance, both group commitment could be developed and students could remain caught up.

## Conclusion

The results of this study has shown that students—especially low ability students—do increase their understanding of basic statistics concepts when testing collaboratively. Although the individual retake scores of students in the collaborative testing group increased only two-thirds of the time, the students' positive attitudes towards the treatment suggest that using collaborative tests is a method worthy of more study. Also, the large increase in scores of low ability students makes collaborative testing especially useful in teaching students whose strengths may not include math. Further research could be done with larger sample sizes, more collaborative training, tests specifically geared toward individual testing as well as collaborative testing, and a more consistent participant groups.

# ASSESSING STUDENT UNDERSTANDING OF AREA MEASUREMENT

| Wenyan Zhou | Cynthia Jones |
| --- | --- |
| Vanderbilt University | The Discovery School at Reeves Rogers |
| wenyan.zhou@vanderbilt.edu | Cindy.jones@cityschools.net |

Practitioners often notice that students have difficulty with area measurement. For instance, students often confuse the area of a rectangle with its perimeter. A review of the literature (e.g., Battista, Clements, Arnoff, Battista, & Van Auken Borrow, 1998; Doig, Cheeseman, & Lindsey,1995; Kamii & Kysh, 2006; Lehrer & Chazan 1998; Outhred & Mitchelmore, 2000; Reynolds & Wheatley, 1996) has indicated that student difficulty with the area tasks is often due to their lack of conceptual understanding of area as a quantitative attribute.

In order to assist teachers to better diagnose their students' conceptual understanding of area measurement, this presentation reports our effort in developing an assessment for student understanding of area measurement. This poster consists of three major parts:

1. *Description of the instrument development process*. Our process of developing the assessment follows a construct mapping approach (Wilson, 2005), which requires us to specify a hypothetical learning progression at the outset of the assessment development. This learning progression is used as a model to guide item design.
2. *Description of a calibration study of the assessment items*: We use the learning progression specified in the beginning to guide interpretation of student responses. Student responses are coded and analyzed using a partial-credit Rasch model. The quantitative results are supplemented with qualitative analysis of selected examples.
3. *Description of a teaching study of area measurement with embedded formative assessment*: We describe a teaching study that embeds the formative assessment items to support the teaching and learning of the concept of area measurement.

# FIRST-YEAR SECONDARY MATHEMATICS TEACHERS' ASSESSMENT CONCEPTIONS AND PRACTICES

Kanita Kimmons DuCloux
University of Georgia
kducloux@uga.edu

This study investigated the factors that contribute to first-year secondary mathematics teachers' assessment practices as well as their conceptions about assessment. Given the fact that teachers spend about 40% of their time in assessment-related activities (Stiggins, 1988) coupled with the current educational reform calls for a much broader role of assessment in mathematics and the continued dominance of paper-and-pencil assessments (Shulman, 1986; National Council of Teachers of Mathematics, 2000), it is important to investigate which influences are important to first-year teachers' assessment practices and conceptions. Three case studies were conducted with first-year secondary mathematics teachers. Literature from the areas of teacher beliefs, beginning teachers, and mathematics assessment provided a lens to analyze the observations, interviews and classroom artifacts.

Results suggest that several factors influenced first-year teachers' assessment practices. Teachers' beliefs about mathematics and its teaching and learning, students and assessment were all intertwined and together impacted how they assessed student learning. The locale of their source of authority (external or internal) along with their perception of external constraints influenced their assessment practices. The teachers were also influenced by the practices of their colleagues and the school culture. Lastly, the presence of the researcher in the classroom played a small role in the assessment decisions and practices of the first-year teachers.

Despite their knowledge of reform efforts in assessment, their assessments were very traditional but looked different in each of the first-year teachers' classrooms. Jack heavily used traditional formal assessments from the school-created teacher test bank. Karen created her own assessments and experimented with nontraditional assessments like a project and a pair test. Angel modified her colleagues' traditional assessments and frequently used informal assessments like peer teaching and student questioning. Teachers thought assessment should provide all students a fair opportunity to show what they know and can do, align with instruction and include multiple sources. Furthermore, informal assessments like facial expressions and students' verbal explanations provided important information about student mathematical knowledge but did not contribute towards the student's final grade.

*In this report, we offer a framework for analyzing the ways in which collaboration influences learners' building of mathematical arguments and thus promotes mathematical understanding. Building on a previous model used to analyze discursive practices of students engaged in mathematical problem solving, we introduce three types of collaboration and discuss their influence on the building of mathematical arguments and student agency. The framework is exemplified using data from a study of the development of mathematical reasoning in an urban sixth-grade informal after school program.*

## Introduction

In recent years, policy makers and researchers have focused on the role of discourse in the mathematics classroom. The National Council of Teachers of Mathematics (NCTM, 2000) emphasizes the importance of communication in students' developing mathematical understanding and suggests that students be afforded the opportunity to share their ideas in a mathematical community and analyze and evaluate the ideas of their peers. Participating in mathematical discussions and reasoning about mathematics requires that students have opportunities to share and to discuss their ideas with others (Lampert & Cobb, 2003).

Collaboration is often viewed as learners supporting each other by offering missing pieces of information needed to solve the problem. Alternatively, a powerful type of collaborative work involves group members relying on each other to generate, challenge, refine, and pursue new ideas (Francisco & Maher, 2005). With this type of collaboration, rather than piecing together their individual knowledge, the students build new ideas and ways of thinking as a group. Martin, Towers, and Pirie (2006) refer to collective mathematical understanding as the kind of learning and understanding that transpires when a group of students work together on a mathematical task. They identify co-acting as a process through which an individual's mathematical ideas and actions are adopted, built upon, and internalized by others, thus becoming shared understandings rather than being limited to the individual. In co-acting, ideas are initially put forth by an individual student and are then picked up by others and built upon, thus they consequently become shared by the group members (Martin, Towers, and Pirie, 2006). In this report, we offer a framework for analyzing the ways in which collaboration influences learners building of mathematical arguments and thus promotes mathematical understanding.

## Theoretical Framework

Davis (1996, 1997) introduced a framework for analyzing the ways that teachers listen to their students. His framework involved three modes of listening: evaluative, interpretive, and hermeneutic. Powell and Maher (2002) extended Davis' categories to analyze "the discursive practices of learners in conversational exchanges" (p. 319) and referred to this phenomenon as interlocution. They identified the four properties of interlocution as evaluative (judging without participating), informative (seeking or providing information without judging), interpretive (teasing out the intention or meaning behind a partner's statement), and hermeneutic (engaging

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

and negotiating the partner in the interaction, participating in a shared project). Powell (2006) modified this framework for the purpose of analyzing students' mathematical discourse. Powell noted that negotiary discourse (hermeneutic) is particularly important in the development of *socially emergent cognition*. This phenomenon, as defined by Powell, is the "process through which ideas and ways of reasoning materialize from the discursive interactions of interlocutors that go beyond those already internalized by any individual interlocutor" (p. 33). Powell found that students' discursive interactions influence their mathematical ideas and reasoning.

When considering aspects of student collaboration and the reasoning that results from this collaboration, we must also consider the issue of agency and the nature of the interplay of mathematical ideas in the mathematics learning environment. Agency involves taking the initiative and making things happen in the classroom (Wagner, 2004). Human agency is exhibited when one creates one's own mathematical idea or extends an established idea (Pickering, 1995). Agency, then, is important in tracing the origin of mathematical ideas as well as the way that discourse, and the participants in the discourse, influence the ultimate mathematics that is constructed.

In this paper, we draw on these ideas to inform our conceptualization and analysis of student collaboration and the mathematics that results from various forms of student collaboration. Our framework highlights three modes of student collaboration, the discursive nature of each, and the significance and interplay of agency and neighbor interactions that take place during collaborative instances.

The first form of collaboration occurs when students engage in the *co-construction* of ideas. This is a form of collaboration in which the dialogue occurs in a back and forth nature (similar to the action that occurs during a ping-pong game) until the argument is built. In other words, the argument is simultaneously built from the ground up.

The second form of collaboration is that of *integration*. This form of collaboration is identified when a student's argument is strengthened using ideas from their peers. In other words the ideas, explanations, or representations of others are assimilated into their original argument.

The primary distinction between co-construction and integration is that in a co-constructed argument, the two interlocutors are creators of the argument. Without one of the participants, the argument would not exist. An argument that results form the process of integration, on the other hand, is established by its originator and is only enhanced by the other participants' contributions.

The third form of collaboration is that of *modification*. This occurs as students attempt to correct a peer or assist him/her in making sense of a model or argument that was originally expressed in an unclear or incorrect way. As the student attempts to make sense of the faulty argument and assist one's partner in seeing the error or sense-making, a sound argument is created that differs significantly in presentation and/or interpretation.

Figure 1 below illustrates the nature of the discourse and of the agency that is typical of each form of collaboration. Co-construction is typified by negotiary discourse, and all participants share agency in the discussion. Integration makes use of both informative and interpretive discourse. The original argument is interpreted by the second participant, who then enhances the argument in a way that informs the originator and allows the first participant to assimilate the information in a meaningful way. During integration, the originator of the argument is the principal agent, but the secondary participant influences the mathematical outcome and thus is a secondary agent in the discussion. Modification is characterized by interpretive discourse, as one student attempts to makes sense of another's faulty or flawed argument. This sense-making student also has the primary agency in the discourse, as he/she has the ultimate control in the mathematical outcome of the discussion.

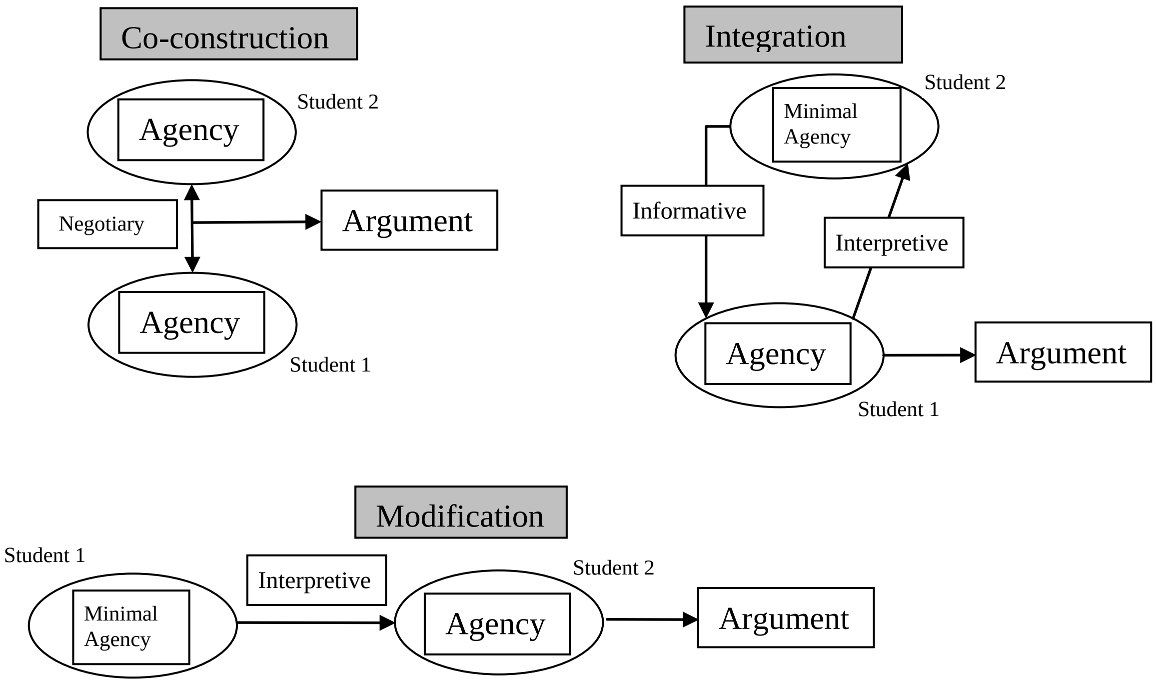

*Figure 1*. Three modes of collaboration.

## Method of Inquiry and Data Source

*Setting*

This research is a component of a larger, ongoing longitudinal study, Informal Mathematics Learning Project (IML), conducted through an after-school partnership between a University and an economically depressed, urban school district whose school population consists of 98 percent African American and Latino students. A goal of the program was to explore how mathematical reasoning develops in middle-school age students over time and under certain conditions. Students worked on challenging tasks, interacted with peers, and were allowed the time and opportunity to explore, explain, and discuss. The IML project spanned more than two and a half years (including summers) and included 30 sessions (each approximately 60-75 minutes in length). During each session a cohort of 24 students was asked to engage in open-ended problem solving working on stands of mathematical tasks, involving topics such as fractions, combinatorics, and probability.

In this paper, we report on the first five sessions of the IML program. Students, seated in heterogeneous groups of four, were given a strand of tasks dealing with fraction ideas in which they were asked to justify their solutions. For many of the students, the opportunity to work collaboratively on open-ended tasks was a new experience. With this in mind, tasks developed from earlier research had been found to promote collaborative reasoning and problem solving. Students were invited to build models of their solutions to the tasks using a set of Cuisenaire rods. The set contains ten colored wooden or plastic rods that increase in length by increments of one centimeter. After each task was posed, students worked in their small groups and were encouraged to build models and share ideas and conjectures. Students were then invited to the overhead projector to share their models and arguments with the whole class. Our analysis in this paper focuses on two groups of students working on two tasks during the second and fifth sessions of the program.

*Analysis*

Four video cameras were used to capture the activity of students working in small groups and presenting at the overhead projector. Video recordings and transcripts were analyzed using the analytical model outlined by Powell, Francisco & Maher (2003). The video data were first viewed repeatedly so that researchers could get a sense of the big picture. Next, the videos were transcribed and critical events were identified. Critical events consisted of students constructing justifications and defending these justifications. The critical events were organized into episodes which were organized in tables that traced the development of the justifications. Codes were developed to flag solutions offered by students, the justifications provided to support these solutions, and the occurrence of students collaboratively building arguments.

A modified grounded theory approach was used to analyze the data for collaboratively constructed arguments. Initial codes for the collaborative actions in building ideas emerging were organized into three categories: building on other's ideas, questioning others, and correcting others. Sub-codes of building on others' ideas included: expanding, redefining, and reiterating. Analysis of the patterns that these codes highlighted enabled the identification of patterns of interaction that were present. The result of our analysis was a coded, sequential narrative of both the justifications that students built collaboratively and the challenges that they made during the five sessions.

## Results

Examining the data across sessions, we found that the majority of arguments were built collaboratively. Upon further analysis, we discovered that the students collaborated in three different ways, and these modes of collaboration were ultimately crystallized and defined as outlined in the theoretical framework. A description of the three ways that students collaborated is organized by presenting an analysis of two episodes in which students collaboratively built an argument.

*Episode 1: Integration and Co-construction*

During the second session of the after-school program students were given the following task: *If I call the blue rod one, I want each of you to find me a rod that would have the number name one-half.* This is an impossible task since the blue rod is 9 cm. long. As such, the task generated many different arguments from the 24 students that included four different types of reasoning (contradiction, upper and lower bounds, cases, and inductive). The students worked for a few minutes and determined that such a rod did not exist. Chris lined up nine white rods under a blue rod and explained that you could find a rod whose length is one-third of the blue rod but not one-half. Danielle and Brittany began to build models of combinations of rods whose lengths were equivalent to the length of the blue rod (for example, a train of a yellow rod and a purple rod). After about five minutes Chris presented his partners with his model and explained:

Chris: If you take out four that's an even number but if you put the four back, that's not a half because it's nine, and nine is an odd number.

Danielle then presented the combinations of trains of rods whose lengths are equivalent to the blue rod (yellow and purple, black and red, light green and dark green, brown and white). Again, Chris explained using his model of nine white rods.

| | |
|---|---|
| Chris: | You can’t find a half of the blue one because if you put all white you only have nine so for nine you can’t really do it. And also if you put the white ones, you – it’s an odd number which is nine, and you can’t do it. |

Referring to the model that she and Danielle built, Brittany explained that none of the combinations of rods were a half because they were not the same length. In response, Chris explained that the blue rod is equivalent in length to nine white rods and nine is an odd number. The following dialogue then occurred:

| | |
|---|---|
| Danielle: | You can’t really divide an odd number; if the two yellow rods were the same length as the blue rod then they would be a half. |
| Chris: | Overall you can’t do it because if you use a white one, it is an odd number so you can’t divide by two. |
| Jeffrey: | Unless you get a decimal or a remainder. |
| Chris: | And you wouldn’t be able to do it anyway because none of these are even. |
| Danielle: | If only we had the two yellows and the yellows were shorter— |
| Jeffrey: | If purple was bigger— |
| Danielle: | Yeah, if the purple was bigger, then the green was kind of shorter so that the same color green could fit on it. |
| Jeffrey: | If the purple would have been a little, like half of the white, it would have been good. |
| Danielle: | Or if the light green was, um, it was, yeah, like a little bigger, then you could only have one up there or two. |
| Jeffrey: | The light green rod would have to be bigger than the purple rod. |
| Danielle: | But the purple has to be bigger; the purple has to be bigger equally because if you take another purple, you’re going to have to add a white. Yeah, you’re going to have to add a white; see, it don’t work. |
| Chris: | The thing we should say is that since we put the white cubes and we got an odd number, then if you have an odd number you can’t divide by two so you get one-half. So you get a decimal or a remainder so you can’t really divide it, right? |

In the above dialogue we see that two different forms of collaboration occurred simultaneously, integration and co-construction. Chris built a model using nine white rods and offered an argument based on a contradiction. Although his partners used a different line of reasoning, Chris continued to use his argument; however he integrated ideas from Danielle (*You can’t really divide an odd number*) and Jeffrey (*Unless you get a decimal or a remainder*) into his original argument. The integration of these ideas strengthened Chris’ original argument. Meanwhile, Jeffrey and Danielle co-constructed an argument based on upper and lower bounds.

Danielle offered the upper bound and Jeffrey the lower bound and together they determined that not rod existed between these two rods.

*Episode 2: Modification*

During the fifth after-school session students were presented with the task: *which is bigger one-half or one-third, and by how much?* Many students initially tried to name the orange rod one but realized that they could not find a rod whose length was one-third of the orange rod. They struggled with finding a model that they could use to compare one-half and one-third. Finally, Michael explained that the dark green rod would be named one, the light green rod one-half, and the red rod one-third. He used a model of the rods lined up next to each other to convince Ian. The students continued working on the task using Michael's model. Eventually Michael shared his "cake metaphor" described below.

Michael: And like, say, say you got five kids and each kid want a different slice [of cake] so one kid gets one-half [he pushes aside a light green] another kid gets this half [the other light green rod]—you only have three pieces left and the other three want small, well not small pieces, medium pieces [the red rods], okay, alright.

The researcher called Michael's attention to the discrepancies in his model (taking away two halves and then taking away three thirds) and walked away. Michael then asked Ian for help. Ian asked Michael a series of clarifying questions about his model. Through this questioning, he made sense of Michael's model and ideas and was able to explain it in his own words.

Ian: Oh, I get what your saying, so you're trying to divide them into different slices, like, if this is a cookie and your only here is a whole [the dark green rod], then when your friend comes over it's a half, you split it's a half [light green rods] and then when another friend comes over you split it into three slices [red rods].

Michael: This [he removes the dark green rod] it ain't a whole no more
So you just cut it right? So those are the three halves [red rods], this is the third.

Ian: Oh, this is the one-third [pointing to the red rods] and this is the half [pointing to the light green rods].

Michael: yeah

Ian: Oh I get what your saying now- if this is the whole cake, this is what you're trying to say, if this is a whole cake, alright so this is one whole and then you can divide it into three so this isn't a whole anymore, you have three pieces but then let's say this is the whole again—you divide this into one-half and you got two pieces instead of three—like one half is bigger than one-third, is that what you're saying?… yeah I get what your saying

Ian and Michael then used Michael's cake model to determine that one-half was bigger than one-third by one white rod or one-sixth. When the researcher rejoined them, both boys simultaneously explained the relationships and presented evidence to show that one-half is bigger than one third by one-sixth.

In this mode of collaboration, Michael initially built a direct argument to compare one-half and one-third using a cake metaphor. However, his explanation was faulty. In the process of making sense of Michael's argument and clearing up the inconsistencies (taking away two halves and having three thirds left), Ian developed a solid agreement for comparing the two fractions and used the model to find the difference.

## Discussion and Implications

In this paper, we extended Powell's (2006) framework for analyzing students' mathematical discourse by examining the effects of the four types of interlocution on the ways in which students collaborate when building mathematical ideas and justifications. In doing so, we offer a framework for analyzing student collaboration and the influence of this collaboration on agency. We show two episodes of students collaboratively building arguments as examples of the three modes of collaboration: integration, co-construction, and modification. In these episodes, it is evident that the nature of student's agency and the type of discourse in which the students engaged were interdependent and thus influenced the arguments that were constructed. The students' discursive interactions clearly had an influence on their mathematical ideas and reasoning. We concur with Powell (2006) that negotiary discourse promotes the development of *socially emergent cognition*, but also contend that informative and interpretive discourse are important in the discursive interactions of students and play a role in the ways in which ideas and reasoning influence students' justifications and mathematical understating.

Research points to the benefits of students working collaboratively on mathematical tasks and suggests that this collaboration influences individual mathematical understanding. We add to the literature by examining how specific types of discourse influence this collaboration and identifying three modes of collaboration that result. In addition, we show that each type of collaboration played a role in developing the strength or validity of the final argument. Analysis of the collaborative moves of students, then, is essential for the promotion of effective mathematical reasoning and argumentation in the learning environment. Ultimately, a more complete understanding of the mechanisms by which collaboration is encouraged can enable educators to facilitate the various forms of collaboration and promote agency and effective mathematical reasoning and argumentation in all students.

# COMPOUND EFFECTS OF MATHEMATICS DISCUSSION ON FIFTH GRADE MATH ACHIEVEMENT

Karl W. Kosko
Virginia Tech
kwkosko@vt.edu

Yasuo Miyazaki
Virginia Tech
yasuom@vt.edu

*Mathematics discussion has been suggested to improve mathematics achievement. The current study investigated the compound effects of students discussing mathematics with one another in both the third and fifth grades using hierarchical linear modeling. Results indicated that having discussion in fifth grade but not in third grade had a positive impact on mathematics achievement. The impact of discussion in both third and fifth grade was not found to be statistically significant from the impact of having no discussion in either grade. However, significant variability found in one variable may explain why a compound effect of discussion was not found.*

## Background and Objectives

According to Silver, Kilpatrick, and Schlesinger (1990), "mathematics deepens and develops through communication" (p. 15). Students gain a deeper understanding of the meaning of mathematics when they communicate with others about it (Goos, 1995; Lee, 2006; Pimm, 1987). Additionally, discussion has been shown to have a positive impact on mathematical achievement (D'Ambrosio, Johnson, & Hobbs, 1995; Grouws, 2004; Hiebert & Wearne, 1993; Koichu, Berman, and Moore, 2007; Mercer & Sams, 2006). Yet, there is evidence that discussion does not always have a positive impact on mathematics achievement (Kosko & Miyazaki, 2009; Shouse, 2001), which may imply that either discussion is not consistently effective in deepening mathematical understanding or that it is not consistently implemented to maximize its effectiveness.

A previous study conducted by the authors (Kosko & Miyazaki, 2009) investigated the impact of discussion on mathematics achievement using data from the Early Childhood Longitudinal Study (ECLS). Results showed that when accounting for prior achievement the difference between the two discussion groups in the study (*weekly* and *less than weekly*) was found not to be statistically significant. However, there was a statistically significant amount of variability in the impact of weekly discussion across schools. This variability was unable to be explained by the authors, even after the addition of covariates.

The previous study conducted by the authors was done with reference only to the impact of discussion in the fifth grade (Kosko & Miyazaki, 2009). The current study seeks to investigate the accumulated impact of discussion on fifth grade mathematics achievement. The large amount of unexplained variability in the previous study led the authors to question if mathematics discussion may take longer than one school year to positively impact math achievement. Yet to determine if this is actually the case, a new study had to be conducted. To date, the authors have yet to find a longitudinal study to investigate the compound effects of discussion on mathematics achievement. Therefore, the purpose and research question for the current study is as follows: Does the frequency of peer mathematics discussion in third and fifth grade have a compound impact on the mathematics achievement scores of fifth grade students.

## Theoretical Perspectives

Student discussion of mathematics has been stated as a means to deepen understandings of the mathematics discussed (Goos, 1995; Lee, 2006; Pimm, 1987; Silver et al., 1990). Students who understand mathematics more deeply should predictably perform better on mathematics achievement tests. According to several studies (i.e. Hiebert & Wearne 1993; Mercer & Sams, 2006; Stigler & Hiebert, 1997) students who were asked to explain and justify their mathematics in discussion had higher gains in mathematics achievement than students who were not asked to do so. Yet in some cases, student discussion of mathematics has been found to have a negative impact on achievement (cf. Shouse, 2001). As mentioned above, a previous study by the authors (Kosko & Miyazaki, 2009) found that the impact of student discussion on mathematics achievement varies significantly between schools. This means that in some schools the impact of achievement can be largely positive while in other schools it is largely negative. While some qualitative research (i.e. McGraw, 2002; Nelson 1997) suggests that it takes time for effective mathematics discussion to be successfully implemented, there is little to no quantitative data to support the impact of time or exposure on the effectiveness of discussion.

## Research Question

Does the frequency of peer mathematics discussion in third and fifth grade have a compound impact on the mathematics achievement scores of fifth grade students?

## Methodology

The current study analyzed data from the Early Childhood Longitudinal Study (ECLS) using a two-level hierarchical linear model (HLM). Hierarchical linear models are typically used when evaluating data nested in many groups (Raudenbush & Bryk, 2002). Since much of what is studied in education exists in hierarchical structures (i.e. students within classes, teachers within schools), HLM is particularly useful in studying differences within and between nested units. A two level hierarchical linear model looks at both the micro units at level-1 and the macro units at level-2. The micro units at level-1 (i.e. students) are nested within the macro units at level-2 (i.e. classrooms or schools). HLM-2 allows factors examined at the first level to be compared at the second level unit of analysis which they are nested in (see Raudenbush & Bryk, 2002 for further information). The purpose of using an HLM-2 model in the current analysis was to take into account the nested nature of the data (students nested within schools).

Third and fifth grade data from 3583 students in 1006 schools was used in the current analysis. The main variables included in the analysis were achievement scores and a teacher assessed item which asked how often the students involved in the study engaged in discussion about mathematics with other students. Teachers were required to complete this item for each student they taught who was a part of the ECLS study and was therefore used as an individual level variable rather than a classroom level variable. The variable addressing how frequently students discussed math with their peers was assessed in both third and fifth grade. For the purposes of simplifying the model for analysis, the variable was dichotomized at both levels to students who did have weekly discussions about mathematics and students who had discussions about mathematics less than weekly.

To investigate the compound effects of discussion on fifth grade achievement scores, four categories of students were compared in the analysis: students who did not have mathematical discussions with other students on a weekly basis in third grade or in fifth grade (*control*); students who did not have weekly math discussion in third grade but did in fifth grade (*disc_0_1*); students who had weekly math discussion in third grade but not in fifth grade (*disc_1_0*); and students who had weekly math discussion in both third and fifth grade (*disc_1_1*). These categories were included as dummy-coded variables in addition to other variables which served as covariates. These covariates included third-grade math achievement scores, race/ethnicity, gender, and socio-economic status.

**Results**

Results showed that students in the *disc_0_1* group had statistically significant higher scores than students who did not have discussion in either third or fifth grade. Students in both the *disc_1_0* and *disc_1_1* groups did not score significantly higher than students without discussion (*control*). At first glance this seems to indicate that there is no compound effect of discussion. However, the variable *disc_1_0* was found to have significant variability across schools, more than four times the impact of *disc_1_0*. Such variability indicates that weekly discussion in third grade had a largely positive impact on math achievement in some schools but also had a largely negative impact on math achievement in other schools. In turn, this variability may have affected the impact of *disc_1_1* on math achievement. Since weekly discussion in third grade was shown to have a negative impact on math achievement for many students, such discussion may, in part, counteract the generally positive benefits of having weekly math discussion in fifth grade. This would therefore explain why a compound effect of discussion was not found in the analysis.

**Discussion**

Mathematics discussion has been shown to have a positive impact on math achievement in some instances (D'Ambrosio, Johnson, & Hobbs, 1995; Hiebert & Wearne, 1993; Koichu, Berman, and Moore, 2007; Mercer & Sams, 2006; Stigler & Hiebert, 1997) and a negative impact in others (Shouse, 2001). The previous study conducted by the authors (Kosko & Miyazaki, 2009) showed a large amount of statistical variability in the impact of discussion that could not be explained. The current analysis sought to explain the variability in the previous study (Kosko & Miyazaki, 2009) and conflicting results of other studies (i.e. Shouse, 2001; Stigler & Hiebert, 1997). Although the results of the current study seem, at first glance, not to support a compound impact of discussion, the statistically significant amount of variability found in the impact of discussion in third grade is reminiscent of the results for analysis of the impact of fifth grade discussion (Kosko & Miyazaki, 2009). Therefore, the current study provides evidence that in a given year the general impact of student discussion on mathematics achievement can vary significantly between school setting if prior exposure to discussion is not taken into account.

One interesting result of the current study was that the impact of weekly discussion in the fifth grade without weekly discussion in the third grade (*disc_0_1*). This result could support claims made by Mercer and Sams (2006) who suggested that younger students may not inherently posses the skills necessary to maintain mathematics discussion without specific guidelines from the teacher. However, it is unknown how much guidance or structure these students received from the teacher in discussing mathematics with their peers.

*In this paper, we provide an account of the evolution of mathematical norms for argumentation that emerged during an ongoing teacher collaboration. The collaboration involves the mathematics and science teachers at Green Valley High School in the southwestern United States. As part of the collaboration, teachers were offered the opportunity to participate in college level courses offered at the school. In the fall of 2008, 21 of the 32 mathematics and science teachers chose to participate in a course that focused on functions and the covariation of the measures of two quantities. The activities that comprised the course were intended to serve as didactic objects around which productive conversations could emerge. Therefore, mathematical arguments developed around key significant mathematical issues. As a result, the norms for mathematical argumentation evolved during the semester.*

## Introduction

Balancing the tensions inherent in simultaneously attending to students' contributions and the mathematical agenda is a hallmark of deliberately facilitated discussions (cf. McClain, 2003). These discussions involve a plethora of decisions that must be made both prior to and while interacting with students. The image that results is that of the teacher constantly judging the nature and quality of the students' contributions against the mathematical agenda in order to ensure that the issues under discussion offer means of supporting the students' mathematical development. This view of mathematical discussions stands in stark contrast to open-ended sessions where all students are allowed to share their solutions without concern for potential mathematical contributions. In order to engage in the process of elevating discussions to the level of sophisticated mathematical argumentation, the teacher must have a deep understanding of the mathematics under discussion (cf. Ball, 1989; Ball, 1993, Ball, 1997; Bransford et al., 2000; Grossman, 1990; Grossman, Wilson, & Schulman, 1989; Ma, 1999; McClain, 2004; Morse, 2000; National Research Council, 2001; Shulman, 1986; Schifter, 1995; Sowder, et al., 1998; Stein, Baxter, & Leinhardt, 1990). This is critical in both being able to advance the mathematical agenda and in judging the quality and worth of student contributions. It requires decision-making in action concerning the pace, sequence and trajectory of discussions in order to ensure that the discussions are mathematically productive.

When focusing on students' offered explanations and justifications, the teacher is seen to actively guide the mathematical development of both the classroom community and individual students (Ball, 1993; Cobb, Wood, & Yackel, 1993). This guiding necessarily requires a sense of *knowing in action* on the part of the teacher as he or she attempts to capitalize on opportunities that emerge from students' activity and explanations. With this comes the responsibility of monitoring classroom discussions, engaging in productive mathematical discourse, and providing direction and guidance as judged appropriate. Similar pedagogical issues are addressed in Simon's (1995) account of the Mathematics Teaching Cycle that highlights the relationship between teachers' knowledge, their goals for students, and their interaction with students.

A focus on the importance of students' contributions also highlights the importance of norms that constitute the classroom participation structure. The importance attributed to classroom norms stems from the contention that students reorganize their specifically mathematical beliefs and values as they participate in and contribute to the establishment of these norms.

In the analysis in this paper, we focus on the discourse between and among the teachers and instructors in a setting in which the authors were the instructors. The analysis will make explicit the evolution of the discussions over the course of the interaction. In doing so we clarify the normative ways of speaking that evolved in the process. This work is significant in that it offers one framework for thinking about how to guide the evolution of productive mathematical argumentation.

## Setting

The authors are involved in ongoing teacher collaboration with a group of high school mathematics and science teachers from Green Valley High School[1]. Green Valley High School serves a student population of approximately 2,800. It contains grades ten through twelve. As part of the collaboration, in the fall semester of 2008, 21 of the 32 mathematics and science teachers at Green Valley chose to participate in a course that was taught on Monday afternoons at the school. The authors served as instructors for the course that focused on covariational reasoning. The teachers were able to earn three hours of college credit for their participation. In addition, all of the mathematics and science teachers in the school attended weekly curriculum planning meetings. The teachers were assigned to groups according to the primary subject they taught. For instance, all of the Biology teachers met together as did the pre-calculus teachers. This meeting time was supported by the Principal as evidenced by his arranging for common planning periods for the teachers. However, for the purposes of the analysis in this paper, data is taken only from the discussions that occurred during the Monday night class.

## Description of the Course

The course was designed to focus on a significant mathematical concept, that of covariational reasoning. Oehrtman and colleagues (Oehrtman, Carlson, & Thompson, 2008) have argued that covariational reasoning is foundational to high school mathematics and should serve as the organizing concept for all courses. We agree with this stance and therefore took covariational reasoning as our mathematical endpoint. In order to achieve the envisioned endpoint of covariational reasoning playing a significant role in instruction, we initially engaged the teachers in activities that were used in an Algebra I class where covariational reasoning guided the development of the mathematics. (These activities were part of a project conducted by Pat Thompson and his research team.) The teachers in the class worked through the series of activities *as students* and then reflected on their prior activity from their position *as teachers*. Following their mathematical investigations, they explored the classroom in which the instructional unit was implemented. This was made possible by video-based case development efforts from Thompson's ongoing grant. Two of the authors, McClain and Coe, had participated in the case development and were, therefore, well equipped to provide instruction based on the case.

Following the case investigation, class sessions turned to materials developed from Project Pathways that was funded by the National Science Foundation under Carlson's direction. She therefore took the lead on the instruction for this portion of the course. The materials begin with an investigation of proportional reasoning as it relates to functions, and they form the basis for an exploration of linear and exponential growth. Throughout the investigations the teachers were encouraged to consider how the measures of the two quantities co-varied in each situation. The grounding of the problems in contextual situations allowed the teachers to work in small intervals to investigate the phenomena (e.g. small increments of time). It also helped support a shift away from what Thompson (personal communication, 2008) calls "shape thinking." Shape thinking involves imagining the "path" of the phenomena and then seeing the graph as a "static" representation of the completed trace of the path. In other words, the graph is static and has already occurred. An example can be seen when students trace the path of a car given the time and distance it has traveled instead of trying to coordinate the measures of the quantities of time and distance.

It is important to note that throughout the semester, the teacher participants were constantly encouraged to *speak with meaning.* Elsewhere we have described speaking with meaning as ensuring that explanations carry meaning for all participants. This requires conceptually based conversation about quantity. The negotiation of the norms for argumentation that resulted lead to improved understanding between the teachers and deeper knowledge of the content. It is these discussions that provide the basis of our analysis.

## Methodology

The general methodology falls under the heading of design research (Brown, 1992; Cobb, Confrey, DiSessa, Lehrer, & Schauble, 2003). Following from Brown's characterization of design research, the teacher collaboration involved *engineering* the process of supporting teacher change. Like Brown, we attempted to "engineer innovative educational environments and simultaneously conduct experimental studies of those innovations" (p. 141). This involved iterative cycles of design and research where conjectures about the learning route of the teachers and the means of supporting it were continually tested and revised in the course of ongoing interactions. This is a highly interventionist activity in which decisions about how to proceed were constantly being analyzed against the current activity of the teachers.

The particular lens that guided our analysis of the data was a focus on the normative ways of arguing about solutions, or what Cobb and Yackel (1996) define as the classroom mathematical norms. Classroom mathematical norms focus on the collective mathematical learning of the teacher cohort[2] (cf. Cobb, Stephan, McClain, & Gravemeijer, 2001). This theoretical lens therefore enabled us to document the collective mathematical development of the teacher cohort over a period of time. In order to conduct an analysis of the communal learning, it is important to focus on the diverse ways in which the teachers participate in communal practices. For this reason, the participation of the teachers in discussions where their mathematical activity is the focus then becomes the data for analysis. The diversity in reasoning also serves as a primary means of support of the collective mathematical learning of the teacher cohort. An analysis focused on the emergence of classroom mathematical norms is therefore a conceptual tool that reflects particular interests and concerns (Cobb, et al., 2001).

## Analysis

Research on effective teaching often characterizes the teacher's classroom decision-making process as informed by the mathematical agenda, but constantly being revised and modified in action based on students' contributions. These characterizations take account of the students' contributions while attending to the mathematics. Attempting to balance the tension inherent in simultaneously attending to students' offered solutions and the mathematical agenda is the hallmark of deliberately facilitated discussions. A critical resource for the teacher in this process is therefore the *means of support* available to help him achieve his mathematical agenda. This support manifests itself in the form of the instructional tasks and the tools available for solving the tasks. For this reason, tools, notation systems, and student generated inscriptions all serve an important role in the mathematics classroom. However, it is not the tool (or the notation or the inscription) in isolation that offers support for the teacher. It is instead the students' use of the tools and the meanings that they come to have as a result of this activity (Kaput, 1994; Meira, 1998; van Oers, 1996). In this way, the tool is not seen as standing apart from the activity of the student. When designed, these objects must be thought of as didactic objects that will form the basis for reflection and discussion (cf. Thompson, 2002). For this reason, the teacher generated artifacts from the course served an important role in supporting the evolution of mathematical discourse.

As an example, one of the first tasks posed to the teachers in the Monday afternoon class is called the *Sprinter Task*[3]. In this task, the teachers first watched a video of Florence Griffith Joyner's Gold Medal 100 meter race. After viewing the race a couple of times, the teachers were asked to qualitatively track the distance from the start against time since the start. In this introductory task, the teachers had to begin to coordinate two quantities[4], distance from start and time from start. As part of the coordination, they were asked to create a graph and then explain the graph in terms of the two co-varying quantities.

As the teachers worked, one group of mathematics teachers was very focused on the accuracy of their graph. They were unable to think about the measures qualitatively and struggled to get exact measures for exact times by continually starting and stopping the video. They were reluctant to share their solution until they were sure that their graph was correct. Our goal was more global. We wanted the graphs to show a qualitative relationship between the measures of the two quantities that could be described generally with wording such as, "As time passes, her distance from start increases." We were also interested to know if the teachers viewed Griffith-Joyner traveling at a constant rate, an increasing rate or other, and we were interested in their understanding of the meaning of these. Our ability to support the teachers' ability to focus on the coordination of the measures of the two quantities depended upon their ability to reason about the situation, not read a graph in the canonical sense.

Unfortunately, we did not achieve our goal on this first task. This is not surprising either now nor was it at the time. The mathematics teachers in particular argued that scaling the axes was an important part of creating a graph. We eventually had to tell them to leave them unmarked. Even so, they were hesitant to present their results.

Although all of the groups of teachers were able to generate a graph that gave a qualitative sense of the how the measures of the two quantities co-varied, conversations at this point were characterized by telling. In this early phase of the class, the teachers were focused on the correctness of the answer and their contributions were a recitation of that correct answer and the procedure used to arrive at it. In addition, they did not question each other, but sat quietly as each group shared. This portion of the lesson took on characteristics of a "show and tell" instead of an intellectual conversation about ideas. We were, in fact, unable to prompt significant conversations at this point. We therefore describe the first mathematical norm that emerged as that of *argumentation as telling.*

A week later, we posed a question that involved the teachers watching another video and then creating a graph of the situation. In this video, a skateboarder skates back and forth on a half pipe. The *Skateboarder task* required the teachers to coordinate the boarder's horizontal distance from start with the time from start. In this task, the teachers had to attend to the quantities being tracked rather than the position of the boarder. This is in sharp contrast to the *Sprinter task* where Griffith-Joyner's position gave information on the distance from start. This task, therefore, focuses on the issue of shape thinking in that if teachers tried to rely on the *position* of the skateboarder, the graph would be incorrect as shown below in Figure 1.

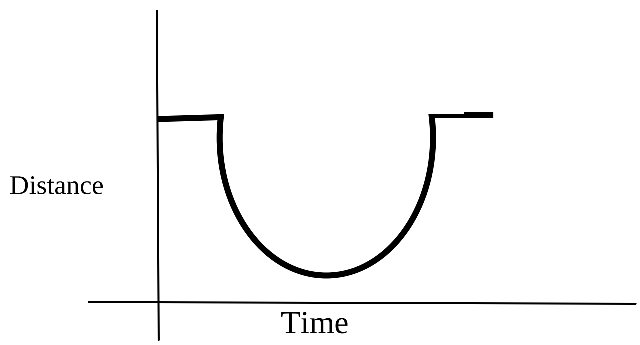

*Figure 1.* Path of the skateboarder on a half pipe.

The other significant issue that emerged was that of explicitly labeling the axes. For instance, using the descriptor "distance" to label the vertical axis does not clarify what quantity is varying. It could be the total distance traveled. When graphed correctly, the vertical axis should be labeled *horizontal distance from start* and the horizontal axis labeled *time from start.* For this reason, the graph is not the trace of the half pipe as shown above, but the coordination of the measures of the two quantities. Therefore, in creating their graphs, the different groups came up with differences in their interpretations as shown below (Figure 2).

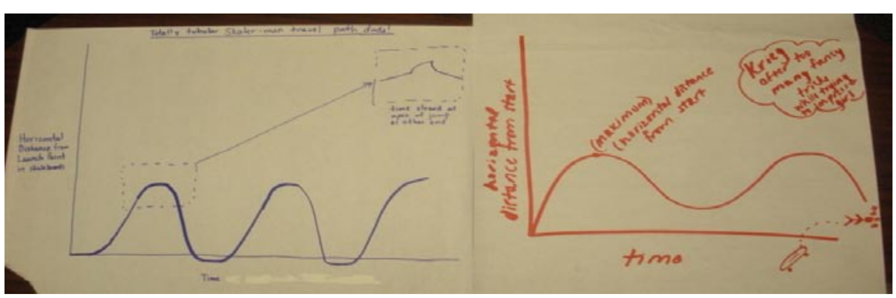

*Figure 2.* Graphs of the skateboarder's distance from start as a function of time.

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

When these were juxtaposed on the board, a lively discussion ensued. The teachers initially fell into their original mode of discussion by engaging in a show and tell. However, the differences in their graphs initiated a shift in the conversations such that the teachers began to take the position of defending their own graph. There was no effort to make a comparison across the different graphs—only to justify why their graph was correct. As a result, the teachers did not attend to each other's argument, but focused only on their artifact. There was no attempt to revise and modify the current graphs to move toward a more accurate representation. That only occurred at our initiation. The teachers just kept pointing to their own solution. As a result, the second mathematical norm that emerged was that of *argumentation as disagreement*.

As the course continued and the teachers continued to investigate situations where they had to coordinate the measures of two quantities, the instructors began to push the teachers to speak meaningfully about their graphs. In particular, as the teachers explained their graphs to the class, they were pressed to talk about what was happening to one variable as the other changed or varied. As an example, in the skateboarder task, it was insufficient to say, "First he went down and then across and then back up." A more meaningful explanation was, "as he dropped down the left side of the pipe, his horizontal distance from start did not change. However, as he moved along the base of the pipe, his horizontal distance from start began to increase. As he went up the right side of the pipe, his horizontal distance from start was the same." In other words, the explanation had to be in terms of the two quantities and how they are covarying. In subsequent problems the teachers and instructors began to renegotiate what constituted an adequate explanation.

In this third phase there was, therefore, a significant shift in that the teachers began to engage in conceptual explanations. However, their goal was not to engage other members of the class in a discussion. The teachers spoke *to* the other members of the class, not *with* them (elsewhere Lima and colleagues have made a similar distinction, (personal communication, June, 2008)). Although the teachers were able to reconceptualize their own thinking about a particular solution, they were still unable to understand what it might mean to speak so that others could comprehend their thinking. As a result, the third mathematical norm for argumentation that emerged was that of *speaking conceptually* ***to*** *another*.

The last mathematical norm for argumentation that emerged was that of *speaking conceptually* ***with*** *another*. In this fourth and final phase, the teachers continued to speak meaningfully or engage in conceptual explanations with their colleagues. However, the teachers were not only able to reconceptualize their own thinking about a particular solution but also do this while thinking about what it might mean to speak so that others might comprehend their thinking. This shift in argumentation was apparent in discussions of the *Bungee Jumper* task. In this task, the teachers were shown a video of a man bungee jumping off of a bridge. The task was to create a graph that coordinated the time since the jumper leapt from the bridge with his distance from the ground. By making the distance quantity the *distance from the ground*, teachers were unable to create a graph that was merely the trace of the jumper's path. Instead, they had to coordinate the variation of the time since he leapt with his distance from the ground. As the teachers shared their solutions, they used their explanations and questions to clarify for both themselves and their colleagues how the distance varied as time changed. In this process there was a concerted effort on the part of the teachers and the instructors to communicate clearly. It was during these conversations that the teachers began to speak conceptually **with** one another.

## Conclusion

In the analysis presented in this paper, we have provided an account of the evolution of the mathematical norms for argumentation that occurred in the course taught to the mathematics and science teachers at Green Valley High School. This work is significant in that it provides a framework for thinking about mathematical argumentation in the context of teacher development. This evolution is similar to data we have analyzed from other teacher development collaborations (see McClain, 2002). For this reason, we argue that we are providing the starting points for what diSessa and Cobb (2004) call a *framework for action*. diSessa and Cobb characterize a framework for action as a first step toward the development of a guiding theory. Therefore, we are not claiming that we have discovered a new theory. Our claims are much more modest. What we are offering is a first step in that direction. As a result, this pattern of evolution will be useful in our future work. The potential of its power as a theory is only determined by its use by others in similar and different situations. The messiness and complexity of teacher development in the context of design research "highlights the pressing need for theory while simultaneously making the development of useful theories more difficult" (p. 79). It is for that reason that we offer this process as a "way of looking" at this significant aspect of teacher collaborations.

## Endnotes

1. Green Valley is a pseudonym.
2. In this analysis, we purposely refer to the group of teachers as a *cohort* instead of a *community*. Documentation of the evolution of the cohort into a community is beyond the scope of this paper. We therefore take the "easier road" by not making assumptions about the nature of the relationships within the cohort at the time of this analysis. We choose to do so because of the importance we place on both establishing *communities* of teachers and verifying their existence with established criteria (cf. Wenger, 1998).
3. The initial tasks were designed by Scott Adamson and Ted Coe as part of their grant work with Pat Thompson.
4. By quantity we mean an attribute that can be measured or that one can imagine measuring.

# MULTIPLE MEANINGS IN MATHEMATICS: BENEATH THE SURFACE OF AREA

Samuel Otten
Michigan State University
ottensam@msu.edu

Beth A. Herbel-Eisenmann
Michigan State University
bhe@msu.edu

*This study applied thematic discourse analysis (Lemke, 1990) to a section of a middle school lesson focused on the relationship between the area of parallelograms and rectangles. This analysis provides a way to show the structure of the semantic relations between mathematical terms, shedding light on points of convergence and divergence between parallelograms and rectangles that can be, and often are, used for instructional purposes. Points of teacher dialogue where the semantic relations between mathematical terms might have been unclear to students are identified and particular attention is given to subtle shifts in the meanings of the terms* base *and* height*.*

## Background

Mathematical language presents several significant challenges to students (Schleppegrell, 2007). For example, mathematical terms are used with a different level of precision than terms in everyday language, in part because a mathematical definition provides both necessary and sufficient information about the term whereas the definition of an everyday term merely describes its meaning. This distinction was taken further by Poincaré who pointed out that a mathematical definition, rather than encapsulating an existing meaning, actually creates the mathematical entity in question (Folina, 1992). Linguistic challenges also arise when words are used differently inside mathematics classrooms than they are outside (Pimm, 1989; Thompson & Rubenstein, 2000), as is the case with *average, power, similar, right*, and even the word *or*. Another challenge of mathematical language, one that is especially relevant to the current study, is that a single term is often used in ways that have subtly different meanings. A mathematician using the word *inverse* may, depending on the context, be referring to an inverse function, an inverse operation, or the multiplicative inverse of a group element. We are not arguing that such uses of mathematical terms are inappropriate or undesirable because we recognize the value in a compact, versatile language that mirrors the myriad connections between mathematical entities. Rather, we are emphasizing that in the process of learning mathematics, which in part means becoming fluent in its language and meaning systems (Chapman, 2003), overcoming such obstacles is non-trivial for students. We contend that more detailed attention to such non-trivial aspects of mathematics learning can be helpful to teachers and researchers, a point we return to in the final section of this paper.

The fundamental geometric concepts of *base* and *height* provide another example of mathematical terms that are used with subtly different meanings at different times. The purpose of this study is to examine a classroom interaction that includes the terms base and height to see whether and how this subtle shift in meaning manifests in the dialogue.

## Theoretical Perspective

Michael Halliday's (Halliday, 1978; Halliday & Matthiessen, 2003) theory of systemic functional linguistics underlies the analytic methods we employ in this paper. A foundational assumption of this theory is that context and language use are intimately related: context influences language choice and language choice helps to construe context. Halliday described three metafunctions of language—ideational, interpersonal, and textual. Language is used to make sense of experience and in so doing serves the *ideational* metafunction; that is, it is used to give cues and clues regarding the meaning of *what* is being talked about. Language is also a means for acting out the social relationships of those *who* are using the language, thus serving the *interpersonal* metafunction. The *textual* metafunction refers to aspects of the organization of the language itself. Unfortunately, we are unable in the present paper to provide a full description of the theory, but we can make note of work in mathematics education that has taken up the general ideas of systemic functional linguistics (e.g., Atweh, Bleicher, & Cooper, 1998; Chapman, 2003; Morgan, 1998). For this study we focus specifically on the ideational metafunction—that is, the content of mathematics—though we recognize the value of research focused on other aspects of language and also recognize the artificial nature of isolating one metafunction from the others. That said, we, along with others (e.g., Steinbring, Bussi, & Sierpinska, 1998), feel that it is important to engage in forms of discourse analysis that focus on mathematical content and meaning.

Lemke (1990), who applied systemic functional linguistics to transcripts of science lessons, viewed language as "a system of resources for making meaning" (p. ix). From this perspective, language does not consist of mere grammar and vocabulary but is also seen as a semantic system or a system of meaning that allows us to create "webs of relationships" among and between ideas. As Lemke highlights, there are many ways to talk about ideas, but the underlying meaning or "pattern of relationships of meanings, always stay the same" (1990, p. x). It is through the patterns of semantic relations that meaning is construed. For example, a group of people may talk about the leg of a table using a wide variety of particular words and sentence structures, but the pattern across the particular instances will be the semantic relation that the leg is a part of the table (a MERONYM/HOLONYM relation). Lemke (1990) articulated a method for thematic analysis, described below, with the purpose of uncovering and examining such patterns. Examples of the semantic relations we drew on in this paper are displayed in Table 1.

*Table 1*
Semantic Relations

| Linguistic Terms | Description |
|---|---|
| MERONYM / HOLONYM | part of a whole |
| HYPONYM / HYPERNYM | subset of a set |
| EXTENT / ENTITY | space associated with an object |
| LOCATION / LOCATED | spatial relationship |
| SYNONYM / SYNONYM | equivalence relationship |

## Methodology

We employed Lemke's thematic analysis method as a lens that would bring into focus the mathematical content of a middle school lesson on area. The lesson comes from a sixth-grade classroom in an urban Midwestern middle school. The teacher, Robert, is elementary certified and had been teaching for seven years. Prior to the collection of the data presented here, Robert had not been a member of any professional organizations and the textbooks he used (there were several) can be described as conventional.

The analysis consisted of several stages. First, we selected the transcript excerpt from a larger corpus of classroom observations.[1] This selection was based on the pervasiveness of content terms used in the excerpt and the fact that a classroom observation of another teacher existed in our corpus that also dealt with the topic of area. (An article involving a detailed analysis of both of these transcripts is forthcoming). Second, we reviewed and filled in details (e.g., what "this" refers to) of the transcript. Third, we identified the content words that were central to the lesson and generated a *clean map* of the semantic relations between these terms. This clean map, which Lemke referred to as an ideal map, was based on our own mathematical understandings of the terms as well as the definitions of the terms presented in various mathematical textbooks. Fourth, we went through the transcript excerpt line by line and, for each occurrence of the identified content words, attempted to identify the semantic relation at play. Finally, we looked across the semantic relations of the transcript for thematic patterns and developed a *transcript map*. The processes of the analysis and the products of the analysis both contributed insights regarding the content of the interaction.

## Results

The mathematical terms that we identified for analysis were *rectangle*, *parallelogram*, *area*, *base*, *height*, *length*, *width*, as well as the non-technical term *bottom*. There is a HYPONYM/HYPERNYM relationship between rectangles and parallelograms since the former are particular instances of the latter. Area is an EXTENT of a polygon because it is a measure of two-dimensional space. The base of a rectangle or parallelogram is defined as one of its sides, thus forming a MERONYM/HOLONYM relationship involving base. In particular, a base is by definition a geometric ENTITY. The height of a rectangle or parallelogram, on the other hand, is defined as the distance between the given base and the line containing the opposite side and so is a quantity. This semantic difference is not always made explicit to students, as we shall see below, and may be confounded when the phrase "base and height" is used in a way that implies their interchangeability. Furthermore, the term *base* can also refer to the EXTENT of the base segment (as in the area formula "base times height" which calls for the quantities), and the term *height* can also refer to a line segment (often dotted) drawn between the base and the opposite side. Thus *base* is defined as a MERONYM of a rectangle or parallelogram but can also refer to an EXTENT (i.e., the length of the base segment). The term *height*, on the other hand, is defined as an EXTENT but is also used to refer to a geometric ENTITY (e.g., the dotted line from the base to the "top" of the parallelogram). This is captured in Figure 1, the clean map, by the fact that these terms appear twice under rectangles and parallelograms (with the term-as-defined above the other usage).

The semantic relations we have just described hold for both rectangles and parallelograms, which we see in Figure 1 because the overall semantic structures of rectangles and parallelograms with respect to area are quite similar. This structural similarity is one of the reasons that Robert, in the excerpt below, chose to teach parallelogram area by appealing to prior knowledge of rectangular area. There are, of course, important differences. For instance, *length* and *width* are terms that are associated with rectangles but not generally with parallelograms. Also, a side adjacent to the given base of a rectangle can be interpreted as a *height* (in the ENTITY-sense) of the rectangle, forming a MERONYM/HYPONYM relationship between the height and the rectangle. However, this relationship does not exist with non-rectangular parallelograms.

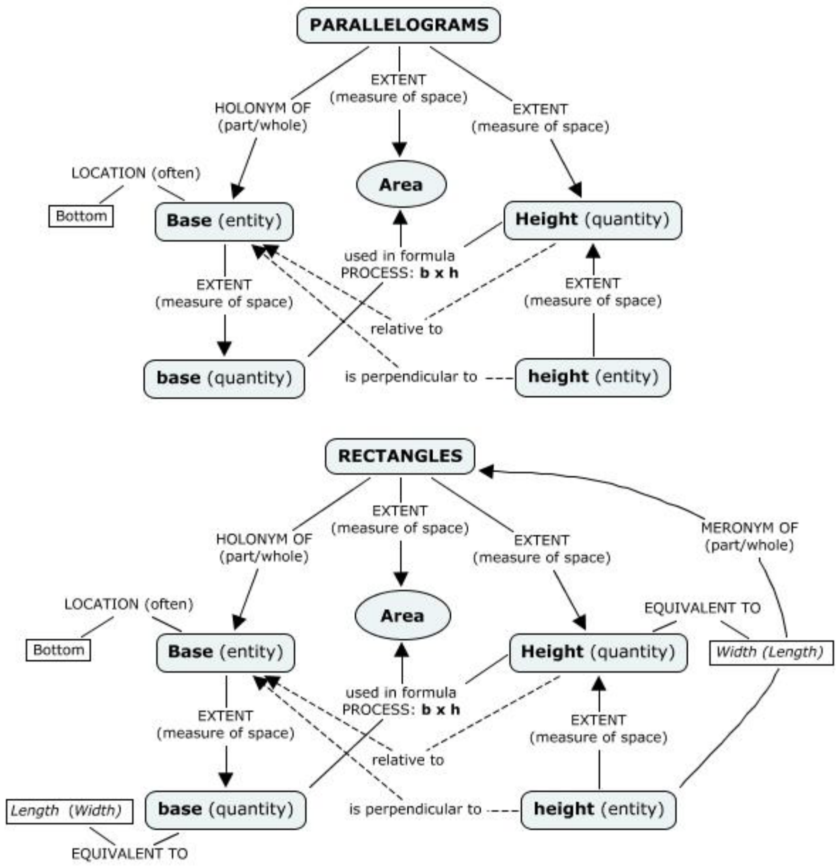

*Figure 1.* A clean map wherein rectangle is a HYPONYM of parallelogram.

Turning now to the classroom transcript, we join Robert after he has reviewed the area formula for rectangles and is about to transition to the development of the area formula for parallelograms. We use boldfaced text to draw attention to the content words in the transcript since these were a primary focus of our analysis.

Robert: OK, now it was important that you brought up parallel because the next one is **area** of a **parallelogram**. You just described to me a **parallelogram**, which was this: **rectangles** are **parallelograms**. [Student: Yeah, just turned.] **Parallelograms** have two sets of parallel sides. That's what a **parallelogram** is by definition. So what would you guess the formula would be for finding the **area** of a **parallelogram**? Adam?

Adam: *Length* times *width*.

R: *Length* times *width*. OK, aren't **rectangles--**, didn't we just decide that **rectangles** are **parallelograms**?

Ss: Yes. Yes we did.

R: We decided because I told you that (laughs).

S: Actually you decided.

R: OK, so using that, **area** would be equal to *length* times *width*. They call it a little different. Instead of saying *length* times *width*, they say **base** times **height**. They say **base** times **height**. [Ms: Face?] **Base**. We're going to make a **parallelogram** from our **rectangle**. On your picture of your **rectangle** I want you to make this…a diagonal line like this. [Draws on overhead a segment from the upper right corner of the rectangle to the interior of the bottom side.] We’re going to make a **parallelogram** from a **rectangle**. OK? Now, when I put this diagonal in what shape did I make?

Ss: Triangle.

R: Triangle. So what we’re going to do, we’re going to take this triangle off and we’re going to put it on the other side [draws a congruent triangle on the left side]. We’re going to put it over here. So if we have our **rectangle**, which is what we had before, and we had our three centimeters by five centimeters. We cut this section off and we just add it on to the other side. OK? So here is our diagonal.

S: That looks like a 3D figure.

S: That’s cool.

R: That’s how they’re getting your **parallelogram**.

From the first teacher turn (lines 1–5) we can identify several semantic relations. The first and last sentences of this turn imply that parallelograms have an area which, as was established in previous classroom interactions, is an EXTENT. Also, rectangles and parallelograms are related by the phrase “rectangles are parallelograms” in lines 3 and 7–8. By this the teacher means that all rectangles are parallelograms (i.e., the set of rectangles is a HYPONYM of the set of parallelograms), but the phrase is unclear because “are” can also be used to mean equivalence (e.g., rectangles *are* quadrilaterals with four right angles). Because of this ambiguity we will denote the relationship using the original term “are” in the transcript map (displayed at the conclusion of the third portion of the transcript). We also see in lines 3–4 a definition of parallelograms, with the implication being that a parallelogram is equivalent to or SYNONYMOUS with a figure satisfying the definition (i.e., containing two parallel sides).

Using reasoning based on the relationship between rectangles and parallelograms, Robert leads Adam to state the area formula of parallelogram, which the student describes as “length times width” (line 6). If we take “rectangles are parallelograms” to mean (correctly) that the set of rectangles is a subset of the set of parallelograms, then this reasoning about the area formula is flawed; the subset relationship would imply that rectangles have the same area formula as parallelograms but not the converse, as was assumed in the excerpt. If, on the other hand, we take “rectangles are parallelograms” to mean (incorrectly) that the two are equivalent, then their area formulas would necessarily be equivalent as well. In lines 12–13, the teacher modifies Adam’s statement to be base times height, noting that “they call it a little different” than length times width. This information from the teacher establishes a sort of equivalence between the terms *length* and *width* and the terms *base* and *height*. Lines 14–27 add another semantic relation between *parallelogram* and *rectangle* as we see that the former can be constructed from the latter. A rectangle, however, is already a parallelogram so what is meant is that a non-rectangular parallelogram can be constructed from a rectangle, but this is not explicit.

We continue in the transcript, picking up directly where we left off.

Robert: OK, now we said that the formulas were similar. We determined that because we said that the **rectangle** was a **parallelogram**, so we said that the formulas are similar. OK, this *bottom* section will be considered our **base** [shades in base on overhead]. OK, **base** is like *length*, so it is similar. That would be our **base** [points to the parallelogram on the projection screen]. Now, when we found perimeter of a **rectangle** what sides did we add? Or, what did we add together? If we were going to find the perimeter of this **rectangle** what would we add?

Students: The sides. The *length*.

R: Which would be what?

S: Fifteen.

R: Five, five, three, and three [points to the sides of the rectangle], correct? [S: Yeah.] So if we were going to find the perimeter we'd go around the outside. OK, this diagonal here is not the **height** of it [points to slanted side of parallelogram on screen]. It is on the outside but it's not the **height**. The **height** has to be perpendicular or at a right angle to the base.

This excerpt begins with the statement that the area formulas are "similar." We see in line 31 that base is "like" length and that they are also "similar." This is slightly weaker than the previous semantic relation, which implied that base and length were different references for the same thing. In line 30 the teacher states that the bottom of the parallelogram will be "considered" the base. The semantic relation in this situation is not clear, but there is some sort of identification or equivalence taking place between base and bottom. Furthermore, in lines 39–42 we see *height* for the first time and learn that it is not the slanted side of the parallelogram and so not a MERONYM. Its relationship to the base is articulated as one of perpendicularity. Since perpendicularity is a characteristic of actual entities and not quantities, this statement about the height implies that it is an ENTITY and not a quantity.

The relations involving height will be further developed in the next excerpt. Before then, however, we would like to point out the subtle semantic shifts occurring in lines 32–38. The teacher begins by asking what would be added in the calculation of a rectangle's perimeter, hinting in line 32 that sides are involved. Students respond that the sides are added. Semantically, however, it is not the sides themselves that are added but the EXTENTs or lengths of the sides. This subtle distinction is even more clearly confounded in line 38 when Robert points to the sides themselves but calls out their measurements. (Again, we do not wish to communicate that such action is negative, but merely to illuminate the fact that two different semantic relations are involved.)

We continue directly following line 42.

Robert: So if this was our **parallelogram**, the **height** would actually be this vertical distance here between these two lines [draws vertical segment in the interior of the parallelogram on the overhead]. OK, so this would be our **height**, from here down. Or it'd be from here down [draws vertical segment in the exterior of the parallelogram]. That would be our **height**. The **height** is actually just the distance between those two **bases**. So, what is the **area** of this figure here? Think about what we did with this [points to the cut-off triangle]. What does it have to be?

Student: Fifteen.

R: Fifteen. Didn't we just take this triangle and move it over here [points to rectangle]?

Ss: Yeah.

R: So doesn't the area have to be the same? [Ss: Yes.] Yeah, so we know the **base** is five and the **height** is three. These side *length*s may be different. They may actually be four or three point seven. They may be some other number. But the height has to be perpendicular to the base. It's got to be straight up and down for a parallelogram. OK?

We see in line 43 and again in line 47 that height is defined as a distance, which corresponds with the definition used in the clean map in Figure 1. This explicit discussion of height does not, however, correspond with the semantic relations in the previous excerpt in which height was characterized as a geometric ENTITY rather than a quantity. The notion of height and base as quantities reappears in line 54 when it is stated that "the base is five and the height is three." The notion of height and base as entities reappears in lines 55–56 when Robert reminds the class that "the height has to be perpendicular to the base." Thus this final turn is another example of the subtle and implicit shift in semantics involving the terms base and height. Figure 2 contains a transcript map based on all three excerpts discussed in this subsection.

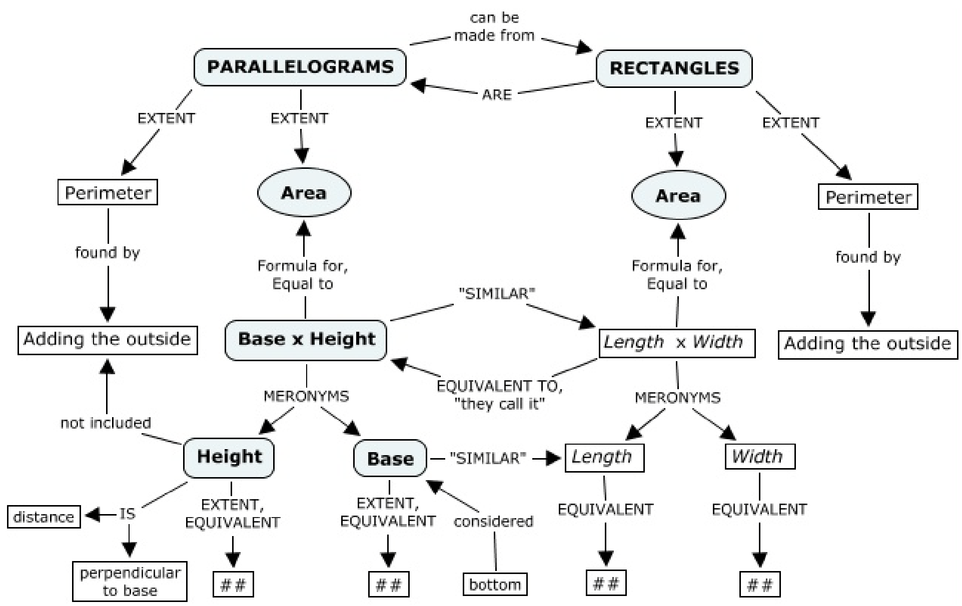

*Figure 2.* A transcript map based on Robert's excerpt.

**Discussion**

In this paper, we used thematic analysis to examine the semantic relations from a middle school lesson on the area of parallelograms. In generating the clean map of the relations between the pertinent mathematical terms (see Figure 1), we became acutely aware of the structural similarities between the semantic relations of rectangular area and those of parallelogram area, similarities that are often exploited in instruction as teachers and curriculum materials relate parallelogram area to rectangles or vice versa. The clean map also allowed us to see where the semantic differences lay between the two types of polygons, differences that could inform instructional decisions. Moreover, the clean map process exposed the difference between *base* (a geometric ENTITY) and *height* (an EXTENT) as mathematically defined, as well as the fact that the same terms *base* and *height* are used to refer to both physical segments and the lengths of those segments. Height has the additional distinction of having the semantic possibility of being a MERONYM of a rectangle but never of a non-rectangular parallelogram. All of these subtleties and possible points of student confusion appeared in the transcript from the sixth grade lesson. *Base* often referred to a side but was also used as a number and plugged into the formula (e.g., line 54). *Height* was explicitly defined as a distance (e.g., line 43) but then was referred to as the drawn-in segment and described as being perpendicular to the base (line 41); a property that only makes sense in reference to a geometric ENTITY. One point the teacher did try to be clear about was that the parallelogram's height was not its "diagonal" side. Perhaps this effort was a result of his experience with students thinking that height, because it is a characteristic of a polygon or because it seems interchangeable with base, is necessarily a MERONYM of that polygon. Indeed, all of these subtleties and implicit shifts in meaning involving height may be related to documented difficulties with the concept (e.g., Gutierrez & Jaime, 1999).

In summary, we have looked closely at the ideational metafunction of language from a lesson on area. We have seen that even the terrain of a topic such as parallelogram area, which appears smooth from a distance, can contain many potential potholes and pitfalls. If, however, researchers and teachers examine and come to better understand the structure and patterns of the semantic relations between mathematical terms, they can make mathematical language, and thus mathematics itself, more navigable for students.

## Endnote

1. This data was collected as part of an NSF grant (#0347906) focusing on mathematics classroom discourse (Second Author, PI). Any opinions, findings, and conclusions or recommendations expressed in this article are those of the authors and do not necessarily reflect the views of NSF. We would like to thank the teachers for allowing us to work in their classrooms.

# LIMITATIONS OF APPEARING AS KNOWLEDGEABLE: AN EXAMPLE OF CONNECTIONS ACROSS MATHEMATIZING, IDENTIFYING, AND LEARNING

Marcy B. Wood
University of Arizona
mbwood@email.arizona.edu

*Identity has become a useful tool for making sense of students' mathematical learning. However, investigations of identity frequently consider students' stories told outside of the classroom. This paper proposes a lens on identity that examines how identity is enacted from moment to moment in the classroom, providing more opportunities to see how mathematical activity, identity, and learning are connected. Use of this lens revealed how one fourth-grade student's identification as someone who already knew limited her mathematical activity and had consequences for her mathematical learning.*

## Introduction

Many mathematics education researchers have turned to the notion of identity to make sense of connections across who students think they are, their mathematical activity, and their mathematical learning (e.g., Boaler & Greeno, 2000, Cobb, Gresalfi, & Hodge, 2009; Sfard & Prusak, 2005). This research has been productive in explaining variations in students' participation in mathematical tasks, in connecting affective factors to mathematical activity, and in establishing links between identity and mathematical activity. However, much of this research examines identity at a level that is removed from actual moments of mathematical learning. For example, researchers have asked students to reflect back upon their experiences in mathematics classes (e.g., Boaler & Greeno, 2000; Martin, 2000). While this delayed narrativization has yielded interesting connections between identity and mathematical activity, it does not examine identity in the moments of mathematical learning, which is when identity might operate on mathematical activity. Zooming in on mathematical activity as it unfolds from moment to moment during a lesson should provide significant opportunities to learn more about the relationship between identity, mathematical activity, and learning.

This paper proposes a lens for capturing identity in these moments of mathematical activity and then uses this lens to closely examine the identifying activity of one fourth-grade student as she worked with two peers to solve a mathematical task. In addition to illustrating how identity might be visible in activity, this case also explores how one student's persistent identification of herself as someone who already knew, in spite of her limited mathematical understanding, had consequences for her mathematical activity and her mathematical learning.

## A Framework for Zooming In: Connecting Mathematizing, Identifying, and Learning

### *Mathematical Activity*

Rendering identity visible at the scale of student activity requires a framework for studying student activity, both activity related to mathematics and activity related to identity, as it occurs during a lesson. Anna Sfard's (2008) commognitive framework provides tools for conducting this analysis. In Sfard's framework, the salient feature of mathematical activity is communication – communication among students and others and communication a student has with him/herself. Sfard focuses on communication because she defines thinking as communication with oneself. She notes that this communication does not need to be inner and it does not need to be verbal.

Defining thinking as communicating makes discourse the object of study, where discourse includes gestures and other nonverbal or nonlinguistic means of communicating along with what might be spoken or written. In the commognitive framework, participation in discourse pertaining to mathematical objects, whether mathematically appropriate or not, is called *mathematizing*.

The commognitive framework also provides a means for making claims about learning. Defining thinking as communicating suggests that learning, as an outcome, can be defined as a change in discourse. As students learn, they are working (even if tacitly) to change their communication with themselves and with others. The effectiveness of the process of learning can be evaluated by comparing the resulting change in discourse with the mathematically desirable discourse.

*Defining Identity*

A definition of identity must link to this framework for mathematizing and it must make identity visible as students engage in mathematizing. The definition proposed by Sfard & Prusak (2005) meets both of these conditions. They define identity as a collection of reifying, significant, and endorsable narratives about a person. They elaborate on this definition:

> The reifying quality comes with the use of verbs such as *be, have* or *can* rather than *do*, and with the adverbs *always*, *never*, *usually*, and so forth, that stress repetitiveness of actions. A story about a person counts as *endorsable* if the identity-builder, when asked, would say that it faithfully reflects the state of affairs in the world. A narrative is regarded as *significant* if any change in it is likely to affect the storyteller's feelings about the identified person. (p. 16-17, italics in original)

For example, statements like "I am a woman" or "I am a math person" are identities for me: I believe them to be true (or endorsable) and important (or significant) to how I feel about myself. In addition, these two statements are *reifications*: They no longer reflect actions I might have performed, such as wearing particular clothes or enjoying a mathematics class. Instead those actions are summarized and frozen into a label. Finally, these statements are also *narratives*.

My use of narrative draws upon the work of Ochs and Capps (2001). They studied narratives arising in everyday conversations, investigating how impromptu, co-constructed narratives help people understand themselves and others with whom they interact. They defined narrative as an account of life events. While some narratives can be quite extensive, Ochs and Capps specifically noted that narratives need not be lengthy: Even short sentences can also be narratives. Dino Felluga (2003) concurred, arguing that statements like "The road is clear" are narratives because they suggest some sequence of events. Similarly, statements like "I am a math person" are narratives because they conjure images of what a person has done or might do.

The connection between minimal narratives and potential actions captures an essential function of identities: They explain and predict an individual's activity. Their ability to do this is tied to the ways in which identities reify or freeze activity. According to Etienne Wenger (1998), reification is "the process of giving form to our experience by producing objects that congeal this experience into 'thingness'" (p. 58). As people tell stories, they tend to summarize the story's action into statements that describe or label people. These statements convert activity into human conditions. For example, a story about a high score on a math exam might become a reification through the statement, "Daren is smart." The story is no longer about one moment in Daren's life. Instead, the score on the test has been translated into an identity for Daren.

Thus far, I have discussed identifications as narratives that are directly uttered. However, individuals can also be identified through their actions and interactions. For example, the teacher could identify Daren as smart by asking him to share his work with the class. This request might specifically include a statement that Daren is smart or his smartness might be implied in the request and the teacher's subsequent reaction to his work as he displays it. This framing of identifying activity draws upon positioning theory. Positioning theory assumes that people use stories and position themselves and any others involved in the activity in the story (van Langenhove & Harré, 1999). Instead of relying only on reified narratives, identification through positioning is based upon the cluster of utterances and actions that are appropriate for that person in context of the story. For example, as the teacher invites Daren to share his work, she positions him through her words and accompanying gestures as smart.

Positioning theory also provides a means for individuals to negotiate their identities. Daren might agree with the identification of him as smart and as someone others can learn from, or he might think that someone else in the class has a better solution and that if he takes the risk of presenting, he will look stupid and not smart. He could dispute this identification of him as smart by refusing to present his work and/or pointing to someone else who he thinks has a better answer. Daren is not bound by this identification of him: His reactions can affirm or refute any identification of him.

Sfard's (2007) recent work on identity elaborates ways of identifying that are consistent with the indirect story-telling assumptions of positioning theory. Sfard has described three ways in which people identify: direct, indirect-verbal, and enacted. *Direct* identifying occurs as a person tells a reifying story about the identified person. I primarily referred to this way of identifying as I elaborated the definition of identity in the sections above. *Indirect-verbal* identifying is when a story is told about a person that does not include reifying statements. Finally, a person may identify him/herself or another through other activities that do not include story telling. Sfard calls this type of identifying *enacted*. As students interact in classrooms, they rarely directly identify each other. Instead, most identifications are enacted or in-direct verbal. Positioning theory's use of story to provides a framework for elaborating these last two ways of identifying.

Positioning theory also supports the specific vocabulary I will use to talk about identities. The notion of positioning emphasizes that identities are constructed by individuals in response to situations and are thus situated and dynamic. Rather than describe individuals as having identities, I draw upon Sfard's (2007) recent work and use the words *identifying, enacting identities, identification,* and *engaging in identifying activity* as a means of emphasizing the ways in which identities are constructed from moment to moment.

*Theoretical Links between Mathematizing and Identifying*

This framework of identifying has many parallels with the description of mathematizing. Because identifying arises from communication of stories, it, like mathematizing, arises in discourse. Both are also central to a definition of learning as a change in discourse: As a student engages in learning, the student both communicates about mathematics and identifies him/herself as a kind of learner of mathematics. His/her communication about mathematics simultaneously tells an identity story and provides the opportunity of changing the learner's mathematical discourse. These connections between identifying and mathematizing suggest that learning arises from the interplay of these two activities (Sfard, 2007). It is the goal of this paper to elaborate the interplay among identifying, mathematizing, and learning. Specifically, this paper explores the effects of the activities of identifying and mathematizing on one another and on the development of mathematics discourse.

## Background and Methods

The student discourse analyzed in this paper comes from one group of fourth grade students interacting during one mathematics lesson. This case was part of a larger study involving over 70 hours of videotape and accompanying student work arising from 28 mathematics lessons in one fourth-grade classroom. The videotapes were analyzed for evidence of student learning: For each lesson, student’s initial discourse was compared to their final discourse using four discursive features elaborated by Sfard (2008): word use, visual mediators, discursive routines, and endorsed narratives. When there were mathematically desirable changes between the student’s initial and final discourse along these four features, the video was further analyzed for mathematizing and identifying activity. The entire lesson was transcribed, capturing not only what was said but also any writing, gestures, and other nonverbal communication. Portions of the student discourse that involved mathematical topics were parsed into message units (Bloome, Carter, Christian, Otto, & Shuart-Faris, 2005).

For each message unit, the identifying analysis considered the range of possible meanings for the speaker and the listeners, seeking to answer questions about what story the speaker and listener(s) might construct from the unit and how each person might be identified or might identify him/herself within that story. Units that identified the focal student as a learner in a consistent way were grouped and labeled as a kind of learning.

The mathematizing activity of each message unit was also analyzed. This analysis focused on the ways in which the discourse of each member of the group resembled desirable mathematical discourse. This analysis used Sfard’s (2008) four discursive features as described earlier. As patterns of mathematizing emerged, message units were grouped and compared to the analysis of identifying activity. Message units that demonstrated patterns across mathematizing and identifying activity were grouped and labeled as a kind of learning. Finally, moments in which the student enacted these different kinds of learning were examined to determine their connection to mathematically desirable changes in the student’s discourse.

I have limited the findings in this paper to one group of students interacting during one lesson. This lesson and this group were selected because the interactions among the students and the mathematical learning of one student demonstrated important aspects of the interplay among mathematizing, identifying, and learning. While some features of the interactions in this group were typical of interactions observed in the classroom, many of the specific details of the activities in this group were unique to this group and this lesson. Thus, the moments of learning examined in this paper reflect the possibilities for activity and learning among students without making any claims about predicting activity or learning in other groups or for other students.

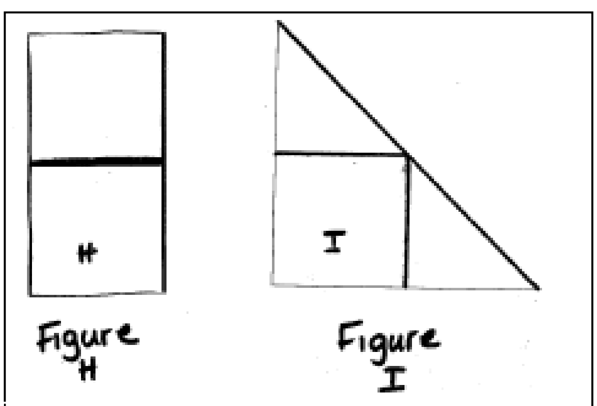

*Figure 1.* Scanned image of Figures H and I.

The group examined in this paper consisted of three students: Minerva, Bonita, and Jessica. The analysis in this paper focuses on Minerva’s learning and how the mathematizing and identifying in the group were connected to that learning. The lesson focused on how to determine the area of triangular figures. The students were given pairs of figures, one triangle and one rectangle (See Figure 1). The students were to determine which figure “covered more area.”

Each figure was partitioned by a square grid placed so that rectangle was partitioned into squares while the triangle (which had the same area as the rectangle) contained spaces that were squares and triangles.

## Findings

Throughout this lesson, Minerva was careful to identify as knowledgeable and in possession of right answers, although this identification stands in contrast to an analysis of her mathematical discourse, which suggests that her mathematical understanding was limited. What was remarkable about Minerva was not her efforts to be seen as knowledgeable and having the right answer – many students work to do this – but instead her skill at using this identification to mask her learning. This *covert learning* – presenting as knowledgeable and hiding learning – had consequences for the effectiveness of Minerva's learning. Her efforts to appear as knowledgeable meant that she worked on when and what to say, but not on exploring the mathematical discourse or probing the validity or consequences of the mathematical statements she uttered. As a consequence, Minerva's verbal discourse frequently seemed mathematically appropriate, but she was unable to construct and explain an appropriate solution to the task. This case of Minerva demonstrates how a focus on right answers and on identifying as knowledgeable can undermine opportunities to fully engage and thus learn mathematical discourse. The findings below provide one extended example of Minerva's covert learning followed by a summary of her other mathematizing, identifying, and learning activities.

Minerva's desire to appear as knowledgeable was most apparent when she resisted her peers' identification of her as someone who needed to learn. This moment occurred early in her group's work to compare the areas of Figures H and I (See Figure 1). The teacher asked the group how they would compare the areas. (Each excerpt from the transcript indicates the line number from the transcript, the speaker, any verbal discourse, and finally, in italics, any nonverbal communication or activity.)

200 Bonita Both the areas, they both have two.
201 Teacher How do you know?
202 Bonita Because two triangles make a square. *Bonita points at the 2 triangles in Figure I.*
203 Minerva No it doesn't
204 Bonita Uhhunh. *This is an affirmative utterance.*
205 Jessica Yes it does!
206 Minerva Nah hunh *This is a negative utterance, said in a sing-song way.*

Minerva's "No, it doesn't" (Line 203) was a direct contradiction of Bonita's statement that "two triangles make a square" (Line 202). Minerva may have disagreed that two triangles made a square or that the information was helpful in determining the area of the figures. In either case, it seemed that Minerva was not thinking about how triangles and squares would be useful in determining the area of the figures. Because successful completion of this task required students to make sense of the relationship between the triangles and the squares, Minerva's utterance in Line 203 demonstrated that she needed to learn in order to complete this task correctly.

As the interaction continued, Minerva's peers identified her as someone who needed to learn and as someone who could learn from them.

209 Jessica Let me see, let me show you
210 Bonita You cut this right off and put it there. *Bonita is holding Figure I. She points to one triangle in Figure I and motions next to the other triangle in the figure. Minerva watches her as she does this.*

211 Minerva Nah hunh
212 Jessica Let me see. See. Look it. Let me show her that it can make a triangle. *Jessica picks up two copies of Figure I. Jessica seems to misspeak here, uttering "triangle" instead of "square."*
213 Minerva Nah hunh. *Minerva watches Jessica.*
214 Jessica See. Look it. *Jessica places both figures together to make a large square.*
215 Minerva Nah hunh, nah hunh, nah hunh

In this excerpt, both Jessica and Bonita explicitly positioned Minerva as a learner and themselves as teachers. Bonita's demonstration of how to rearrange the figure (Line 210) and Jessica's insistence on showing Minerva how to make a square (Lines 209, 212, and 214) communicated their understanding that Minerva did not understand something they both understood.

Rather than respond with questions about the explanations, an acknowledgement of understanding, or a definite denial of the role of learner, Minerva reacted to Bonita and Jessica's positioning with a persistent, mocking "Nah hunh." Minerva countered each utterance of Bonita and Minerva with "Nah huhn," continuing for a full minute after the interaction above and uttering this phrase 32 times in total. Her "Nah huhn" had a sing-song quality and mocking tone that seemed to communicate that Bonita and Jessica's explanations were unnecessary and trivial. It seemed to be an attempt to portray her initial disagreement in Line 203 ("No it doesn't") as a jest or a joke and suggested mockery of the serious, explanatory tone used by Bonita and Jessica. Through her repeated utterance of "Nah huhn," Minerva seemed to communicate her rejection of the identity of learner.

In spite of Minerva's work to reject this identity, the timing of her utterances and her attention to Minerva and Bonita's activity provided her with an opportunity to learn from them. Minerva could have interrupted or ignored Bonita and Jessica. Instead, she carefully watched their demonstrations and timed her "Nah huhn" so they punctuated rather than disrupted Bonita and Jessica's explanations. Furthermore, in spite of Minerva's disagreement with Bonita's statement that "two triangles make a square," Minerva adopted this statement in her subsequent discourse. She incorporated these words into her first solution to the problem and she repeated these words on two separate occasions. In addition, all but one of Minerva's solutions to the task included the arrangement of the two triangles into a square. Minerva's use of Bonita's statement and arrangement of triangles suggests that Minerva learned from Bonita even while she resisted her identification as a learner.

This covert learning was not an isolated incident: There were four occasions in which close observation of Minerva revealed that she was unsure about the solution or how to proceed in the task or that she was not yet articulating the teacher-approved response to a question. In each of these instances, rather than admit that she didn't know, Minerva carefully and unobtrusively observed her peers and the interaction between her peers and the teacher. She then repeated the discourse of her peers that had the approval of the teacher. For example, Bonita stated and the teacher concurred that the areas of Figures H and I were the same. Eight turns later, Minerva articulated this same idea for the first time. Her use of this idea was in contrast to her previous solution which did not show the areas of the two figures as equivalent. Thus, Minerva seemed to be listening and learning from the interactions occurring at her group and using this learning to appear knowledgeable, but she was not overt about this learning.

While Minerva frequently repeated the discourse of others, her use of their discourse was limited. For example, she was able to use Bonita's statement that "two triangles make a square" to appropriately respond to the teacher's question about the area of Figure I and she cut out and connected the two triangles from Figure I into a square. However, one of her initial solutions to the task focused on demonstrating that the two triangles made a square and not on how that information contributed to a comparison of areas. Her final solution also placed the two triangles into a square, but, rather than compare areas, Minerva joined all of the pieces of both figures together and counted the total area, recording an answer of “4.” While four was the count of the area of both figures in terms of square units, this answer failed to compare the areas of the two figures. Minerva’s later work also demonstrated her understanding of area as an operation in which two figures were combined and total area was determined, rather than understanding area as a property of each figure that could be compared.

This limited understanding of mathematical discourse may have been tied to Minerva’s limited use of mathematical discourse. She was very skilled at identifying and repeating mathematical statements that were valued by the teacher, but she only used these narratives to reply to teacher questions. Her mathematical discourse was limited to brief responses, almost exclusively uttered only in the presence of the teacher. She did not talk mathematics with Bonita or Jessica. She did not explore the solutions of her peers, explain her own work (even when asked to do so by Jessica), or ask questions about the mathematics. Indeed, she asked only two questions throughout the lesson, both at the beginning of the lesson: one about the context of the problem and one about what to do. Her limited use of mathematical discourse provided her with few opportunities to explore the mathematical words, connect the words to representations, or examine the verity of the statements she used.

Perhaps if Minerva had been willing to identify as a learner, if she had been less insistent about appearing as knowledgeable and more curious, she might have done more exploration of the mathematical discourse. These changes in her mathematizing and identifying may have resulted in more effective learning.

## Conclusion

This case of Minerva’s covert learning demonstrates how mathematizing and identifying are intertwined and have consequences for learning. Minerva’s mathematizing communicated her identification as someone who knew answers: She could successfully respond to the teacher’s questions and she did not ask questions or request explanations. Minerva reinforced this identification through nonmathematizing moves when she resisted Jessica and Bonita’s identification of her as someone who needed to learn mathematics.

While these mathematizing and identifying moves were meant to demonstrate competence and knowledge, they limited Minerva’s mathematizing such that the changes in her mathematical discourse were primarily limited to adoption of the mathematical statements uttered by others. As a consequence, her mathematical learning was limited. She incorporated some mathematically desirable statements (i.e. “Two triangles make a square”), but her final discourse (which employed combining rather than comparing areas) was mathematically troublesome. Perhaps if Minerva had identified in a way that allowed her to ask more questions (of her peers or her teacher) or to explain her work to her peers, she would have engaged in more mathematizing and perhaps experienced more desirable learning.

Minerva’s identifying and mathematizing also had consequences for the learning of her peers. As she discouraged mathematical conversations between herself and her peers, she also limited the mathematizing and consequently the learning of her peers. Thus, Minerva’s activity has implications for mathematics pedagogy and curricula that emphasize group work and learning from conversations among peers. This case seems to imply that if students are to learn from each other, they must be willing to overtly identify to each other as learners.

This case of Minerva provides a perhaps extreme example of the consequences of focusing on right answers. It suggests that as teachers and schools seek to support students in learning mathematics, they may want to support students in valuing mathematizing and identifying activities that demonstrate questioning and exploring and a willingness to learn rather than quickly knowing. Eleanor Duckworth (2006) notes, “What you do about what you don’t know is, in the final analysis, what determines what you will know” (p. 67). How students mathematize and identify as they engage in mathematics will have consequences for the mathematics they learn.

## Introduction

This paper contributes to a body of literature that is concerned with supporting our understanding of how to facilitate whole-class mathematical discussions. In this paper, we share an analysis of four fifth grade mathematics teachers who are teaching with a worksheet that is designed to target students' understanding of fractions. Our analysis targets the relationship between particular teacher moves and the nature of mathematical ideas that get on the table in the classroom discussion. This paper makes a unique contribution because it looks across multiple classrooms in order to examine the nature of particular teacher moves that impact whole-class discussions.

Whole-class discussion is a key part of reform mathematics classroom practice, but one that is challenging and takes some time to master. As such, orchestrating whole-class discussions has been the topic of significant attention, although as a field we are still working to document practices that teachers can leverage which consistently support high-quality discussions. More specifically, while it is clear that the culture of the classroom significantly impacts the kinds of conversations that can take place amongst students (Cobb, 1999), teachers play a key role in the facilitation of whole-class mathematical discussions. Even within classrooms that create cultures of discussion, the difference between conversations that build to key mathematical understandings (as opposed to those that result in merely sharing ideas) appears to be related to the particular moves a teacher makes in the course of the conversation, and which create opportunities to engage with mathematics in particular ways.

Key challenges involve the tricky business of tracking the nature of the mathematical topic under discussion, the potentially fruitful and potentially unanticipated sidepaths, the sites to locate and address misconceptions, and the orchestration of students' own emotions and agency as contributors to these discussions. In her book *Teaching problems and the problems of teaching,* Maggie Lampert (2001) described the myriad conflicting goals that she often negotiated in the course of a single 10-minute discussion. Likewise, Deborah Ball (1993) has described the challenging task of unpacking the key mathematical ideas at play in the course of a discussion, and knowing how to most productively step in to either support the trajectory of the conversation, or redirect it.

This paper contributes to the growing body of literature that focuses on the relationship between particular teacher moves and mathematical meaning-making (Ball, 2001; Gravemeijer, 2004; Stein, Engle, Smith, & Hughes, 2009). In the work we present here, we focus specifically on the ways teachers' moves *position students* as mathematical meaning-makers, and *position content* as rules to be remembered versus ideas to be interrogated. Below, we unpack the idea of positioning and explain how it is used in this analysis. We then detail the methods and results of our study, and discuss implications for future work.

## Positioning in Practice

In this work, we leverage the notion of *positioning* as a lens for analysis. Positioning, as a mechanism, helps to bridge the space between the opportunities that are available for participation in particular ways and what individual participants actually do. In our work, we have examined two aspects of positioning: how students are positioned relative to content (disciplinary positioning), and how they are positioned relative to others (interpersonal positioning) (Greeno & Hull, 2002; Gresalfi, in press). For example, students are positioned relative to the discipline of mathematics through the ways in which content is organized to afford particular mathematical insights and understandings. This speaks not only to the design of different tasks, although design of course creates significant opportunities (Stein, Smith, Henningsen, & Silver, 2000), but also to the ways content itself is treated in conversation as a series of rules to be learned (*procedural engagement*) or a set of ideas to be interrogated (*conceptual understanding*) (Gresalfi, Barab, Siyahhan, & Christensen, in press), Likewise, practices around *doing* mathematics can create opportunities for students to become positioned relative to each other, such as being expected or obligated to convince or constructively challenge someone else (Carpenter & Lehrer, 1999; Lampert, 1990). In so doing, both what it means to do mathematics, and who is capable of engaging mathematics, is constructed.

Positioning takes place at two levels--as a moment-by-moment process through which particular students are given opportunities to participate in particular ways (Davies & Harre, 1999), and over time, as students become associated with specific ways of participating in classroom settings (e.g., (Holland, Skinner, Lachicotte, & Cain, 1998); (Wortham, 2004)). At the moment-by-moment level, positioning can be seen most easily in talk, as students and the teacher speak to each other about academic content, about themselves, and about their current work (van Langenhove & Harre, 1999)). When looking over slightly longer time periods, students can be positioned as being certain kinds of people through the emergent *participant framework* (Goffman, 1974; Goodwin, 1990; Herrenkohl & Guerra, 1998; O'Connor & Michaels, 1996)) of a classroom which shapes the ways that students are expected, obligated, and entitled to participate with content and with others in the classroom. For this paper, we consider two types of positioning:; the ways that students are positioned relative to others, or their *interpersonal positioning*; and, the ways they are positioned relative to content, or their *disciplinary positioning.*

*Interpersonal Positioning*

The idea of interpersonal positioning is closely aligned with van Langenhove and Harre's (1999) work on positioning, which concerns the fluid positions, roles, or characterizations that people make available for themselves and others through their talk. As Holloway (1984) states: "Discourses make available positions for subjects to take up. These positions are in relation to other people. Like the subject and object of a sentence…women and men are placed in relation to each other through the meanings which a particular discourse makes available" (p. 236, quoted in van Langenhove & Harre, p.16). Interpersonal positioning refers explicitly to the ways that students recognize themselves and others in relation to one another, for example, how are students expected or obligated to talk to each other? To challenge each other's ideas? Do some students become positioned as more or less competent than others?

One central way that students get positioned relative to one another involves their relative status—including aspects of status that are not necessarily relevant to academic work (Cohen & Lotan, 1995)). Interpersonal positioning also includes implicit and explicit comparisons between students, and between their ideas. Students' ideas might be positioned as equally valuable (even if they are not both accurate, c.f. (Lampert, 1990)), or one idea might be positioned as less important than another—for example, in a classroom that is more competitive. In some classrooms distinctions between who is “smart” and who isn’t may become a particularly dominant form of positioning, while in others, such distinctions are rarely made. In this paper, we attended to teacher moves that positioned students relative to each other in terms of their mathematical discussions; for example, teachers might position students as (productive) “critics” by asking them to “listen to this strategy and see what you agree with and what you disagree with.” Likewise, teachers might position students as “comparers” by setting them up to “see if your strategy is similar or different to the one you hear.”

*Disciplinary Positioning*

Students are also positioned relative to particular subject matter. Disciplinary positioning is related to both the affordances of the mathematical tasks, and the way those tasks are realized in the classroom. For example, in some classrooms, students are positioned primarily as *receivers* of knowledge (Boaler & Greeno, 2000). In such a classroom, students have opportunities to record and practice particular mathematical procedures, but possibly not to engage in acts of deeper meaning-making. In contrast, other classroom practices position students more actively and create opportunities for them to *construct* new information. In such spaces, students become both active consumers and producers of new knowledge and are positioned as having authority in justifying and determining the accuracy of their solutions (Gresalfi, Martin, Hand, & Greeno, submitted).

For example, Lampert (1990) describes an effort she undertook in her own classroom to position students to be both *courageous and modest* in their mathematical activity. By positioning students as courageous relative to the content—taking risks in sharing information that they weren’t necessarily confident about, and modest about their proposals (in other words, being ready and willing to accept suggestions and revisions to their ideas)—Lampert was positioning her students relative to the content of mathematics in ways that supported deep engagement with the subject matter. As a consequence, both the ways that students engaged with the content—sharing mistakes, listening to and offering suggestions about others’ work—and the actual content with which students were engaging—thinking about proof or rationales behind why particular decisions were meaningful—changed from the beginning to the end of the year. In this paper, we attend to teacher moves that positioned students relative to content by tracking utterances that positioned content as either “stable” or “shifting,” by noting the kinds of opportunities to engage content that were offered to students. For example, when teachers tell students information without asking for challenge or feedback, they are positioning content as unmalleable and students as receivers of information. In contrast, when teachers ask students to justify why a solution is sensible, they are positioning content as open to challenge, and students as active meaning-makers.

## Methods

The topic of this paper is four fifth-grade teachers and their students in a suburban school in southern Indiana. The data for this paper comes from one day of instruction in each of these four classrooms, during which time all students were working on the same worksheet about multiplying fractions. The worksheet was designed to promote discussion by posing open questions that could be answered in more than one way, and by asking students to explain to each other how they knew their answers were sensible. Specifically, the worksheet began with open-ended problems that targeted multiplication of fractions, and ended by asking students to explain if the fraction multiplication algorithm would work every time. These four teachers were participants in a larger project whose purpose was to support both small group and whole-class discussions about mathematical content. As a part of the project, all teachers had participated in four full-day professional development sessions whose purpose was to highlight key mathematical ideas with which students were grappling, and to devise strategies to support student discussion. The strategies that were developed in the professional development sessions primarily targeted key mathematical ideas that students might understand or have misconceptions about.

All four teachers used this worksheet in conjunction with the same lesson from their usual textbook, Everyday Mathematics. All teachers had their students begin by working collaboratively in groups of 3-5, and concluded with having students share and discuss their solutions collectively with the entire class. Beyond this common structure, teachers were free to discuss the worksheet however they pleased; as an example, some teachers had a member of each group share their solution while others selected particular students to share their work. Some teachers had common expectations for group work as a coherent part of their classroom practice, while others used collaborative group work less often in their everyday practice. Each teacher had between 25-30 students in their classroom. All classes were heterogonous, and the small groups were arranged heterogeneously.

Data was collected using three video cameras; two of which were focused on a small group, and the third of which followed the teacher. Data for this paper considers only whole-class discussion times, and draws from the teacher camera. All videoed segments of whole-class discussions were transcribed and entered into a qualitative database (NVivo8). Codes were developed using both *a priori* and emergent methods; drawing from previous work that targeted productive teacher moves, we began with a list of codes that we thought would be useful descriptors of teachers' moves. After watching the videoed segments of classrooms while using these *a priori* codes, additional codes were developed in order to capture emergent themes. A final coding scheme consisting of both forms of codes was then refined, and the codes were used on all four transcripts. The coding scheme documented both the kinds of teacher moves that were undertaken (for example, press, emphasizing expectations, telling), and the nature of the mathematical ideas those moves targeted (for example, making connections, procedural engagement, conceptual engagement) All coding was undertaken collaboratively between the first and second author, and disagreements between codes were discussed until agreement was reached.

## Findings

Our analyses revealed, unsurprisingly, that teacher moves that emphasized procedural aspects of mathematics were related to procedural mathematical ideas being introduced, while moves that emphasized conceptual aspects of engagement led to conceptual aspects of mathematics being shared. Specifically, 100% of teacher moves that emphasized procedural aspects of mathematics led to mathematical discussions that focused on procedures. An example of such an exchange (coded as "set expectations" "justify" and "procedure") is below. It begins with the teacher giving her students instruction on what a good drawing would look like in order to be convincing. The problem that the students were working on involved taking 2/3 of ½ of a pan of brownies. Some students divided the pan of brownies into halves, and then divided only one side of the pan into thirds, and arrived at the answer of 2/6. The teacher was concerned that students cut up the entire pan of brownies in order to "prove" that their answer is correct:

T: So, as you guys continue on, have you realized that once are working with this whole, if you divide it into more pieces equally, do you just do a part of it? Do you just divide a part of it? Will that work? It kind of worked, because you guys are smart enough that you can visualize and even though a lot of you did not divide both halves into sixths, you're smart. And you're like, "I know that's two-sixths, because you can see it in your head. But, as you get into more complex problems, you may not be able to see that so easily. So, it's very important that when you- that you keep that whole in equal-sized pieces; otherwise, our fractions aren't balanced."

This utterance was coded as procedural because although the teacher was focused on helping students to think that they needed to prove their answers, the source of the proof could be seen in students' accurate use of procedures; in this case, ensuring that they divided an entire figure equally, instead of visualizing the division of a figure into pieces. In this utterance there was little justification of why this was more convincing, except for the idea that it would help when problems became more complex. In this way, the utterance served to position students relative to content as mere executers of algorithms; they were not asked to critique solutions, but rather to ensure that they were able to perform solutions accurately. This positioning created opportunities for students to engage procedurally with content. As can be seen in the following exchange, procedural mathematical content was discussed following this utterance. In the exchange below, students were solving the next problem on the worksheet; one that involved taking 1/3 of ¼. A student had just come up to share her solution, and the teacher claimed that this solution was a wonderful proof:

T: Why does this prove it to me? Why does this prove it? Talk to me, guys. Talk to me. Why does this prove it? When I look at that entire pan of brownies, what do I see?

St: She divided it into fourths and then thirds?

T: OK, but what do I see? I'm the accountant. I don't know one thing about serving brownies. I just have to know how many- I have to know for sure how many brownies were sold, so I can keep my accurate records for your business. How do I know how many brownies that pan was cut into? Talk to me!

St: She divided it into twelve equal parts?

T: It's in twelve equal parts!

In this exchange, the teacher and the students were focused on the appearance of a problem, and a justification that focused on procedural aspects of understanding. Thus, the mathematical content that got established as a topic of conversation involved a procedure for proof: divide a figure into equal parts. These coupled exchanges detail the relationship between the ways that students are positioned to engage content, and their resulting opportunities to learn that content.

Likewise, students who were positioned to engage conceptually with content had opportunities to participate in discussions that focused on conceptual aspects of doing mathematics. Almost 65% of teacher moves that were classified as conceptual led to mathematical discussions that focused on conceptual understanding. An example of a teacher utterance that was coded as pushing on conceptual understanding can be seen below:

T: OK. Turn to that problem on the back page real quickly, 'cause that's sort of where the connection was. How can you multiply and end of with a smaller amount than you started with? How does that work? 'Cause normally if you multiply two times three, you're going to get six. How come we're multiplying, and we're getting something smaller?

In this utterance, the teacher focuses on the conceptual aspect of mathematics by asking students to consider why things work as they do. Thus, they are focused on justifying, rather than following rules. Specifically, students are positioned as investigators whose role is to make sense of mathematics. This positioning created opportunities for students to engage conceptually with content, as can be seen in the following exchange that led to conceptual mathematical content being discussed in the classroom. In the exchange below, students were working on answering the teacher's question of why multiplying by fractions makes things smaller:

St: Um, well, because fractions are less than one, so, um, like, um, multiplying is like, I mean, um, like, three times two. Three two times is six.
T: OK.
St: Um, so, one times point five, because point five is a decimal and decimals are (like) fractions-
T: Mmm-hmm.
St: That would be, um…one times a half and that's (a half)

In this exchange, a student was focused on trying to justify and explain how mathematics works. Although she did not produce a complete explanation, the topic of conversation shifted to justifying, rather than following rules. As could be seen in the procedural exchanges, these coupled exchanges detail the relationship between the ways that students are positioned to engage content, and their resulting opportunities to learn that content. Specifically, our analysis documents that teachers' moves which position students as meaning-makers lead to opportunities to engage in activities of meaning making, while moves which position students as following rules lead to opportunities to merely enact those rules.

Because our interest in this work is on better understanding how whole-class conversations lead students to have opportunities to engage mathematical meaning-making, our analysis has also detailed the specific moves that teacher make that are likely to support such meaning-making. Although space prevents us from detailing these practices in this paper, our presentation will detail the specific moves that were associated with conversational exchanges that focused on mathematical meaning-making.

## Conclusions

Understanding how students come to participate knowledgably with a domain and to see themselves as capable of doing so requires renewed attention not only to what students do, but to what they have opportunities to do. By attending closely to these opportunities, it is possible to see how students are positioned in moments of interaction relative to aspects of classroom practice. In this paper, we consider two types of positioning: how students are positioned relative to content (disciplinary positioning), and how they are positioned relative to others (interpersonal positioning). For example, students are positioned relative to the discipline of mathematics through the ways content is organized to afford particular mathematical insights and understandings. This speaks not only to the design of different tasks, but also to practices around doing mathematics. These aspects of mathematical practice can create opportunities for students to become positioned relative to each other, for example, as being expected or obligated convince or constructively challenge someone else. In so doing, both what it means to do mathematics, and who is capable of engaging mathematics, is constructed.

# TEACHERS REFLECTING DIFFERENTLY: DECONSTRUCTING THE DISCURSIVE TEACHER/STUDENT BINARY

David W. Stinson
Georgia State University
dstinson@gsu.edu

Ginny C. Powell
Georgia Perimeter College
gpowell@gpc.edu

*This session explores the ways that practicing teachers came to reflect differently regarding the discursive teacher/student binary during a graduate-level course entitled "Mathematics Education within the Postmodern." Using Dewey's concept of reflective thinking, as well as Foucault's discourse and Derrida's deconstruction, we show how the course provided new suggestions for the students as they continued their journey of becoming teachers. Through interweaving comments written by the students with concepts borrowed from postmodern philosophers and theorists, we illustrate how the teachers began to understand that teachers and students might indeed be described differently in the postmodern.*

## Introduction

Most, if not all, mathematics teachers, educators, and policymakers would agree that the documents produced by the National Council of Teachers of Mathematics (NCTM) over the past 30 years describe a different mathematics classroom than that which is experienced by most students in U.S. schools (see, e.g., NCTM, 2000). Although the impact of these documents in reforming mathematics teaching has been somewhat limited (see, e.g., Wilson & Goldenberg, 1998), research has shown that these documents have had an impact on how mathematics teachers define and practice "good" mathematics teaching (see, e.g., Wilson, Cooney, & Stinson, 2005).

Wilson, Cooney, and Stinson's (2005) research on the perspectives of seasoned mathematics teachers about good teaching suggests that efforts to reform mathematics teaching are seldom all or nothing affairs. Their research illustrated that even as seasoned teachers reformed (some of) their teaching practices that most often they continued to maintain a belief in the teacher-centered classroom and the infallibility of mathematics. It has been argued that the latter of these beliefs is counter to reform-oriented mathematics teaching, thus securing the continuation of traditional practices (see, e.g., Davis & Hersh, 1981; Ernest, 1998). To make it possible for teachers to create mathematics classrooms that are consistent with the constructivist, student-center objectives of reform-oriented mathematics teaching, we believe that teachers must be provided an opportunity to challenge and "trouble" both traditional mathematics teaching and the reform efforts themselves. In understanding the mathematics classroom as a pedagogical space for teachers and students to "reason together" (David and Hersh, 1981, p. 282) through the socially constructed discipline of mathematics (Ernest, 1998), we argue that postmodern (or poststructural) theory provides a *different* theoretical framework for teachers to trouble both traditional and reform-oriented mathematics teaching as they explore their own pedagogical philosophies and practices.

The value of postmodern theory is found in its awareness of and tolerance toward social differences, ambiguity, and conflict; it requires developing new languages, conventions, and skills to address the moral and political implications of knowledge (Seidman, 1994). In short, postmodern theory requires shifting the "focus from foundations and familiar struggles of establishing authority toward exploring tentativeness and developing scepticism of those

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

principals and methods that put a positive gloss on fundamentals and certainties" (Walshaw, 2004b, pp. 3–4).

**Foucault's Discourse, Derrida's Deconstruction, and Dewey's Reflection**

As Foucault (1969/1972) reinscribed the concept *discourse*, he argued that discourses are not a mere intersection of words and things but are "practices that systematically form the objects of which they speak" (p. 49). That is to say, for Foucault, "discourses do not merely *reflect* or represent social entities and relationships; they actively construct or *constitute* them" (Walshaw, 2007, p. 19, emphasis in the original). Foucault (1976/1990), however, also conceived discourses "as a series of discontinuous segments whose tactical function is neither uniform nor stable" (p. 100), which provides for the occasion of developing different discourses—and, in turn, different knowledges. Thus, we are not forever doomed by discourses. In general, Foucault's (1969/1972) analysis of discourse replaces the concept of the "nature" of knowledge with the "discursive formation" (p. 38) of knowledge. His analysis rejects the "natural" or taken-for-granted concepts of knowledge found in humanism, such as Descartes' dualism of mind-body (which argues that the thinking subject is the authentic author of knowledge) or Comte's positivism (which argues for a "scientific" knowledge gained from methodologically observing the sensible universe) (St. Pierre, 2000). Foucault uncovered knowledge as a discursive formation through the means of performing an archeological analysis, which examines the history of a discourse. But rather than being concerned with uncovering the "truth" by an examination of facts and dates, it is concerned with the "historical conditions, assumptions, and power relations that allow certain statements, and by extension, certain discourses to appear" (St. Pierre, 2000, p. 496). In short, this methodology allows for the understanding of "how knowledge, truth, and subjects are produced in language and cultural practice as well as how they might be reconfigured" (St. Pierre, 2000, p. 486).

In other words, there is no origin, or understood in another way, no center to discourse. Derrida (1966/1978) argued that accepting discourse as having no center allows discourse to be open for the "movement of play" (p. 289). He defined play as the "disruption of presence" (p. 292). In this context, play rejects the totalization of humanism with its "dreams of deciphering a truth or an origin which escapes play" (p. 292). This movement of play provides more freedom. This reconstitution of freedom as play is implicated in Derrida's *deconstruction* of discursive binary oppositions (see, e.g., Derrida, 1974/1997). Although Derrida refused to limit the possibilities of deconstruction through definition (1983/1991, see also Derrida & Montefiore, 2001), others have described it as the methodology of exposing discursive binary oppositions defined interdependently by mutual exclusion, such as good/evil or true/false (Dillon, 1999). For Derrida, these binary oppositions shape the very structure of thought by constructing an "essential" center and authorizing presence—a center and presence that, it is assumed, will collapse if the binary opposition is undermined (Usher & Edwards, 1994). Within the context of mathematics education, some of these binary oppositions are: mathematical *T*ruths/mathematical *t*ruths, teacher/student, effective teacher/non-effective teacher, reform teaching/traditional teaching, mathematically able student/non-mathematically able student, high-level course/low-level course, and so forth.

The deconstruction of binary oppositions identifies the first term, the "privileged" term, as being dependent on its identity by the exclusion of the other term, demonstrating that primacy really belongs to the second term, the subordinate term, instead (Sarup, 1993). Deconstruction, therefore, involves unsettling and displacing (or troubling) binary hierarchies, uncovering their historically contingent origin and politically charged roles, not to provide a “better” foundation for knowledge and society but to dislodge their dominance, creating a social space that is tolerant of difference, ambiguity, and playful innovations that favors autonomy and democracy (Seidman, 1994). In short, deconstruction acknowledges that the world has been constructed through language and cultural practices; consequently, it can be deconstructed and reconstructed again and again (St. Pierre, 2000).

In the past 2 decades or so, the discourse of *reflection* has been identified as a crucial characteristic of exemplar teachers by numerous national, state, and local organizations, foundations, and boards (Rodgers, 2002). For example, the NCTM (2000) stated, “opportunities [for teachers] to reflect on and refine instructional practice—during class and outside of class, alone and with others—are crucial in the vision of school mathematics outlined in *Principles and Standards*” (p. 19). Mewborn (1999), in her study on reflective thinking among preservice elementary mathematics teachers, traced the emphasis of teacher reflection to Dewey, suggesting that he believed the primary purpose of teacher education should be to help teachers reflect on problems of practice. Although Mewborn rightly noted that there is little agreement as to the content and nature of Dewey’s reflective thinking in general, she did find some commonalities present within the literature, including that reflective thinking is qualitatively different from recollection or rationalization, and is both an individual and shared experience. Rodgers (2002) argued that reflection is not an end in itself but a tool used in the transformation of raw experience into meaning-filled theory—grounded in experience and informed by existing theory—to serve the larger purpose of the moral growth of the individual and society.

## The Course

Teacher reflection was a primary objective as I (the first author) planned the course “Mathematics Education within the Postmodern,” a graduate-level, mathematics education course. The course, a reading intensive seminar, began by engaging students in a brief overview of postmodern theory, reading book chapters by foundational French scholars such as Gilles Deleuze and Félix Guattari (1980/1987), Jacques Derrida (1966/1978), Michel Foucault (1976/1990), and Jean-François Lyotard (1979/1984). In addition, the students read book chapters and essays by education theorists who position their scholarship within postmodern theory, such as Patti Lather (2000), Robin Usher and Richard Edwards (1994), and Elizabeth St. Pierre (2000, 2004). This overview provided the foundation for students to begin an initial critical analysis of essays contained in Margaret Walshaw’s (2004a) edited book *Mathematics Education within the Postmodern,* essays that deconstruct and trouble the discourses of knowledge, learning, teaching, power, equity, and research, among others, within the context of mathematics education (for a review of this book see Powell, 2007).

The specific learning objectives of the course were for students to develop an introductory understanding of the philosophical underpinnings of postmodern theory and to explore and (re)position the philosophical and structural foundations of mathematics, mathematics teaching and learning, and research in mathematics education within a postmodern framework. The intended purpose was not to “change” their teaching practices per se, but rather to provide the opportunity for mathematics education professionals to reflect differently on mathematics, mathematic teaching and learning, and, in turn, their pedagogical practices in light of postmodern theory. In short, the purpose of the course was for students to take the familiar discursive binaries of mathematics education (noted earlier) and to undergo a deconstructive process, individually and collectively.

Twelve students (8 women and 4 men) took the course; all but one were part-time graduate students and full-time mathematics teachers, ranging from elementary to college, with 5 to 15 years of teaching experience. A daily written assignment for the course was to maintain a reading journal (i.e., annotated bibliography) that included written summaries of each assigned reading, student-selected significant quotations from each reading, and comments regarding the student's struggles with each reading and how it might (or might not) assist in her or his teaching (and research). The final for the course was a reflective, academic essay (eight text pages in length) in which each student was to discuss her or his understanding of mathematics education framed in the postmodern and her or his struggles with and remaining (or new) questions of such a framing.

### Teachers Reflecting *Differently*

No matter what the students' initial comfort level with the ideas of postmodern theory, in the following discussion we argue that their final reflective essays demonstrate that in most cases each student's thinking attempted to take a new "line of flight," in which they endeavored to "make a map and not a tracing" (Deleuze & Guattari, 1980/1987, pp. 11–12) of the meanings and *t*ruths of mathematics teaching and learning. Through using the first phase of Dewey's (1933/1989) five phases of reflecting thinking—suggestion—the discussion attempts to capture (some of) these new lines of flight, illustrating how these practicing teachers began to reflectively think differently. The discussion is not about tracking or documenting mathematics "teacher change." We understand mathematics teacher change to be a complex endeavor that most often occurs when teacher professional development opportunities are long-term, school-based efforts conducted within a community of learners that provide teachers opportunities to grapple with significant mathematics and to consider how students might engage with that mathematics (Mewborn, 2003). Like the NCTM *Principles and Standards* (2000), however, we believe that teaching is a continual journey. "Effective teachers" do not master teaching, but rather find themselves in a continuous state of growth and change (Mewborn, 2003).

Within Dewey's (1933/1989) reflective thinking phase of "suggestions, in which the mind leaps forward to a possible solution" (p. 200), we believe that postmodern theory offered these seasoned teachers the possibility of different suggestions as the familiar discursive binaries of mathematics education underwent deconstruction, and, in turn, motivated different suggestions. Given the space limitation of this paper, we focus the discussion on the discursive practices that classify and describe teachers and students through interweaving comments written by the students with concepts borrowed from postmodern philosophers and theorists, illustrating how the teachers began to understand that teachers and students might indeed be described differently in the postmodern (Hardy, 2004).

In a postmodern frame, a new suggestion emerges that attempts to pry loose the binary (Spivak, 1974/1997) teacher/student, deconstructing the binary both in identity and relations of power. Within postmodern theory, teachers and students are (re)defined as *subjects* rather than as individuals. The term *individual* is a humanist term that implies that there is an "independent and rational being who is predisposed to be motivated toward social agency and emancipation—what Descartes believed to be the existence of a unified self" (Leistyna, Woodrum, & Sherblom, 1996, p. 341). A postmodern perspective, on the other hand, defines the person as a multiplicitous, fragmented subject who is subjugated, but not determined, by the social structures and discourses that constitute the person.

This conception provides for a different suggestion of power and, in turn, agency. *Power* in a postmodern frame is reconstituted, not as an object that can be shared, deployed, or taken away, but as a dynamic and productive event that exists in *relations of power* (Foucault (1976/1990). Deanne (a pseudonym, as are all student names throughout) used this Foucauldian reconstitution of power when she argued that teachers can challenge discourses by the decisions they make in their classes, for their students, everyday. Deanne also wrote, “Teachers in a postmodern classroom (occupied by subjects who transfer power between the teacher and each other in order to gain knowledge) attempt to create a space where students [and teachers] can learn through communication with others in the class.” Similarly, Lauren wrote, “I must consciously acknowledge my students, not as objects, but as [subjects], using power, resisting power, and interacting with each other and with the mathematics.” While reconstituting power as “‘letting go’ of the control in their classroom” and allowing “for the possibility of being ‘found out’ as not being *the* authority,” Charles wrote: “Teachers need to embrace their lack of expertise. …By joining the learning process in the classroom, teachers can model the open-mindedness necessary for students so that they might begin questioning, discussing, and constructing their own mathematical knowledge.” This joining in the learning process allows for a different interaction between teacher and students—and mathematics—that supports the mathematics classroom in becoming a pedagogical space that is open for *“negotiation of intentionality*” (Valero, 2004, p. 49, emphasis in original).

Valero (2004) suggested that when students (and teachers) are defined as agents who negotiate the intentions of the mathematics classroom—using power, resisting power, interacting with each other and the mathematics—that real empowerment might take place. Here, empowerment is understood as *self*-empowerment: “a process one undertakes for oneself; it is not something done ‘to’ or ‘for’ someone” (Lather, 1991, p. 4). Within the context of a postmodern mathematics classroom, Valero claimed that empowerment is not passed from teacher to student through the transference of “powerful knowledge,” but rather might be defined in terms of the potentialities for students (and teachers) to participate in (i.e., to negotiate) the discursive practices of school mathematics. Sarah noted, “I hope to help my students empower themselves to overcome the discourses…to overcome the limitations society and our culture has put on them.”

Coupled with this different understanding of student and teacher empowerment was a different suggestion of understanding students and teachers as fragmented subjects. Lauren wrote: “I have been many in my life—there is no one *woman* who defines me. I am mother, wife, teacher, daughter, boss, and student—each time made anew by social context and relationships with others.” As these seasoned teachers began to understand themselves as fragmented subjects constructed through discourses and relations of power, they, in turn, began to view their students as fragmented subjects. For example, Nancy stated: “Educators should begin to look at their students as multiplicitous subjects rather than as individuals; it is important to remember students are not identical in math or English class, in sports or hobbies, at home or school.” She continued, “I need to accept my students as multiplicitous—each one coming to me with different levels of prior mathematical knowledge and different ways of learning.” Likewise, Susan wrote: “If nothing else, I have come out of this class knowing that students think differently, react differently, and position themselves differently; I need to recognize and respect these multiplicities.”

The multiplicitous is a key reconstitution of self, others, and knowledge found within Deleuze and Guattari’s (1980/1987) characterization of the rhizome. The rhizome, as described by Deleuze and Guattari, is not “reducible neither to the One nor the multiple. …has neither a beginning nor end, but always a middle (*milieu*) from which it grows and overspills” (p. 21). Fleener (2004), building upon the rhizome, argued for the importance of seeing teachers and students (and the mathematics curriculum) as multiplicitous, and that teachers should shift their “focus to the in-between, the relational, and the dynamic” (p. 213). Through “engaging the in-between, students build their own understanding, not as foundations, but as complex webs of the nexus of relationship in the abstract world of mathematics” (p. 214). Sarah began engaging in the in-between, writing: “Typically, in mathematics we think there is one right answer to a problem and focus on developing our students’ knowledge of how to get to that answer, [but] it is…the ‘in-between’ that matters the most.”

A new suggestion of the in-between brought about a different suggestion regarding the possibilities of classroom communication. Within the postmodern, Cabral (2004) claimed, language ceases to be regarded as a means of “communication,” but as the very process of constitution of the subject; that is, the discipline of mathematics, students, and teachers are constituted within a language community. Therefore, Cabral argued, “we need to stop talking and start listening to the student...it is through speaking that one learns and through listening that one teaches” (p. 147). Lauren wrote: “I will listen more, talk less. …Let the students guide the lesson, hear what they have to say, to me and to each other, about the mathematics, about their understandings, questions, and confusions.” Nancy noted, “Actively listening to students’ questions and concerns may lead to further areas of exploration outside of the daily…lesson.” Dorothy, a doctoral student, spoke about the importance of teachers listening to their students, and of students listening to each other: “There have been many times in my classroom when I could not understand the point a student was trying to make. It took another student, in different words, to relay the message so that I could understand.”

## Conclusion

The preceding discussion attempted to capture the different suggestions that engaging in the postmodern provided these seasoned teachers as they began to think differently about the discursive binary teacher/student. These suggestions motivated different classifications and descriptions for teachers’ and students’ identity, agency, and empowerment, and, in turn, a different suggestion of teacher and student participation in the mathematics classroom. There were several other instances in the teachers’ final essays in which other familiar discursive binaries were deconstructed or troubled. Some troubled the binary of mathematical-able student/non-mathematical-able student, while others troubled the effective teacher/non-effective teacher binary. And, in rare occasions, even the discursive binary mathematical *T*ruths/mathematical *t*ruths was troubled. For instance, Marcus, a doctoral student, wrote, “Are we confining ourselves and our students by the rules and laws of mathematics that do not allow for them to do the unexpected, to go beyond their own reality?” Likewise, Nicholas noted, “I was blown away by the thought that mathematics, something that I had found comfort in because of its absolute nature, was being viewed as a science of uncertainty that could not be defined by its absolutes any longer.” In general, the teachers limited their comments regarding the *t*ruths of mathematics, or, similar to Nicholas, somehow resisted reconstituting the “absolute nature” of mathematics. It appears that although mathematics has been argued to be the roots of postmodern thought (see, e.g., Tasić, 2001), to deconstruct the capital-T truths of mathematics might prove to be the most difficult deconstruction to undertake; it may be, nonetheless, the most important.

# LEARNER-FOCUSED DISCOURSE IN LEARNING MATHEMATICS: A TEACHER'S PERSPECTIVE

Olive Chapman
University of Calgary
chapman@ucalgary.ca

*This paper discusses learner-focused, whole-class discourse from an elementary teacher's perspective based on her thinking and practice in teaching mathematics. A learner-focused perspective based on agency, collaboration, and reflection frames this study of classroom discourse. Analysis of data obtained through interviews and classroom observations produced six central ideas involving reflection on "self" and the sharing and guiding of thinking that formed a key basis of learner-focused discourse. These ideas are discussed with examples of how they occurred and were supported by the teacher's thinking and actions. This learner-focused discourse is shown to be important to empower "self" in the learning of mathematics and to allow students to talk mathematically from and about their experiences and to make sense of mathematical ideas, mathematics in their lives, and their ways of thinking or learning.*

## Introduction

This paper is based on a two-year study of discourse that facilitates mathematical thinking as practiced in the classroom in the teaching of elementary school mathematics. The focus here is on the aspect of the study that investigated the teacher's perspective of learner-focused discourse in whole-class settings as a basis of facilitating the learning of mathematics.

## Related Literature

Many studies in mathematics education have dealt with various aspects of discourse that occurs, or ought to occur, in mathematics classrooms (e.g., Hiebert & Wearne, 1993; Hufferd-Ackles, Fuson, & Sherin, 2004; Knuth & Peressini, 2001; Lampert & Blunk, 1998; Sherin, 2002; Steinbring, Sierpinska, & Bussi, 1998; Wertsch & Toma, 1995; Wood, 1999). Sfard (e.g., 2000a & b, 2001) and Cobb, with colleagues (e.g., Cobb & Bauersfeld, 1995; Cobb et al., 1997; Cobb, Wood & Yackel, 1993; Cobb, Yackel, & McClain; 2000), in particular, have written extensively about discourse in learning mathematics. Some studies offered units of analysis in studying discourse, For example, Sfard (2000b) identified three foci that exist in any analysis of mathematical discourse – the pronounced focus (i.e. the words used by the interlocutor); the attended focus (i.e., what the interlocutor is looking at, listening to, etc.); and the intended focus (i.e., the inter-locutor's intention in contributing to the discourse). Ryve (2006) identified four types of math-ematical communication, i.e., discourse focused on: intrinsic properties – typically produced by students who ask "why"; identification of similarities – reasoning that relies on identified surface similarities; established experiences – discourse that does not fit into other categories; and non-mathematical – often about practical issues related to completing an assigned task. (Knuth & Peressini, 2001) identified "dialogic" and "univocal" as a basis to unpack the nature of discourse.

Some studies focused on the relationship between discourse and learning. For example, Cobb et al. (1997) examined the relationship between classroom discourse and mathematical development. They concluded that collective participation in classroom discourse, although useful to the learning of children, does not by itself determine that mathematical learning or

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

development occurs. Other studies focused on the teachers' role, the tasks, and the learning community to support discourse. For example, Wood (1999) discussed argumentation as an interactive process of knowing how and when to participate in an exchange. She offered examples of strategies used by a teacher to establish the classroom norms necessary to lay the foundation for argumentation as a form of learning. In some studies, the teacher's role in relation to listening has been explored as an important aspect of discourse since the teacher must listen to students to sustain discourse. Wallach & Even (2005) identified five characteristics of how their participant heard or misheard her two students: over-hearing – when a teacher thinks she has head statements that were not made by the students; compatible-hearing – attributing meaning to what students are saying; under-hearing – not hearing or noticing cognitive progress made by students, e.g., believing that students have stumbled upon the correct answer, when in fact they have systematically arrived at a suitable solution; non-hearing – disregarding part of what students said; and biased-hearing – impacted by prior knowledge of students and views held by the teacher. Davis (1997) discussed three categories of listening – *evaluative*: listening for a particular, preconceived "right" answer or explanation, or listening to respond; *interpretive:* listening for sense-making, and for student understanding; and *hermeneutic*: listening to the speaker as a prelude to and as a component of a negotiation for meaning in a situation. He emphasized the importance of listening to discourse.

This increased interest in discourse in mathematics education in recent years can be linked to learning theories and reform recommendations such as those of the National Council of Teachers of Mathematics (NCTM, 1991) that emphasize the importance of a different form of classroom communication from that of traditional mathematics classrooms. NCTM (1991) describes this reform-oriented discourse as dealing with the ways of representing, thinking, talking, and agreeing and disagreeing as a way to learn about, and engage in, mathematics as a domain of human inquiry with characteristic ways of knowing. This discourse attends to reasoning and evidence for sense making and to the development of ideas and knowledge collaboratively. It allows students to create their own understandings. It provides opportunities for individual students to connect and integrate their mathematical learning. It makes thinking public and creates an opportunity for the negotiation of meaning and agreement (Cobb & Bauersfeld, 1995). It provides collective support for developing one's thinking, drawing it out through the interest, questions, and probing ideas of the teacher and others (Cobb, Wood, & Yackel, 1993). It enables students to articulate what they know as a way to clarify their own understandings (NCTM, 1991). It is important in helping students develop and sharpen their mathematical thinking (Watson & Mason, 1998). In general, this discourse involves a more dialogic-type of interaction.

Both the teacher and students have vital roles in this discourse process in order to initiate and sustain it (NCTM, 1991). But this form of discourse can be difficult for teachers to implement and manage. Kilpatrick, Swafford, and Findell (2001) explained: "Managing discourse is both one of the most complex tasks of teaching and the least thoroughly studied. Research needs to make visible teachers' considerations as they handle classroom discourse and the consequences of their moves for students' learning" (p. 346). Teachers who are able to implement meaningful, reform-oriented discourse offer a basis for such research in ways that could inform mathematics teaching and teacher education. This paper reports on a study based on such a teacher and provides insights of discourse that is learner focused from the perspective of the teacher.

## Theoretical Perspective

Theoretically, discourse can be considered from different perspectives (Steinbring, Sierpinska, & Bussi, 1998). Social constructivist or socio-cultural perspectives tend to be more common in conceptualizing it in studies in mathematics education. While these perspectives are applicable to this study, the focus, instead, is on highlighting the learner and the personal as central features of the discourse. Thus, a learner-focused perspective of discourse, as a basis to compare the teacher's perspective, is adopted based on Bruner's (1996) description of four "crucial ideas" of framing learning: agency, collaboration, reflection and culture.

Bruner (1996) explains: "The agentive view takes mind to be proactive, problem-oriented, … selective, constructional. …Decisions, strategies, heuristics – these are key notions of the agentive approach to mind" (p. 93). This means, "one can initiate and carry out activities on one's own" (p. 35). Thus, agency involves one being able to take control of one's own mental activity. In this context of agency, Bruner notes: "the child … [is] somebody able to reason, to make sense, both on her own and through discourse with others" (p. 57). This view of children as thinkers requires the teacher to give "effort to recognize the child's perspective in the process of learning" (p. 56). Agency, then, is about learner-focusedness and vice versa. This means that in learner-focused, classroom discourse, students are allowed to participate in ways that might include: initiation of a discussion; re-direction of discussions in a relatively teacher-unscripted direction; responses unanticipated by the teacher; responses with an element of creativity, students' intentions, and personalization; and expression of students' interests or agendas.

Bruner (1996) associates collaboration with "sharing the resources of the mix of human beings involved in teaching and learning" (p.93). He explains that agency and collaboration need to be treated together to account for the individual and the collective in learning. He notes:

> Mind is inside the head, but it is also with others. It is the give and take of talk that makes collaboration possible. For the agentive mind is not only active in nature, but it seeks out dialogue and discourse with other active minds. And it is through this dialogic, discursive process that we come to know. (p. 93)

Thus, agency and collaboration should be integrated in the design of a learner-focused classroom culture. For example, students should not only generate their own hypotheses, but also negotiate them with others—including their teachers. The authority for knowing mathematically must be shared between participants—either teacher and student or student and student—when constructing new meaning or developing students' understanding of mathematics.

Regarding reflection, Bruner (1996) describes it as: "not simply 'learning in the raw' but making what you learn make sense, understanding it … going "meta," turning around on what one has learned through bare exposure, even thinking about one's thinking." (p. 58). Thus, like agency, reflection is about learner-focusedness and vice versa. This means that learner-focused discourse, for example, should allow or prompt students to notice for themselves and to become aware of their own thought processes, that is, "to become more metacognitive—to be aware of how she goes about her learning and thinking as she is about the subject matter she is studying" (Bruner, 1996, p. 64). Finally, regarding classroom culture, Bruner (1996) suggests that it is crucial to support learning and is the way of life and thought that we construct, negotiate, and use for understanding and managing the classroom. For a learner-focused, classroom culture, this will include creating, for example, a supportive and non-judgmental attitude to allow students to feel comfortable to share their thinking and experiences.

## Research Process

A case study was conducted with an experienced elementary teacher and her Grade 3 class. The teacher's practice embodied social constructivist principles with discourse playing a prominent role. The teacher regularly engaged her students in whole-class and small-group discussions and inquiry-oriented mathematical activities. Whole-class discourse occurred consistently throughout the school year, sometimes for most of a lesson, for the first half of a lesson, or integrated with small-group activities. The whole-class discourse was usually centered on problem-solving tasks or introduction of a new mathematics concept from the curriculum. Data sources consisted of interviews with the teacher, weekly classroom observations throughout three consecutive school terms, and classroom artifacts. The open-ended interviews focused on the teacher's thinking about discourse and her discourse behaviors in the classroom. For example, she was prompted to talk about her understanding of, goals for, and role in the discourse; her goals for students in relation to discourse; her approaches to questioning, listening, and task selection; how/why she intervened during discourse; how she established the classroom context; and her understanding of mathematical thinking. The interviews and all whole-class discourses for the lessons observed were audio taped and transcribed. Field notes were made of learning tasks, board work, and non-verbal teacher-student interactions relevant to discourse. The artifacts obtained included relevant students' written work and teacher's notes.

Data analysis for the larger project focused on identifying characteristics of discourse and the relationship to facilitating students' learning and mathematical thinking. Initially, a process of open coding was carried out. Corbin and Strauss (1990) describe this as taking data and segmenting them into categories of information. Two research assistants conducted this open coding independently of the researcher, and independently of each other. Only after initial categories had been identified were the results discussed and compared and revisions made where needed based on disconfirming evidence. Coding included identifying: (a) types of questions/prompts that elicited mathematical thinking (guided by Watson and Mason, 1998) and reflection; (b) what the teacher attended to in students' responses; and (c) different teacher's actions and/or thinking that determined or influenced different features of discourse and the nature of students' participation and learning. Themes emerging from the initial coded information were used to further scrutinize the data and then to draw conclusions. Learner-focusedness emerged as an umbrella theme that characterized discourse in this classroom. The findings presented here focus on the nature of it based on the teacher's thinking and classroom behavior during whole-class discourse.

## The Teacher's Perspective of Learner-Focused Discourse

The teacher's perspective of learner-focused discourse during whole-class settings was evidenced in her classroom behaviors that promoted and supported students' reflection on "self" and her thinking that emphasized connections to the students' world in learning mathematics. The central ideas of this discourse (Table 1) are interrelated, but discussed separately here.

*Table 1*
Central Ideas of Learner-Focused Discourse

| |
|---|
| Learner-focused discourse involves students: |
| 1. Reflecting on (making connection to) personal "real-world" experience |
| 2. Reflecting on conceptions |
| 3. Reflecting on preconceptions |
| 4. Reflecting on thinking |

| |
|---|
| 5. Sharing thinking<br>6. Guiding thinking |

*Reflecting on/making connection to personal real-world experience* was a central aspect of discourse in this teacher's classroom. Students were required to reflect on their out-of-school, real-world experiences to decide on and identify what mathematics they embodied, as in these three cases. (1) Students reflected on their experiences to identify examples of mathematics. Their challenge was to decide on what was an example of mathematics in their real-world experiences. This was initiated by the teacher posing questions, usually at the beginning of lessons, such as: "Where is math in your world?" "Did anything happen in your life that involves math that you want to share?" "Who experienced a math situation since we met in class yesterday?" "What math is happening in your world since I've seen you last?" (2) In contrast to case (1) where a mathematics concept was not specified, for this case, students reflected on their experiences to identify a specific mathematics concept. This occurred during the introduction and discussion of a mathematics concept and involved students associating real-world applications or significance of the concept. For example, in introducing a discussion of the concept of one million, the teacher asked, "Where would you find the number one million used in your world?" During a discussion of a line graph, students drew on their experiences to respond to the teacher's question: "where have you seen it?" (3) Students reflected on their experiences to associate real-world meanings or interpretations as in the following situation: "We're going to look at numbers on the calendar and try to think of how many ways to make this number. …Is there anything that you can think of in your life that makes you think of 17?"

This focus on real-world experiences was also central in the teacher's thinking. The teacher emphasized the importance and connections of mathematics to students' world as a central goal for her students. She explained: "I want them to think it's important in their world, I want them to see it's around their world, and I want it to be positive." She elaborated that this involved:

> How they interpret it [math], how they use it,…where they were seeing it. …Viewing things that are math. … Thinking that math is not just numbers on a page or just work in school. … Seeing the real world connections and patterns. …I question them to bring it [math] back and make a connection to their lives, because a lot of times they don't do that. You have to link them with those questions. …I always tell them "see the math."

*Reflecting on conceptions* during discourse involved students thinking about what they knew about a mathematics concept based on their past experiences, in particular, what they learned in prior grades in school. The teacher prompted students to unpack a concept based on the conceptions they had constructed of it. For example, the teacher probed students' thinking about the shape making up the bar graph they were discussing. She asked, "How do you know it is a rectangle? Make me believe that it is a rectangle." Students were able to recognize the rectangle, but initially encountered a problem explaining why. To prompt their reflection, the teacher asked, "How did you know it wasn't a circle." This led them to talk about what the rectangle was not. The teacher then prompted, "Think about the art project we did," as a way for them to find the language to describe the rectangle, which they were able to do. This discourse allowed the students to reflect on what they knew, i.e., their conceptions, based on making comparisons and connections within and outside of their mathematical experiences.

*Reflecting on preconceptions* during discourse involved students thinking about their real or imagined preconceptions of a mathematics concept, that is, what they thought they knew about it before formally learning it, as in the following three cases: (1) Students reflected on a concept or process of which they likely held preconceptions. For example, at the beginning of a lesson on linear measurement, the teacher initiated the discourse with: “We are going to determine our height today. … How could we do that? … What tools do we need to use for math today to determine our height?” The students’ responses led to a discussion of both the tools and units of measurement based on their preconceptions. (2) Students reflected on a concept of which they unlikely held preconceptions, but to which they could relate. For example, during a lesson on representing a number numerically in different ways, the teacher asked: “But just talking about numbers, does anybody really know where numbers came from and why we have numbers?” (3) Students reflected on a mathematics concept they likely or actually had formed a preconception of, but had not explicitly thought of or articulated, as in the situation when the teacher asked: “What’s the biggest number you can tell me?”

*Reflecting on thinking* during discourse involved students thinking about their own thinking, that is, engaging on a metacognitive level, as in these four cases. (1) Students reflected on what they looked for, or thought of, in order to make sense of, or interpret, a mathematics concept. For example, the teacher asked, “We are going to take a look at how numbers are made up … what do you do when you read a large number?” (2) Students reflected on their problem-solving processes or strategies, as when asked, “What did you think of first when you read the riddle?” (3) Students reflected on their choices of tools to aid learning, as when asked, “Who used the place value mat? … Can you tell us why you chose to use that?” (4) Students reflected on the affective aspect of their problem-solving experience, as when asked, “How many people had a little bit of difficulty trying to solve it? … How many people found it a challenge?”

The preceding situations of reflecting on thinking and (pre)conceptions were also central in the teacher’s thinking. For example, she explained: “I always say, ‘Hands down, brains on.’ That’s my saying so that every brain can have a chance to at least think about what they know.”

*Sharing thinking* during discourse involved students expressing their ideas in their own ways. This was supported by the teacher’s questions, such as: How do you make sense of that? Can you say out loud what’s going on in your head? Do you have an “aha!”? What have you noticed? Can you explain that more? What do you know about this? Can you talk about it; describe it?

One unique aspect of the teacher’s goal for discourse that supported this focus on students’ sharing was her own learning. She explained: “I want to learn something. I want to be “aha’d!” and surprised. I want them to teach me something. … I’m not afraid to take a risk so I just put myself out there and see what I can learn too.” In addition to her learning, she explained: “Always, my kids know you have to explain the why, not just an answer. … I really want to know the process…how they got there. It tells me a lot more about the kids.” She helped “to bring them out, to get them to think they have something to contribute, … to make everyone feel important and have a voice.” She believed that the best way to listen was: “Get rid of an answer in your head as you focus on their answer.” She added, “They see me trying to figure out what’s in their heads as opposed to wanting them to figure out what’s in my head – the answer I want.”

*Guiding thinking* during discourse involved students taking the discussion in different directions based on their thinking and questions as in the following situations: (1) The teacher invited students’ guidance; for example, “We’re going to do patterns…what do you want to know about patterns?” (2) The teacher used students’ responses as a basis of follow-up questions for discussion. As she explained: “When I am planning a lesson, I think of some good questions as openers…to get them thinking about the concept and then from there the other conversational questions just come from what they are sharing or asking.” She would also “do an off-shoot on something one might say, take it somewhere else, and that will lead someone else to participate…in oral discussion.” (3) The teacher probed students’ ideas, for example, on occasions “When I know they have something that will help the others understand or something that I never thought of to bring into a lesson.” (4) The teacher provided a question box in response to students’ request. She explained, “They wanted their own claim to the lesson. …It was unexpected to hear clearly that they wanted more empowerment to ask the questions they wanted or to learn the things that they wanted.”

The teacher noted that “the math questions that the kids are asking” triggered conversation that developed in mathematically significant directions. Also, “Because they were given freedom to say, ‘tell me what you want to learn’… what triggers it is the interest from the kids.” She also supported students’ thinking when she repeated or paraphrased their responses. Her intent was often to check her understanding of what they said or meant; to get clarification of what they intended; to allow them to correct her interpretation; and “to spring off into another math topic.”

## Conclusion

This teacher’s perspective of learner-focused discourse embodies notions of agency, reflection and collaboration as discussed earlier in the “theoretical perspective” section. It provides one way of understanding this view of discourse that could enhance the teaching and learning of mathematics. At the center of this view are the students’ thinking and real-world experiences as a basis of their learning of mathematics. Students get to personalize mathematics, to see mathematics in their personal world, and to mathematize their personal world. In general, this view of discourse takes account of students' personal experiences, thoughts, and feelings. It capitalizes on and values students’ contributions to their learning. It provides opportunities for students to bring their own backgrounds, personalities, and beliefs into the construction of their mathematical knowledge. Thus, through it, students can come to realize that their ideas are valued and, as a result, have more authority over their learning and engage in more voluntary participation.

This learner-focused discourse empowers “self” and gives students “voice” in learning mathematics. Human agency, therefore, is of significant importance. This form of agency was also promoted by Boaler (2003) in terms of the “I”-voice. She promoted classroom discourse that prompts students to take initiative, to demonstrate human agency. However, the learner-focused perspective promoted through this study includes the unique aspect of reflection on “self” i.e., students become the subject in the process of their own reflection and learning. Thus, there is a connection between personal experience and conceptual sense making. In general, this study suggests that discourse framed in agency, reflection and collaboration can allow students to talk mathematically from and about their experiences and to make sense of mathematical ideas, of mathematics in their lives, and of their way of thinking or learning. This way of empowering self makes the learning of mathematics personal, real, relevant, important, and meaningful.

This study also suggests that in order to support this view of discourse, the teacher’s role has to be framed by the intent to listen to learn from the students and to listen to know them mathematically. For example, based on this Grade 3 teacher’s perspective, this required her: to be aware and accepting of alternative ways of thinking or approaching something; to be able to recognize the students’ logic or believe that there was a logic; to believe that she can learn something from the students; and to understand students’ knowledge of a concept, their strategies, their prior experiences with the concept and their preformed perspectives and understanding. This view to learn from and about the students is supported by an "intersubjective" (Bruner, 1996) perspective where the teacher applies the same theories to herself as she does to her students. For example, the teacher creates approaches that are as useful for students in organizing their learning as they are for her, i.e., approaches that support each other's learning. From this intersubjective stance, the teacher is also interested in what the student is thinking and thus is concerned with formulating a basis of discourse that she can use to satisfy this and facilitate the efforts of the student.

# THE RELATIONSHIP BETWEEN THE WRITTEN AND ENACTED CURRICULA: THE MATHEMATICAL ROUTINE OF QUESTIONING

Jill A. Newton
Purdue University
janewton@purdue.edu

*This study investigated the relationship between the written and enacted curricula through an analysis of their mathematical features, including (a) Mathematical Words, (b) Visual Mediators, (c) Endorsed Narratives, and (d) Mathematical Routines. The results from the examination of the mathematical routine of questioning are reported here. The study revealed similarities and differences between the questions included in the written and enacted curricula indicating the utility of this framework for documenting the characteristics of curricular implementation.*

## Background

The National Council of Teachers of Mathematics (NCTM) published a series of three standards documents beginning nearly twenty years ago that provided a new vision for school mathematics (NCTM, 1989; NCTM, 1991; NCTM, 1995). This vision advocated for a student-centered model focused on mathematical reasoning, problem solving, and communication. Subsequently, the National Science Foundation (NSF) funded the development of mathematics curricula based on the NCTM standards. These curricula, and the standards on which they were based, have been challenged to prove their effectiveness. The resulting evaluation and comparative studies have been criticized for inadequate documentation of the implementation of the curricula (e.g., Senk & Thompson, 2003; National Research Council, 2004) saying that in order to credit a curriculum for students' learning or blame a curriculum for lack thereof, some degree of fidelity of implementation must be established. Textbook-use diaries, table-of-contents implementation records, classroom observations, interviews, and surveys have been used in recent studies to document curricular implementation. What has been missing from these methods of accounting for implementation has been a focus on mathematics. That is, how is the mathematics presented in the written curricula, how is it enacted in the classroom, and what is the relationship between the two? In this study, I use the commognitive framework (Sfard, 2008) to compare the mathematical features of written and enacted curricula.

## Theoretical Perspectives

Commognition (formed from *communication* and *cognition*) treats communication (interpersonal exchange) and cognition (intrapersonal exchange) as two forms of the same phenomenon. It was developed to emphasize the relationship between these two processes. The commognitive framework proposes that *mathematics* is discourse about mathematical objects and *learning mathematics* is a change in participation in mathematical discourse. The framework suggests an examination of the discursive features of mathematics, including (a) Mathematical Words, (b) Visual Mediators, (c) Endorsed Narratives, and (d) Mathematical Routines.

Mathematical words are those that signify quantities and shapes (e.g., number) and those that highlight relationships between these quantities and shapes (e.g., equivalence). Visual mediators are artifacts created for the primary purpose of mathematical communication (e.g., symbols, graphs). Narratives include any text that is framed as a description of objects, of relations between objects or processes with or by objects, and which is subject to endorsement or rejection (i.e., being labeled true or false). Definitions, axioms, theorems, and proofs are commonly endorsed narratives in mathematics. Finally, mathematical routines are repetitive characteristics of mathematical discourse. A detailed comparison of these four mathematical features in the written and enacted curricula provides new ways to talk about curricular implementation that highlight the mathematics. The overarching question of this study is: What does an investigation of the key features of mathematical discourse, using the commognitive framework, in the written and enacted curricula reveal? Of particular interest in this paper: What does an investigation of the mathematical routine of questioning in the written and enacted curricula reveal?

## Methodology

I utilized the commognitive framework to investigate the relationship between written and enacted *standards*-based mathematics curricula. To this end, I made use of two primary data sources, (a) the written version of a *standards*-based mathematics curriculum and (b) an enactment of the same *standards*-based mathematics curriculum.

*The Connected Mathematics Project* (hereafter referred to as *CMP*) (Lappan, Fey, Fitzgerald, Friel, & Phillips, 2006) was used as the written curriculum. In particular, *Multiplying with Fractions*, an Investigation in *Bits and Pieces II: Using Fraction Operations* was used. The written curriculum is conceptualized here as the union of this Investigation in the Teacher's Guide and the Student's Guide.

I used videotapes of Investigation 3 in a sixth grade classroom as the enacted curriculum. This particular class is heterogeneous in mathematical ability (i.e., the students are not tracked). It is located in a middle school in a small rural town in the Midwest. The teacher of this particular class is a veteran *CMP* teacher. She has attended and conducted professional development for *CMP* and verbally endorses the curriculum. The discourse of the classroom (i.e., the union of the words and actions of the teacher and the students) is considered the enacted curriculum for this study.

My data analysis entailed, broadly speaking, comparing the mathematical features of the commognitive framework in the written and enacted curricula, and using the results of these analyses to investigate both the relationship between the two curricula as well as the usefulness of the framework to describe the results. Here, I report only on mathematical routines, and only on the routine of questioning.

## Findings

Routines are "well-defined repetitive patterns in interlocutors' actions, characteristic of a given discourse" (Sfard, 2007, p. 574). Questioning is a widely used mathematical routine in both the written and enacted curricula. The *CMP* Teacher's Guides contain a section entitled "Suggested Questions" for each Problem in the Investigation. Given the fact that learning mathematics is conceptualized here as changing discourse practices, the questions included in the written and enacted curricula are worthy of examination. That is, "What discursive practices are elicited through questions in the written and enacted curricula?"

The written and enacted curricula include 110 questions and 579 questions, respectively. A series of analyses was conducted on these questions: (a) Leading Words of Questions, (b) Elicited Answers to Questions, (c) Mathematical Processes addressed by Questions, (d) Questions that Address the Answer, and (e) Miscellaneous Questions.

*Leading Words of Questions*

For this analysis, the first word of each question in the written and enacted curricula was noted. Figure 1 summarizes the relative frequencies of the first words of questions that are present in at least 10% of either the written or enacted curriculum or both.

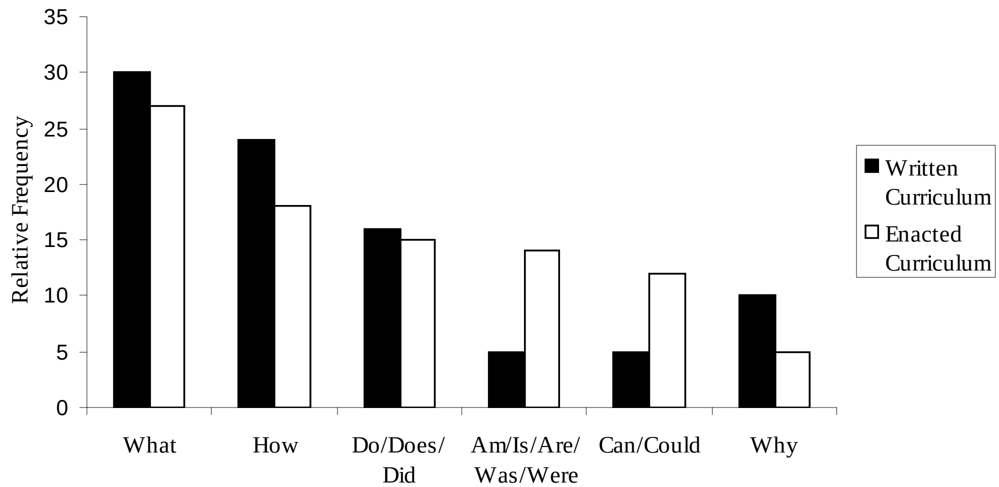

*Figure 1.* Relative frequencies of leading words of questions.

"What" and "How" are most common in both curricula. In both cases, however, the relative frequency in the written curriculum is greater than in the enacted curriculum. "Why" is not prevalent in either curriculum, but is twice as common in the written curriculum as in the enacted curriculum. Here, learning mathematics is defined as changes in participation in mathematical discourse. Given this, it seems that "open" questions (i.e., questions that require more than 1-2 word answers) would be preferable to "closed" questions, as they would provide both opportunities for students to engage in extended mathematical discourse as well as opportunities for the teacher to monitor mathematical learning. "How" and "Why" questions tend to be open, whereas the "Do" "Am," and "Can" families of questions are more likely closed. Contrasting these categories reveals that 34% and 23% of the questions in the written and enacted curricula, respectively, are open questions. "What" questions are not obviously open or closed and they appear in fairly equal frequencies in both curricula, therefore they were not included in this calculation.

*Elicited Answers to Questions*

The questions in the written and enacted curricula ask students either to say something or to do something. If learning mathematics is conceptualized as a change in ways of participating in mathematical discourse, then what students are expected to say and do is of critical importance. In particular, if students are expected primarily to "do," then it is questionable how much mathematics learning can take place. In both the written and enacted curricula, questions asking students to "say" something are much more common than questions asking students to "do" something (i.e., 84% and 86% "saying" questions, respectively).

The questions were classified into *what* the students are expected to say or do. When expected to "say" something, three types of responses are represented in at least 10% of either the questions in the written or enacted curriculum or both: (a) explanation, (b) yes or no, and (c) a number. Table 1 provides examples from the written and enacted curricula of questions eliciting each of these types of responses.

Table 1
*Sample Questions Eliciting Particular Response Types*

| Response | Written Curriculum | Enacted Curriculum |
|---|---|---|
| Explanation | *"Why does it make sense that the product [of reciprocals] is always 1?" (TG, p. 81)* | *S: "Why did you write twenty twos, though?" (Day 5)* |
| Yes/No | *"Do you think Takoda's strategy works?" (Student's Guide [SG], p. 38)* | *T: "So, is it fair to say that these two girls took each one of these thirds and split them into seven pieces?" (Day 1)* |
| Number | *"What fraction of a whole pan does Mr. Williams buy?" (SG, p. 33)* | *S: "So, how many thirds?" (Day 5)* |

Figure 2 summarizes the relative frequency of each category of response.

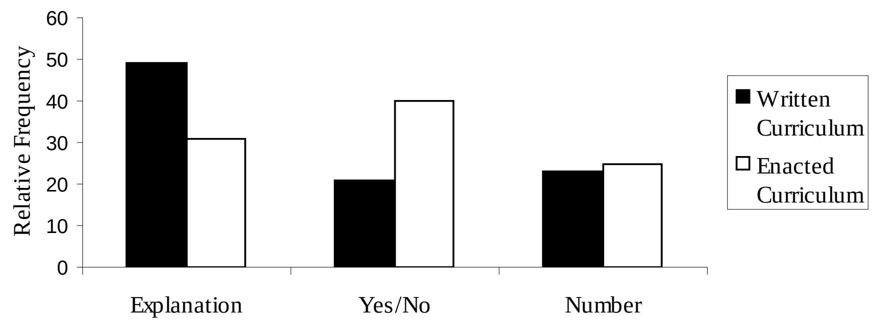

*Figure 2.* Relative frequencies of categories of elicited answers to questions.

Figure 2 indicates that explanations are the most commonly elicited type of response in the written curriculum, whereas Yes/No responses are slightly more common than explanations in the enacted curriculum. This analysis supports the conclusion from the previous analysis that "open" questions are more prevalent in the written curriculum than in the enacted curriculum.

When a question expects the students to "do" something, the actions include constructing a symbolic mediator (e.g., a number sentence); and constructing, manipulating, or indicating an iconic mediator (e.g., a diagram). Table 2 provides examples of questions from each category.

Table 2
*Sample Questions Eliciting Particular Actions*

| Action | Written Curriculum | Enacted Curriculum |
|---|---|---|
| Construct Symbolic Mediator | *"Ask groups to write the number sentences for the problems on their transparency." (TG, p. 72)* | *T: "Can you write that [number sentence] next to it?" (Day 1)* |
| Construct Iconic Mediator | *"How would you represent* $\frac{1}{4} x \frac{2}{3}$ *on a number line?" (SG, p. 34)* | *T: "Who can come up and show what that would look like on a long, skinny model?" (Day 3)* |
| Manipulate Iconic Mediator | *"What could you do in your drawing to make this clearer?" (TG, p. 60)* | *T: "Could you continue them as if this brownie were here, or this part of the goal was there?" (Day 4)* |
| Indicate Iconic Mediator | *"Where do you see this [the numerators] on the brownie pan drawing?" (TG, p. 61)* | *T: "So where is one whole ounce?" (Day 5)* |

Figure 3 summarizes the relative frequencies of the types of "doing" responses to questions in the written and enacted curricula.

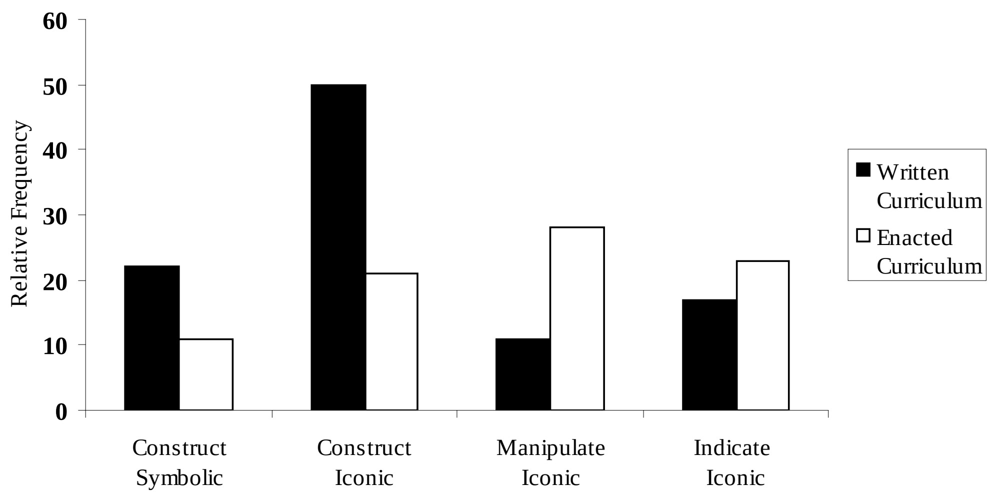

*Figure 3.* Relative frequencies of "doing" question responses.

Figure 3 illuminates several differences between the "doing" question responses in the written and enacted curricula. First, constructing iconic visual mediators is more than twice as common as any other expected "doing" question response in the written curriculum. In fact, half of all "doing" questions in the written curriculum expect this action. In contrast, several categories have relatively similar frequencies in the enacted curriculum. However, it should be noted that all three of the responses with the highest relative frequencies in the enacted curriculum involve iconic visual mediators.

*Mathematical Processes Addressed by Questions*

The mathematical processes addressed in at least 10% of the questions in either the written or enacted curriculum or both include: (a) estimating, (b) decomposing numbers, (c) using a model (including concrete, iconic, and symbolic mediators), and (d) using an algorithm. There are also questions that address mathematical processes in general. Table 3 includes sample questions from the written and enacted curricula which address each process.

Table 3
*Sample Questions Addressing Particular Mathematical Processes*

| Process | Written Curriculum | Enacted Curriculum |
|---|---|---|
| Estimating | *“Who can explain how they estimated $1\frac{1}{2}$ x $2\frac{9}{10}$?”(TG, p. 72)* | *T: “If I said I was going to get one half of two and nine tenths, Graham, how could we think about estimating that answer?” (Day 4)* |
| Decomposing Numbers | *“Would you want to use this strategy [distributive property] with the problem $3\frac{7}{8}$ x $2\frac{5}{6}$?” (TG, p. 77)* | *T: “Could I do ten groups of two and a third and then a half of a group of two and a third?”(Day 5)* |
| Using a Model | *“How does your drawing help someone see the part of the whole pan that is bought?” (TG, p. 60)* | *T: “So how far, what fraction of a whole mile is this one little piece right here [pointing to part of model]?” (Day 3)* |
| Using an Algorithm | *“What observations can you make from Questions A and B that help you write an algorithm for multiplying fractions?” (SG, p. 35)* | *T: “Do you think that these are the steps that we should tape - take?” (Day 3)* |
| General | *“What method did you use to solve the problem?” (TG, p. 81)* | *T: “Can you do this in a whole day, so how could you figure out what you do in a half of a day?” (Day 5)* |

Figure 4 summarizes the relative frequencies of the mathematical processes addressed in the questions.

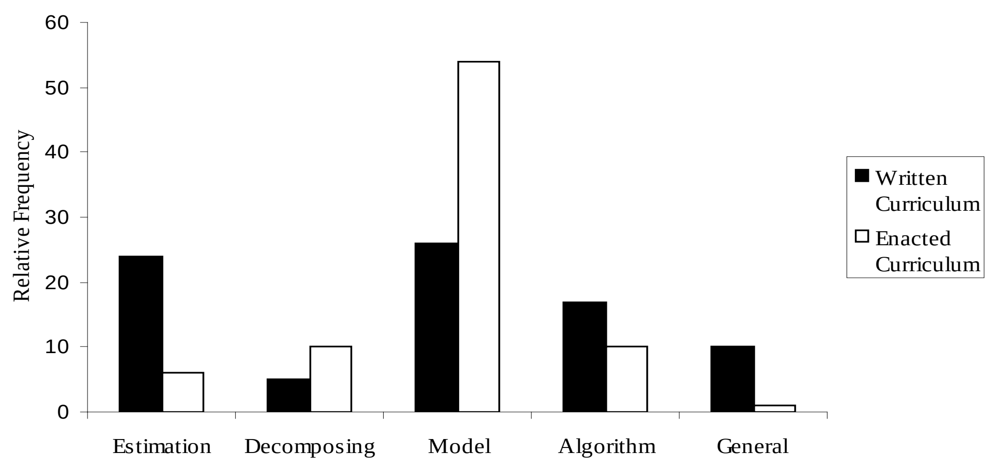

*Figure 4.* Relative frequency of mathematical processes addressed in questions.

Figure 4 indicates that more than 50% of the questions in the enacted curriculum address the use of a model. In contrast, 25% of the questions in the written curriculum address the use of a model and another 25% address the use of estimation. Questions addressing algorithms and general methods also represent at least 10% of the questions in the written curriculum. The same is true for algorithms and decomposing numbers in the enacted curriculum.

*Questions that Address the Answer*

Questions that address the "answer" are very common in both the written and enacted curricula. In fact, 45% of the questions in the written curriculum address the "answer" compared to 23% of the questions in the enacted curriculum. These questions take several forms including (a) asking for the answer, (b) asking for an explanation of the answer, (c) asking about the relative size of the answer, and (d) asking about the answer's relationship to another answer. Table 4 provides examples of questions from these categories.

Table 4
*Sample Questions Addressing the Answer*

| Question Type | Written Curriculum | Enacted Curriculum |
|---|---|---|
| Asking for the Answer | *"What fraction of a whole pan does Aunt Serena buy?" (SG, p. 33)* | *T: "What fraction of the candy bar did I eat?" (Day 1)* |
| Explaining the Answer | *"How did you come up with $2\frac{1}{2}$?" (TG, p. 71)* | *T: "How did you decide three eighths?" (Day 1)* |
| Asking about the Relative Size of the Answer | *"Does multiplication with fractions always lead to a product that is less than each factor? (TG, p. 67)* | *T: "Is your answer going to get bigger, or is your answer going to get smaller?" (Day 1)* |
| Asking about the Answer's Relationship to Another Answer | *"Who can use their model to prove that the answer $\frac{8}{12}$ is sensible?" (TG, p. 76)* | *T: "Do you think that it's one fourth or do you think it's showing one sixth of the whole bar?" (Day 3)* |

*Miscellaneous Questions*

Table 5 provides examples of several types of questions that each represent approximately 2-3% of the questions in the curricula.

Table 5
*Sample Miscellaneous Questions*

| Question Type | Written Curriculum | Enacted Curriculum |
|---|---|---|
| What is the Meaning of Fraction Multiplication? | *"What does it mean to find $\frac{1}{3}$ of $\frac{2}{3}$?" (TG, p. 60)* | *T: "What does that mean again, one third times one fourth?" (Day 2)* |
| Do You "Agree" with a Suggested Answer or Strategy | *"Do you agree with this answer and the reasoning?" (TG, p. 72)* | *T: "Do you agree with that, Jacob, or no?" (Day 2)* |

| | | |
|---|---|---|
| Does a Suggested Answer or Strategy "Make Sense"? | *"Do you think Paula's strategy of rewriting the mixed numbers as fractions is sensible?" (TG, p. 80)* | *T: "Could you guys live with that, does that make sense?" (Day 3)* |
| Do You "Understand" an Answer or Strategy? | ----- | *T: "Everybody understand what Katie did?" (Day 3)* |

## Discussion

The question addressed in this discussion is, "What does an investigation of the mathematical routines (in this case, the routine of asking questions) in the written and enacted curricula allow us to see?" That is, "What do we know now about the relationship between the written and enacted curricula that we did not know before?" Table 6 summarizes the findings from this investigation of questions.

Table 6
*Summary of "Mathematical Routines" (i.e., Questioning) Analysis*

| | Written Curriculum | Enacted Curriculum |
|---|---|---|
| Leading Words of Questions | "What" and "How" are the most common first word of a question in both curricula | |
| | 10% of questions begin with "Why" | 5% of questions begin with "Why" |
| | 34% of the questions are open | 23% of the questions are open |
| Elicited Answers to Questions | Approximately 85% of the questions ask students to "say" something rather than to "do" something | |
| | The most common elicited answer to "saying" questions is an "explanation" (49%) | The most common elicited answer to "saying" questions is "yes/no" (40%) |
| | Approximately 25% of the "saying" questions elicit a "number" in both curricula | |
| | 49% of the "saying" questions are open | 31% of the "saying" questions are open |
| | Nearly all elicited responses to "doing" questions involve visual mediators | |
| Mathematical Processes addressed by Questions | 26% of the questions address using a model and 24% address estimating | 55% of the questions address using a model and 6% address estimating |
| | Approximately 10% of the questions address the relationship between two or more mathematical processes | |
| Questions that Address the Answer | 45% of the questions address the answer to a Question | 23% of the questions address the answer to a Question |
| Miscellaneous Questions | Both curricula include questions that ask for the meaning of fraction multiplication, requests for agreement/disagreement, and whether particular mathematics makes sense | |

Table 6 and the more detailed analysis described earlier highlight many discursive similarities and differences between the questions included in the written and enacted curricula. Table 6 indicates (in several places) that a greater proportion of the questions in the written curriculum require an explanation (i.e., are open questions). If learning mathematics involves changing participation in mathematical discourse, then the opportunities that "open" questions provide for students to participate actively in mathematical discourse (i.e., beyond short answers) make a difference in students' learning.

# OPEN, ONLINE, CALCULUS, HOMEWORK FORUMS: ARE STUDENTS POSITIONED TO LEARN?

Carla Currin van de Sande
RIMSE, Arizona State University
carla.vandesande@asu.edu

*Free, open, online, calculus forums are websites where students can post course-related queries that may be viewed and responded to by others. Is this a prescription for cheating or mastery-oriented help-seeking? I investigated one such site, FreeMathHelp.com, with a focus on the positioning of students as they sought help on their coursework. Two hundred exchanges on limit and related rates were collected and examined for evidence that students are contributing ideas and proposals for action, challenging and questioning others' proposals, and indicating that the issue was resolved. Of particular interest was the serendipitous finding that students sometimes engaged in self-reflection.*

## Background

Open, online help forums are websites where students can post course-related queries that are then visible to the public. These forums are "open" in the sense that they are not affiliated with any particular course or institution; members are attracted to them by necessity and interest. People learn of the forums' existence, access the web sites, and then choose whether or not to join in the conversation, either by posting a question, responding to an unanswered question, or contributing to an ongoing exchange. In this way, these forums alter the very nature of tutoring as it is traditionally conducted and transform it from a private activity between tutor and tutee to a public activity between people who share an interest in the subject domain. In this study, I explore how participating in this conversation engages students and tutors in mathematical and pedagogical discourse in ways not characteristic of traditional one-on-one tutoring.

## Theoretical Perspective

Traditional one-on-one, face-to-face tutoring is a popular form of instruction that offers benefits not generally provided by classroom instruction, mastery learning, computer-aided or programmed instruction, or computer tutors (Chi, 1996). One feature that distinguishes tutoring sessions from other means of instruction is the pattern of dialogue between participants. In contrast to the 3-step Initiation-Response-Evaluation dialogue frame that often marks classroom discourse (Cazden, 2001; Mehan, 1979), the dialogue in traditional tutoring sessions generally follows a 5-step dialogue frame (Graesser, Person, & Magliano, 1995): (1) Tutor asks question (or presents problem); (2) Learner answers question (or begins to solve problem); (3) Tutor gives short immediate feedback on the quality of the answer (or solution); (4) Tutor and learner collaboratively improve the quality of the answer; (5) Tutor assesses learner's understanding of the answer. This dialogue pattern occurs in a context in which the tutor explains a pre-determined set of topics to the tutee, often with the goal of providing remediation or augmenting an instructional explanation. Questions or problems are chosen by the tutor for the purpose of assessing the learner's understanding, and, in fact, the learners generally ask few questions during the tutoring session (Graesser & Person, 1994).

Alternatively, consider an instructional episode spawned by a particular problem that a student has encountered in coursework and has posed to a peer or more experienced other. In order to distinguish this type of instructional episode from traditional tutoring sessions, we have referred to them as “tutorettes” (van de Sande, 2007; van de Sande & Leinhardt, 2007a) and considered them as a form of student-initiated help-seeking (Nelson-Le Gall, 1985) that occurs in university help centers (face-to-face) and in online forums (computer-mediated). In these situations, the student selects the question(s) that begins the discussion, indicates the acceptability of the tutor’s responses, and generally decides whether the goals of the interaction have been met (i.e. whether the exchange was helpful). Thus, a typical dialogue frame (for a single student-tutor pair) for this type of encounter might look like the following: (1) Student asks question (or presents problem); (2) Tutor answers question (or begins to provide scaffolding); (3) Student gives feedback on the quality of the help; (4) Student and tutor collaboratively work on solving the problem; (5) Student assesses whether tutor’s responses were helpful.

Although tutorettes share many features of tutoring sessions (such as personalized instruction and support), they are also different in terms of initiation, goals, and instructional objectives. One key difference between online tutorettes and face-to-face tutoring encounters (either tutoring sessions or tutorettes) is the presence of an audience. Face-to-face sessions are generally conducted between a single student-tutor pair in relative privacy, whereas the exchanges in open, online forums are public and can be witnessed by others. In addition, in some forums, more than a single member can contribute to an ongoing exchange with alternative solutions, corrections, and commentary on mathematical issues as well as pedagogical approaches. The broader social dimension afforded by these open, online help forums reframes tutoring as a collective activity in which the exchanges become a public conversation between individuals who share a common interest in doing mathematics and helping others (van de Sande & Leinhardt, 2007b, 2008a).

## Methods

*Design*

In order not to disrupt this natural phenomenon in any way, this research was conducted by collecting a sample of 100 exchanges on the limit and 100 exchanges on related rates (both dating back from 4/29/08) from the archives of the calculus homework help forum on a representative site.

*Site choice and description.* The calculus forum at FreeMathHelp.com was selected because this site has an extensive history (archives dating back to 2005), includes a search mechanism for locating exchanges by a keyword or phrase, and is active in terms of daily postings and membership. In addition, the forum policies (such as achievement of member status) are explicit, and member “reputation” is an implicit mechanism of the social arena rather than being quantified (e.g. by others’ ratings of one’s postings or by some ranking determined by the forum site administrator) and made an explicit part of forum identity. In addition, all forum members can initiate threads in a discussion forum (e.g. as students posting mathematics questions) and can respond to others’ posts (e.g. as tutors providing help).

The prescribed etiquette for participation is located in a “sticky” that is the lead posting within each help forum. This covers administrative issues (e.g. posting to an appropriate category) and politeness (e.g. patience while waiting for response). In addition, there are three rules that specifically address the content and framing of posts: include problem context (“Post the complete text of the exercise”), show initial work (“Show all of your work [including intermediate steps that may contain errors]”), and attend to clarity (“Preview to edit your posts [to minimize errors]”).

*Topic choice.* Students enrolled in “introductory calculus” are exposed to a large number of topics from differential and integral calculus. Although the exact coverage of the syllabus will vary across programs and institutions, there is a large amount of overlap in the topics that are presented. Two such topics are the limit concept and related rates. Coming to grips with the limit concept is one of the first challenges that students in an introductory calculus course face. There is general consensus that many students struggle with constructing a coherent understanding of limit (Cornu, 1991; Cottrill et al., 1996; Tall, 1993; Williams, 1991) and that many fail to achieve this through instruction (Szydlik, 2000). Some part of student difficulty can be chalked up to the abstract nature of the limit concept; it is based on a never-ending process and therefore requires the contemplation of an infinite number of computational steps – a large conceptual leap from topics encountered in algebra and precalculus. In contrast, the topic of related rates encompasses a class of problems that involves the relationship(s) between two or more changing quantities, one of which is unknown and must be determined. These exercises generally appear in introductory calculus instruction as applications of implicit differentiation and the chain rule and are framed as word problems meant to reflect authentic situations with the solution to such problems scripted as a 5-7 step process. Yet, students struggle with this topic as well (Engelke-Infante, 2007; Martin, 2000). The concept of limit and related rates, then, were chosen as topics for this study to reflect the diversity of problem types characteristic of the subject domain and to capture tutoring interactions on topics that are challenging to students.

*Sample characteristics.* FreeMathHelp.com features participants’ profiles that include information on occupation, location, and interests. Whereas many student participants do not provide this information, the participating tutors in the calculus forum are self-reportedly students, educators, professionals, and retired mathematics professors. The most frequent tutor participants are from the United States, although there are representatives from a variety of other countries as well.

Although some tutors and students post more frequently, numerous tutors and students frequent MathHelpForum.com. The sample contained 100 related rates exchanges initiated by 65 different students, with responses from 18 different tutors and 100 limit exchanges initiated by 67 different students, with responses from 23 different tutors. There was some overlap in participants (both students and tutors) across the two mathematical topics: 17% of these students posted queries on both limits and related rates, and 63% of the tutors provided assistance for both topics.

*Coding and Analyses*

*Conversational complexity*. In order to characterize forum tutoring dialogue patterns, each exchange was assigned a participation code that tracks the number of participants, the total number of contributions in the exchange and the sequence of participation. For example, a code of 1231 would be assigned to a thread with four postings containing contributions from 3 different participants: a student (designated 1) posted a problem and then two different tutors (designated 2 and 3, respectively) responded, followed by a final contribution by the student. These codes permit one to catalogue exchanges that involve multiple conversational turns, multiple participants, and multiple contributions by a single participant. In addition, although the participation codes are agnostic with respect to the quality of the contribution (e.g. mathematical accuracy and depth, and pedagogical sensitivity), the codes do provide some indication of interaction within an exchange: for example, 1213121 is more likely to be an exchange in which two tutors are conversing with a student, whereas 1213232 is suggestive of dialogue between two tutors.

Based on these participation codes, each exchange received a conversational complexity index defined as the sum over code entries. For example, an exchange with participation code 1231 would have a complexity index of 1+2+3+1=7. While this index makes arbitrary use of the categorical indices – the numbers in the codes have *no* value beyond marking the sequence of participants – the index appears "well-behaved" (van de Sande & Leinhardt, 2008b). Lower sums correspond to exchanges that do not contain intense mathematical discussions and elements of pedagogical sophistication. Exchanges in which mathematical principles are invoked and perspicuous mathematical reasoning is present have higher indices (which is not to say that all discussions with higher indices are of high caliber, but simply that quality exchanges are marked by higher indices). Thus, the complexity index provides a rough guide as to which exchanges are "simple" versus which are "complex" that suffices for examining the effect of various positioning moves within an exchange.

*Positioning.* In order to explore aspects of student positioning in forum activity, each exchange was examined for the presence of three types of student activity that are consistent with active student participation and agency (Greeno, 2006): (i) assertions and proposals for mathematical actions (e.g. "THis is what i did. I don't know exactly how to solve for this but, my logic is that it'll go to zero eventually, because the bottom goes to infinity faster than the top so it'll to go zero. But i am not sure exactly if this is right can someone prove this or tell me if i'm intuatively correct. Thanks"), (ii) questions and challenges of others' proposals (e.g. "to find the derivative of this last part, i get that deriv of cos is -sin, but where does the -2 go. did you use the product rule. if so, what did you make 'f(x' and 'g(x)' for product rule?"), and (iii) indications of resolution coded according to strength (e.g. "i got it, forgot to factor, btw -14/sqrt(18) = -3.30, which is the correct answer" was counted as strong resolution, whereas "Thanks" was counted as weak resolution). Cohen's κ, a conservative statistic for establishing reliability, showed considerable inter-rater consistency on a sample of 20 exchanges: assertions and proposals for action (Cohen's $\kappa = 1$, standard error = 0); questions and challenges of others' proposals (Cohen's $\kappa = 0.77$, standard error = 0.22); degree of resolution (Cohen's $\kappa = 0.74$, standard error = 0.14); all differences in coding were resolved following discussion.

## Results

Although the forum participants acting as tutors are generally more experienced mathematically than forum members who bring their queries to the forum, students can position themselves with authority in an exchange in three ways: by contributing to the construction of a solution; by questioning or challenging the contributions of others; and by indicating that an issue has been resolved. In this section, we look at each of these three indicators of student authority in turn to reveal how students are positioning themselves as they participate in the forum. In the analyses, the threads are partitioned into sections with descriptive labels that are intended to convey and characterize the positioning of participants in that portion of the interaction.

### *Student Makes Assertion or Proposes Action*

Students participate in the forum for different reasons: because they have reached an impasse while attempting a problem, because they wish to confirm the accuracy of a solution that they have constructed, or because they have questions regarding an explanation that they have encountered in their studies. When a student posts a query on the forum, s/he can assume either a passive or an active position in the construction of the solution or explanation. One mark of active participation involves making assertions or proposing mathematical actions (even if these are hedged or couched in uncertainty), and the exchanges were examined for this aspect of positioning.

**Error! Reference source not found.** contains the percentage of exchanges in which the student made (or failed to make) an assertion or proposed a mathematical action within each topic by location in the thread (initial versus subsequent posting or both). The results indicate that students are generally positioning themselves as contributors to the discussions on solving the limit and related rates problems. The pattern of the location of these contributions in the thread is shared across topics, with students following the participation guideline to "show all of your work" in the initial posting 60% (limit) and 68% (related rates) of the time and contributing at some location in 69% (limit) and 79% (related rates) of the exchanges. Out of all 200 exchanges 74% involved students making some sort of assertion or action in the thread, and, of these, nearly three quarters involved exchanges with a complexity index greater than 6. That is to say, students proposed actions or made assertions in contexts that proved to have higher conversational complexity.

**Table 1.** ***Percentage of Exchanges Containing Student Proposals by Location in Thread***

| Topic | No assertion or proposal | Within initial posting only | Within initial and subsequent postings | Within subsequent posting only |
|---|---|---|---|---|
| Limit | 31 | 45 | 15 | 9 |
| Related rates | 21 | 54 | 13 | 12 |

*Student Questions or Challenges Assertion or Proposal Made by Others*

Contributions that question or challenge others' assertions or proposals are another indication of the way participants position themselves in the interaction. When a forum tutor offers advice, constructs part of a solution, or produces a hint, a student can either accept or question the information (just as contributions are either accepted or rejected in Clark's (1992) model of conversation). A student adopting a position as an active participant in a forum exchange may ask questions or challenge contributions as part of a self-regulatory learning strategy and in order to repair knowledge deficits.

Nineteen percent of the exchanges on limit and 20% of those on related rates contained a contribution in which the student questioned or challenged the contribution of a forum tutor. Only one of these exchanges in each topic had a conversational complexity index less than 7, and both of these had a participation code of 1212 (complexity index of 6). In other words, when a student introduced a question or challenge into a discussion, the outcome was an extension rather than a termination of the conversation. The patience and politeness that characterized this tutoring exchange are particularly noteworthy as an indication of how the forum functions as a tutoring environment in which students can safely challenge the contributions of more experienced others.

*Student Indicates that the Issue has been Resolved*

In the classroom, it is generally the teacher who is positioned to evaluate the understanding of the student(s) and makes the decision whether to continue or terminate a discussion (e.g. the IRE dialogue pattern in which the teacher asks a question and then evaluates a student's response (Mehan, 1979). Similarly, in tutoring sessions, the tutor is the participant who assesses the understanding of the student and decides whether to extend the discussion or move on to the next topic. In contrast, in an open, online forum, it is the student who initiates the exchange and who is ultimately responsible for deciding whether the goal of the interaction has been achieved to her/his satisfaction.

The perceived importance of indicating resolution within an exchange is underscored by the existence of automated “thank you” responses in some online help forums. For instance, MathHelpForum.com appends a “thanks” button to each post so that members can, with the click of a mouse, generate a response reading “The following users thank [name of contributor] for this useful post: [name of member].” This feature was introduced in the forum to support and encourage public recognition of the usefulness of member contributions.  However, because not all forums include this feature (including the forum chosen for the current study), and because students may indicate that an issue is settled in other ways, it is worthwhile to consider a broader range of resolution markers.

There are several ways that a participant can indicate that an issue has (or has not) been resolved. First of all, participants can be silent and opt not to further contribute to an exchange. Silence in computer-mediated exchanges may indicate acceptance or rejection of another’s contributions and does not offer evidence for (or against) the achievement of resolution. Thus, in the forum discussions, if a student does not return to the exchange beyond the initial posting or following tutor interventions, it is not clear whether the student feels that the issue has been settled or not. Exchanges of this type are referred to as “hangers” since other forum participants are, in some sense, left hanging regarding the helpfulness of their contributions. On the other hand, when a student does acknowledge tutors’ contributions, they can do so in either a weak or strong manner. For instance, an expression of appreciation, such as “Thank you,” indicates a weak level of resolution on the part of the participant since this may simply be a residual of polite manners, that is, a customary response to receiving assistance. In contrast, the contribution of mathematical actions (e.g. the presentation of a solution to the problem) and assessments (e.g. reflections on differences in understanding) are stronger indications that the issue has been resolved to the satisfaction of the student. Finally, an exchange can evince a lack of resolution, as when a student receives no response to a query or receives a refusal from forum tutors to provide further assistance. **Error! Reference source not found.** shows the number of exchanges for each topic in which resolution could not be determined (hangers), in which resolution was evident and the strength of the expression (weak versus strong), and in which there was no resolution.

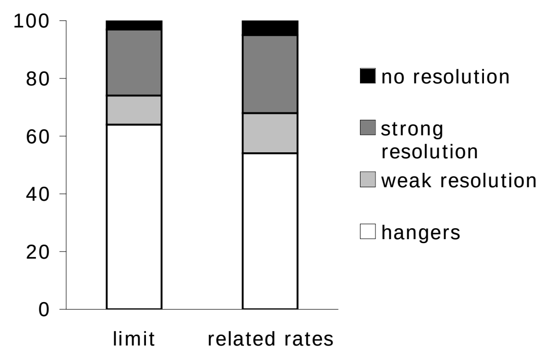

***Figure 2.*** **Student indications of resolution by topic.**

The majority of the exchanges that were not “hangers” (with unspecified resolution) exhibited resolution from the student’s perspective, in either a weak or strong manner. This means that roughly 40% of the exchanges showed some level of resolution, surely a level that is higher than most classroom exchanges in which the teacher has little indication whether students “got it.” In addition, the number of exchanges exhibiting characteristics of strong resolution outnumbered those in which only weak resolution was evident by a factor of two, a finding that is consistent with the amount of student activity in the forum. Over three quarters of the exchanges evincing weak resolution had low conversational complexity (index of 7 or less), so that exchanges in which a student received help and merely thanked the tutor(s) without demonstrating why the intervention was helpful were more likely to be brief transmissions of information rather than interactive discussions. Furthermore, there were very few exchanges (3 on limit and 5 on related rates) for which the issue was not resolved and in which the outcome of the exchange from the student’s perspective could be characterized as inconclusive or unhelpful.

## Conclusions

Free, open, online, help forums have transformed tutoring and instructional assistance outside of the classroom in a grass roots fashion. These help forums have grown up in response to a prevailing and universal need for accessible, efficient, and cost-effective homework assistance. The operational principle behind of these forums is that they connect students with a group of others who are willing to contribute their time, expertise, and support to help anonymous students arrive at solutions to course-related queries. Sites that are staffed by volunteers who spontaneously visit and come to the aid of students − the “Good Samaritans” of mathematics (van de Sande, C. & Leinhardt, 2008) − host collaborative dialogues so that tutoring in this venue is realized as a public and often many-to-one conversation between participants rather than as a private, one-on-one activity.

In some forums, students are positioned to learn calculus in nonstandard ways as they make mathematical assertions and proposals, question and challenge others’ proposals, and take initiative in demonstrating that the issue at hand has been resolved. As they work through course assignments and materials, students must both formulate and communicate their ideas, thoughts, and reasoning on the mathematics behind the solution to a problem to someone else through the computer. In addition, students in the forum may freely engage in self-reflection following tutor intervention. Student participation in such cases goes beyond the construction of a correct solution to the exercise to an analysis of the discrepancy between a novel and prior understanding that is then shared openly with other participants as a natural contribution to the exchange. This practice, consistent with the assumption of responsibility by students for their own learning efforts and advancement of understanding, has been observed in other online learning environments and appears to be facilitated by a computer-mediated mode of communication (Muukkonen, Lakkala, & Hakkarainen, 2005).

This study on authentic student-initiated online help-seeking positions us as researchers and educators to better understand how students are working on assignments outside of the classroom. In this emergent learning environment, many students are positioning themselves to learn and, through interaction with members of a larger mathematical community, taking away much more than just solutions to exercises. The impact such participation has on students’ broader mathematical endeavors and experiences remains to be addressed.

*This case study examined the efficacy of tasks designed for promoting multiplicative reasoning in students with learning disabilities. Chad's (grade 4) construction of a mixed-unit coordination scheme was nurtured in the context of a teaching experiment with 14 students in two USA Midwest elementary schools. The analysis focuses on how a sequence of tasks, tailored to Chad's available conceptions, brought forth his transfer of a crucial mathematical idea to novel, realistic problem situations. We argue for the use of such conceptually tailored tasks as a means for promoting students' progress from what they know to a transfer-enabling stage (anticipatory).*

## Background

How can one design tasks that draw on available conceptions of students with learning disabilities (LD) in mathematics to effectively promote their conceptual understanding of a key idea, including 'transferring' this idea to a novel, realistic problem situation? The present study addressed this problem, which is particularly vital for students with LD who, too often, are left behind when facing the challenges of reasoning multiplicatively. A common denominator of LD is a severe discrepancy between the student's academic achievement and his/her normal or near normal potential (Mercer & Pullen, 2005). "Mathematics disabilities represent a learning disorder that has specific cognitive, behavioral, and potential neurological profiles" (Geary, Hoard, Nugent, & Craven, 2007, p. 83). Research indicates that the mathematical performance of a 9-year-old student with LD remains at about grade 1 level; the gap grows over time, as a 17-year-old student with LD performs at about grade 5 level (Cawley & Miller, 1989). In the USA, two Federal Acts—No Child Left Behind of 2001 and Individuals with Disabilities Education Amendment (IDEA) of 2004—have mandated that students with LD should achieve the same rigorous academic standards as their peers. However, while procedural, rote memory approaches are common practice in special education settings, conceptual knowledge of students with LD has not been studied methodically (Geary et al, 2007), particularly not their learning to reason multiplicatively.

This study focused on how carefully designed tasks/activities facilitate the understanding of *schema of correspondence* (Piaget, 1965) and *double counting* (e.g., Steffe, 1994), which are fundamental to multiplicative reasoning (Vergnaud, 1983, 1988, Nunes & Bryant, 1996). We were particularly intrigued by the difficult-to-grasp scheme of mixed-unit coordination. In this scheme, a learner has to figure out the number of singletons (units of One, 1's) or numerical composite units (larger numbers, CU) that, combined, constitute two sets of objects. For example, a child may be presented with 5 groups (e.g., 'sport teams') of 8 items (e.g., 'players') and 24 additional single items, and asked how many players are in all, or how many teams can be

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

created if the 24 players were grouped, too. Mixed-unit coordination strengthens the understanding of what unit (singletons or CU) the student is operating on.

## Conceptual Framework

A constructivist perspective rooted in Piaget's (1985) and von Glasersfeld's (1995) core notions of assimilation, anticipation, and reflective abstraction, served as the overarching framework for this study. In particular, we used Tzur and Simon's (2004) recent distinction of two stages—*participatory* and *anticipatory*—in the construction of new mathematical conceptions via the mechanism of *reflection on activity-effect relationship* (Ref*AER, see Simon, Tzur, Heinz, & Kinzel, 2004). *Ref*AER* commences via assimilation of a task into the learner's extant schemes, which engender an anticipated global goal, and possibly sub-goals, toward which the learner carries out mental activity sequences with/on objects. The reflective process consists of two types of comparison the mind continually executes, through which learning—transformation in one's anticipation—occurs. Type-1 involves comparison between the learner's goal and the actual effect(s) of his/her activity. This allows the learner to notice effects s/he had not noticed before and relate them with the activity, hence re-structure their awareness (Mason, 1998, 2008). Type-2 involves comparison across his/her re-presented *AER* records. Common to both stages is the invariant anticipation of particular effects that follow an activity; the stages differ in the extent to which a learner has access to that anticipation. At the participatory stage a learner can only access an evolving anticipation if she is prompted for the activity that generates its effect(s). At the anticipatory stage, s/he can spontaneously access the anticipated relationship to consistently and properly employ it for solving similar tasks, that is, for the desired phenomenon that educators call 'transfer.'

The *Ref*AER* framework entails a particular stance toward design and implementation of tasks for promoting and assessing students' learning that elaborates on Simon's (1995) hypothetical learning trajectory notion. To promote learning, Simon and Tzur (2004) and Tzur (2008a, 2008b) suggested a cyclic process that necessarily begins with analysis of every student's available conceptions. To analyze such learning, Tzur (2007) proposed the fine-grained assessment method, in which tasks are sequenced from 'hard' ones (prompt-less) to 'easy' ones (prompt-inclusive). This method is consistent with several recent studies (Sullivan, Mousley, & Zevenbergen, 2004; Watson & Mason, 1998; Watson & Sullivan, 2008; Zaslavsky, 2007) as it focuses on identifying what in a learner's mathematics allows his/her to independently initiate activities that, via reflection, can bring forth intended changes in his/her conceptualizations.

The Explicitly Nested Number Sequence (ENS, see Steffe & Cobb, 1988) was the central content-specific notion that guided this study. ENS refers to a number scheme a child constructs in which abstract composite units (CU), integrated from units of one (1's), are embedded within and linked to one another. For example, 8 is nested within 9, is nested within 10, etc. Most importantly, such CU can be embedded within larger CU (e.g., 3 CU of 2 and 5 CU of 2 are embedded within 8 CU of 2). It is the ENS that underlies the foundational scheme, multiplicative mixed-unit coordination (mMUC), on which the present study focused. A critical aspect of the ENS is that the child's standard number sequence (1, 2, 3, 4, etc.) is used for counting two *distinct* types of units (CU, 1's) that must be explicitly differentiated prior to operating on/with them, particularly when it is possible to select and operate on the other.

## Methodology

This study was conducted within the larger context of the NSF-funded, *Nurturing Multiplicative Reasoning in Students with Learning Disabilities* project[1] (Xin, Tzur, Si, 2008). The second author (Ron) led a constructivist teaching experiment (Cobb & Steffe, 1983; Steffe, Thompson, & von Glasersfeld, 2000) to promote and study how seven pairs of 4th and 5th graders with LD construct multiplicative conceptions. The data presented in this paper focuses on five consecutive episodes with Chad and his partner Tara (pseudonyms), which took place at their elementary school's group education auditorium.

Data include the children's solutions to and the tasks posed in the context of a turn-taking, 'platform' game we call, "Please Go and Bring for Me …" (PGBM). Its basic version involves sending a student to a box with Unifix Cubes, to produce and bring back a tower made of a few cubes. After taking 2-9 'trips' for bringing same-size towers, students are asked how many towers (i.e., composite units, CU) they brought, how many cubes each tower has (i.e., unit rate, UR), and how many cubes (1's) there are in all (hereafter, $MT_N$ indicates $M$ towers of $N$ cubes; $7T_5$ means 7 towers of 5 cubes each). The PGBM game, and particularly its basic version, was designed to promote learners' anticipated creation of and differentiation among 1's and CU. These two anticipations are crucial if the learner is to ever construct the mental operation of multiplicative double counting (mDC, see Steffe & Cobb, 1998), that is, to operate with his/her single number sequence on two different unit types. A variation of PGBM, central to this study, was designed to promote construction of a multiplicative mixed-unit coordination (mMUC) scheme, which indicates the explicitly nested number sequence (ENS, see Steffe & Cobb, 1988). For example, a teacher may ask: "I covered $9T_6$ here and 18 cubes there. If you put all 18 cubes into $T_6$ and moved them under the other cover, how many *towers* will you have in all?"

Analysis began after each episode, with a team's discussion for noting major events and their significance. These notes served for planning tasks for the next episode(s) and for later, retrospective analysis. Next, team members read the transcripts of each episode and highlighted segments with critical events (teaching moves, changes in learners' anticipation), including conjectures as to why children solved or failed to solve a problem the way they did. This phase focused on two principal issues: the unit a child operates on and the operation s/he uses (Steffe & von Glasersfeld, 1985). Highlighted segments were then discussed retrospectively, to identify explanatory segments. All segments were organized in a story line (presented next) that interweaves theory-based tasks and prompts with our inferred models of the children's available and evolving conceptions.

## Analysis

We organize this section chronologically, along the 5 teaching episodes during which Chad progressed from having no idea of multiplicative mixed-unit coordination (mMUC) to the anticipatory stage of this scheme. This stage, as we predicted, enabled his independent solution of a novel, realistic task a month after the teaching took place (Episode 5). We briefly report on the first 2 episodes, as they served to lay the conceptual groundwork for Chad's learning during the 3rd episode. We culminate with data that indicate Chad's spontaneous use of the mMUC scheme to solve PGBM and realistic tasks (a week and a month later, respectively).

*Episode 1 – November 8, 2008*

The first teaching episode with Chad and Tara familiarized them with the PGBM game. All tasks were posed in the basic form—asking each child (in turns) to bring towers of cubes from the box at the top of the auditorium. After the towers were brought to the bottom of the auditorium and the *known* quantities were spelled out (# of towers=CUs, cubes in each=UR), the children were asked about the total number of cubes (1's). For $3T_5$ and for $3T_4$, Chad added the number of cubes three times; for $5T_5$ he used skip counting, apparently due to his familiarity with multiples of 5. Yet, for $4T_7$ he 'slowed down' and used counting-on from 7 into the second tower, from 14 into the third, and from 21 into the fourth tower. Although not yet fully intentional (anticipatory), Chad's solution indicated multiplicative double-counting (mDC) at least at a participatory stage. The episode culminated by the students sending Ron to bring $3T_9$, which he solved via skip counting (9-18-27) coupled with keeping track of CU on his fingers.

Using the PGBM basic form in *Episode 1* supported two key conceptions for Chad's later learning of mMUC. First, making one tower at a time oriented his awareness to the *anticipated* production of a *composite unit* via the activity of iterating the unit of One (1's). Second, it engendered his use of counting of CUs that he, or others (Tara and Ron), produced. Combined, these activities would underlie not only his mDC, but also differentiation and selection of the unit (1's, CU) he would need to operate on.

*Episode 2 – November 18, 2008*

The second episode focused on both promoting and assessing Chad's and Tara's *AERs* of *production*, *differentiation*, *selection*, and *operation* on 1's and CU. Starting with a task to assess a possible anticipatory stage of mDC for solving a measurement (quotitive) division task, we posed a 'What if?' form of PGBM: "Pretend we would put these 18 cubes in $T_3$, how many towers can you make before running out of cubes?" Chad spontaneously began counting, 1-2-3, 1-2-3, etc., and found he could make 6 towers. To see if Chad used mDC, Ron asked, "Could it be that [in your head] you did, 1-2-3 is '1', 6-7-8 is '2', and so on?" Chad confirmed, which led Ron to pose the follow-up task: "What if we added 9 more cubes and put them in $T_3$; how many towers would you have?" Here, instead of first operating on the 9 cubes and composing them into 3 towers, then adding those to the $6T_3$ (total = $9T_3$), Chad operated on 1's by adding the 9 and 18 cubes via counting-on, announcing the total was 27. Ron responded by first asking Chad if he meant '27 towers'; Chad confirmed. Ron asked him to make the towers, a task that was *particularly geared* toward orienting Chad's reflection on the actual effect of his composition of the 9 cubes into towers. As Chad completed his action and found there were only $9T_3$, he also noticed, and made explicit to himself and to Ron, his confusing of the units: "Oh, yeah, I meant 27 cubes." Indeed, Chad's inability to solve the mixed-unit task even within the context of producing and differentiating towers from cubes indicated that he has not yet constructed the mMUC scheme even at a participatory stage. It is this confusion among 1's and CU in a mixed-unit situation that became the focus of our ongoing analysis, and turned into a set of tasks designed for first promoting *explicit* unit differentiation.

*Episode 3 – December 2, 2008*

We began this episode to examine, and possibly claim, an anticipatory stage of a new conception. In particular, we asked both students to pretend they would bring $7T_3$ and figure out, in the absence of real cubes, how many cubes there would be in all. Already in answering the questions about the givens in the task ("How many cubes in each tower?") Chad's response ("7") indicated the aforementioned confusion of units. Unlike Tara who intentionally kept track of CU, Chad first just counted CU of 3 (1-2-3, 1-2-3, ...) to find the total. Thus, Ron replicated Tara's method—to possibly prompt Chad's re-activation of mDC. This intervention was useful, as Chad added keeping track to his counting of CU (1-2-3, 4-5-6, etc.). When Chad was done, Ron introduced the first among many statements of emphasis on the unit with which one operates as it relates (or not) to the answer requested in a task. That is, Ron initiated the socio-mathematical norm (Cobb, Yackel, & Wood, 1992) of *always* making explicit which unit a person is operating on and/or talking about.

The second task of this episode then moved to assessing the students' operation on CU. Ron asked Chad and Tara to pretend they brought 2 more $T_3$ and added them to the given $7T_3$, and to figure out how many such *towers* there would be in all. Consistent with our ongoing analysis conjecture, both students shifted to operating on 1's, figuring out there would be 27 cubes. Like in the previous episode, Ron asked to clarify if they found how many towers or how many cubes, and Chad realized ("Aha") that he responded in terms of cubes. Ron re-negotiated the aforementioned norm then moved on to a task designed for promoting unit differentiation.

The third task aimed to promote awareness to the difference between 1's and CU. Ron asked Tara and Chad to produce $9T_5$ and $7T_5$, respectively, and then name all differences and similarities they could detect between their sets. After announcing several non-mathematical ones (e.g., colors), Tara suggested and Chad agreed that common to both sets were 5 cubes in each tower. Next, Chad also noticed and used *counting-up of CU* to figure out a difference: "I got 7 [$T_5$]. I added 2 more and got 9 [$T_5$] so she got 2 more." Ron asked, "Two more what?" and Chad responded, "Two more towers." Then, Ron engaged them in solving how many cubes they had in both sets. Chad used mDC, skip counting by 5's and his 10 fingers (failed); later he used his 10 fingers and 6 of Ron's to figure out – 80. Thus, we turned to a task conjectured to bring forth Chad's first solution to a mixed-unit task, at least when prompted.

Ron showed Chad and Tara how he produced $6T_4$ (CU), then covered the towers. He then placed 12 additional cubes (1's) on the desk, and asked while pointing to those cubes: "If you put all of them in towers of 4, how many towers will we have?" Taking a few seconds to contemplate the task, Chad then spontaneously began manipulating the visible cubes into groups of 4, counted the groups, and (as he later explained his solution to Tara) used counting-on of $T_4$ to solve the task: "9." Ron repeated Chad's solution for Tara as well as to boost Chad's confidence: "If you put them in $T_4$, you have 3 of those [points to the groups of 4] and adding the $3T_4$ to the $6T_4$ will make 9."

Chad's (but not Tara's) successful operation in the mixed-unit situation included the following activity sequence: (a) selecting the singleton set (1's) to operate on, (b) composing them into groups of four 1's, selecting the proper quantity (CU) from the other set—6 *towers* (of 4 *cubes in each* with total of 24 *cubes*), and (c) operating 'additively' on the CU from both sets. We specify this sequence precisely because Chad was not yet able to anticipate it in its entirety in the absence of tangible objects.

For the last task, Ron produced $7T_5$ and covered them; placed 10 singletons nearby and covered them, then asked: "If we put those 10 cubes into $T_5$ and 'mush' them altogether with the $7T_5$, how many $T_5$ will we have?" This time, both Tara and Chad were at a conceptual loss. Quietly and persistently using his fingers, Chad seemed to mightily struggle with executing the activity sequence—but to no avail. After about 3 minutes, Ron decided to examine if Chad had constructed the mMUC at least at the participatory stage and, as a prompt, lifted *only the cover above the* $7T_5$. Soon after the towers became visible, Chad joyfully exclaimed, "9." In response to Ron's follow-up question Chad explained, while explicitly using his open hands to indicate a 'tower-of-five' on each hand: "Five right here (lays left hand on desk), and five right here (lays right hand), so that is 2 towers… so that is 1-2-3-4-5-6-7 [counting visible T5] and put 2 more like I did last time and [so we] get, 8-9."

There were three crucial pedagogical moves, explicitly informed by the *Ref*AER* account, in that last task of Episode 3. First was the increase in conceptual demand on the students' mental operations, via covering both sets of objects (1's, CU). This move proved powerful particularly when considering how the second move—prompting by lifting the cover—enabled Chad's completion of the activity sequence. Before the prompt, Chad could anticipate executing the first two components of the sequence (selecting 1's, composing them into CU), but not the third (selecting the $7T_5$ and adding the $2T_5$ resulting from the prior actions). Once prompted, Chad quickly reinstated his evolving, participatory stage of mMUC. The third move—asking Chad to explain his solution to Tara—opened the way for Chad's re-presentation of and reflection on records of his solutions to the last *two tasks*. It must be noted that Chad was not asked about the similarity between the situations; rather, he spontaneously and quite proudly announced they were alike. Thus, we argue that the reflection-orienting follow-up question opened the way for a *twofold* realization on Chad's part. He realized that his 3-step activity sequence, particularly the final step, produced an effect identical with his global goal in the task and that this activity-effect production was invariantly applicable across the last two tasks. Accordingly, we conjectured he might be able to independently solve such tasks in the next episodes. This conjecture, which amounts to saying we attributed to Chad an anticipatory stage of the mMUC scheme, was strongly confirmed (See Episodes 4-5).

*Episode 4 – December 9, 2008*

This episode consisted of 3 mixed-unit tasks, all posed within the context of PGBM in the absence of cubes. Chad solved all three with clear anticipation of the 3-step *AER* underlying the mMUC scheme. During the first task, ($5T_4$ & 8 cubes), he found out that 2 more towers would be composed, but lost track of the number of towers (not of the unit to operate on!) and added 4+2 to arrive at $6T_4$. He immediately corrected himself ($7T_4$) when Ron briefly lifted the cover above the $5T_4$. Then, Chad independently and straightforwardly solved the second ($7T_6$ & 18 cubes) and third ($9T_7$ & 21 cubes) tasks, though he experienced some difficulties explaining why the second would yield $10T_6$. Furthermore, unlike previous events in which a different answer by Tara would confuse Chad, her response (13) to the second task did not impact him whatsoever. We concluded that Chad had constructed the anticipatory stage and conjectured he would solve 'transfer' tasks in realistic situations in the same way.

*Episode 5 – January 13, 2009*

A month and a few holidays after Episode 4, Ron presented Tara and Chad with the following problem printed on a paper. "Grandma bakes chocolate chip cookies for birthday bags. She puts **6** cookies in each bag, and has already filled **9** bags. She now has **12** more cookies waiting to cool down. Once she'll put these cookies in bags, how many birthday bags ready for the party will she have?" Consistent with our theory-based prediction, Tara was unable to solve the problem (15, via adding 9+6), whereas Chad could again ignore her response, confidently announce, "11," and quite simply explain that grandma could fill 2 bags with 6 cookies in each, and hence 11 bags (9+2). Ever since, Chad solved any mixed-unit problem situation in a similar way and with much confidence.

## Discussion

This study contributed to two novel and important understandings. First, it showed how effective tasks designed on the basis of fine-grained assessment of evolving mathematical conceptions of a student with LD could be in promoting such students' learning. In particular, analyses of units (quantities—1's, CU, UR) a child operates on in situations that call for relating those units multiplicatively enabled designing a sequence of tasks, as well as creating on-the-spot follow-up prompts and questions that promoted transition to a participatory and then an anticipatory stage of mMUC. We claim that the latter, which is consistent with Steffe and Cobb's (1988) ENS construct, is the root for Chad's capacity to transfer his thought processes to the novel, realistic situation.

Second, this study demonstrated the possibility for effectively teaching students like Chad to properly reason (coordinate, or 'translate' quantities) in situations that are divisional in nature. That is, mixed-unit situations like those Chad successfully solved in different contexts (e.g., $7T_6$ + 18 cubes) require acting on the two sets by *segmenting* (Steffe & Cobb, 1998) the composite unit (18) with a given unit rate (6 cubes per tower, quotitive division) while maintaining the composite unit (set) of composite units (7 towers) of units (six 1's per tower).

# EXPLORING THE CHANGING PERCEPTION OF MATHEMATICS AMONG ELEMENTARY TEACHER CANDIDATES THROUGH DRAWINGS

Megan Burton
University of South Carolina
Burton3@mailbox.sc.edu

*Elementary teacher candidates enrolled in a mathematics methods course were asked to "draw math" at the beginning and end of the semester. Findings display the vision of mathematics that teacher candidates have before and after exploring teaching methods and implementing these methods with elementary students. In addition, it examines the specifics of the changes that occurred during the semester of methods and field placement experience.*

## Background

What is math? Often people reflect back to their vision of school mathematics, while others reflect upon its relevance to the real world when this question is asked. Vinter (1999) found that teachers often struggle to find the application of much of the math they teach. This can be due to the lack of meaningful experience with the content taught in the elementary grades (Ball & Bass, 2000). In addition to lack of experience with math, many elementary teacher candidates have high levels of mathematics anxiety (Swars, 2006). These factors can affect the impression of mathematics that teachers give to their students. Through examining their own perceptions of mathematics, teachers and teacher candidates can begin to explore how to deepen their own understanding, overcome anxiety, and connect the content to elementary students.

This article documents an elementary mathematics methods course, which begins by asking teacher candidates to draw math and write a few sentences describing the drawing. The drawings often involved students communicating and reflecting upon their emotions and past experiences associated with the content, including mathematics anxiety. In addition it became a theme of the course throughout the semester, inviting students to revisit their perceptions as various methods and content were introduced. This simple task provided insight into the perceptions teacher candidates bring to their teacher preparation programs and the impact that positive experiences with students and content can make upon these perceptions.

### *Drawing*

Student drawings have been used to examine students' perceptions about various content areas for years. In literacy, drawings of reading and writing have been used to understand their perceptions of the subject areas (McKay & Kendrick, 2001). Students' impressions and attitudes of scientists and science have been studied in many elementary and teacher candidate classrooms in order to understand student perceptions (Thompson et al., 2002). Drawing images before writing or verbalizing ideas can foster more creative responses and help generate ideas, because often language can slow down the creative process (Caldwell & Moore, 1991). Ideas can be explored through drawing without the cognitive demands often found when using language.

Art is often used in therapy, because thoughts and emotions can be expressed vividly through images (Lusebrink, 2004). These same techniques can be useful in supporting meta-cognition and addressing negative emotions often tied to mathematics by elementary teacher candidates. Drawings by teacher candidates of various subject areas can reveal dispositions, attitudes, and experiences related to a subject area. These drawings allow the artist to establish and reflect upon these attitudes and experiences in a non-threatening way (Rule & Harrell, 2006).

By acknowledging and giving voice to negative emotions and experiences, such as mathematics anxiety, through drawings, one is better able to deal with and move beyond those negative emotions and experiences (Rule & Harrell, 2006). This study relies on the theoretical understanding that the relationship between the conscious and unconscious mind can be expressed through images and thus given a voice where it otherwise might be ignored (Hillman, 1992). Often the negative emotions surrounding a concept, such as mathematics, develop in ways that distort original experiences. Instead reflection upon past experiences tends to reflect the current emotional attachment that has evolved over time and repeated experiences with that concept (Hillman, 1992). Sometimes images used to express the larger concept, such as mathematics, can be literature snapshots of a particular event and at other times they are more representational. However, both reveal a deep insight into the true relationship of the artist to the subject, such as mathematics (Rule & Harrell, 2006). By examining his/her own understanding and perception of a subject, the artists are better able to improve the negative emotions related to the concept and this in turn allows them to focus on the learning, without the obstacles associated with their negative experiential baggage. Watkins (1984) suggests that by investigating images and discussing feelings related to the images, the artists become empowered to engage actively in changing the negative perceptions related to the subject.

*Mathematics Anxiety*

Mathematics anxiety often begins in elementary school when students have negative interactions with the content and are taught by procedural, rather than conceptual teaching methods (Harper & Daane, 1998). Tying instruction to the exact procedures in the textbook, timed tests, hostile teacher behavior, embarrassing students in front of peers, only accepting one method of solving a problem, and lack of differentiation based on student needs are all factors that can contribute to mathematics anxiety (Swars, 2006). Hembree (1990) found the highest level of mathematics anxiety among college students came from elementary teacher candidates. To resolve mathematics anxiety, teachers need to have positive experiences with mathematics and see the purpose behind the mathematics they are teaching and have mathematical experiences with manipulatives and working in groups (Harper & Daane, 1998; Swars, 2006). Vinson (2001) found that exploring the conceptual content in meaningful ways with manipulatives before learning the procedural aspects of mathematics reduced the mathematics anxiety among teacher candidates. This impacts the way they teach their students.

When teachers are confident in their mathematics ability they spend 50% more time teaching mathematics than those who have mathematics anxiety (Schmidt & Buchmann, 1983). In addition teachers with math anxiety spend less time implementing standards based instruction and more time teaching to the whole class and assigning seat work (Bursal & Paznokas, 2006; Bush 1989). These activities perpetuate the notion that mathematics lacks real-world meaning.

*Perception of the Use of Mathematics*

Vinter (1999) found that many teacher candidates lack an applied understanding of mathematics and this in turn affects their ability to make the content meaningful for their students. Resnick (1987) suggests that many times teachers prepare students to do school math, but this is not the same as mathematics beyond the classroom. NCTM (2000) stresses the importance of problem solving, communication, and connecting math content, which requires teachers to have a deeper understanding in order to support these connections. Chappell and Thompson (1994) expressed the importance of the mathematical courses that teacher candidates experience in their preservice programs. The preservice program is crucial to the development of teacher candidate's beliefs, content knowledge and attitudes about the way math should be taught at various grades and their effectiveness as educators.

## Research Questions

1. What is the perception of mathematics held by elementary teacher candidates at the beginning of a mathematics methods course?
2. How do elementary teacher candidates perceptions of mathematics change during a mathematics methods course?

## Methodology

This study examined the symbolic representations of math drawn by teacher candidates at the beginning and end of a mathematics methods course. The drawings were analysed and categorized to explore the initial impressions of mathematics that teacher candidates bring to their teacher preparation courses and the changes experienced through opportunities to discuss anxieties, work with students, and explore various pedagogical theories for mathematics.

Sixty-two teacher candidates were enrolled in a mathematics methods course for elementary teachers at a midsized university in the southeast. The study took place over a period of two years with the same mathematics instructor, but four different sections all offered in the spring of their junior year. There were fifty-nine females and three males, fifty-five Caucasian, four African-American, and three Latino teacher candidates.

During the first class meeting, participants were asked to draw pictures of math. Teacher candidates were told to draw whatever came to mind and not to filter images. When they asked for further details about what to draw, the instructor simple advised them to draw what comes to mind about math. It was emphasised that the grades in the course would in no way be influenced by the drawings. Teacher candidates were asked to put the last four digits of their student identification number on the paper in order to compare pre-test and post-test results. Then they were asked to write a few sentences related to their drawing on the back of their paper.

During the semester teacher candidates spent one day a week in a practicum experience. In addition during the weekly three-hour mathematics methods course, each teacher candidate spent 30 minutes working with two fourth graders exploring various mathematics content. A portion of the methods course involved discussing the lessons learned from the fourth graders. In addition, teacher candidates explored various theories about teaching and learning mathematics, effective use of technology in mathematics, and the role of manipulatives in mathematics.

Throughout the class, there were informal conversations about the impressions of math that teachers bring to the classroom. Teacher candidates were able to evaluate the content and their experiences with their students with a conscious understanding of their lens that developed from their personal experiences as a learner. For example, those who understood algorithms were able to listen to students with misconceptions or invented algorithms. Teacher candidates who entered the methods course with hesitation due to their own struggles with math often found their struggles could help them relate and better explain the content to their students.

The same drawing activity was conducted the final day of class. Teacher candidates were asked to draw math and write a few sentences about it. In addition they were asked to write 2-3 sentences describing if and how the course changed their impressions. These drawings, and sentences were used to investigate the mathematics views held by the teacher candidates and the changes experienced over the course of the semester.

*Data Analysis*

The writing was used as needed for clarification of the meaning behind the drawings. Drawings were categorized in three ways: positive, neutral, and negative emotions; particular experiences and general meanings, and classroom, abstract or real world connection. Positive, negative and neutral were based on if the drawings or descriptions had specific emotional prompts, such as faces with smiles or tears. Next, the pictures were grouped by particular experiences or general meaning. Particular experiences were drawings in which one point in time was displayed, such as drawing on the board. When pictures simply had mathematical images such as a fraction, this was classified as general meaning, Finally, the drawings were categorized based on if the pictures showed images connected to the classroom, were abstract, or were connected to the real world. Pictures that were connected to the classroom displayed images such as books, teachers, or a white board. Abstract images were images such as fractions, multiplication problems and algorithms. Real world connections, had images such as shopping or cooking. This type of classification for analysis is based on the evaluation technique used by Rule and Harrell (2006). These categories were confirmed by a member of the mathematics education faculty. This faculty member evaluated and supported the initial findings, categories, groupings, and count. This confirmation provided validity of the interpretation. Then the analysis to determine the change was charted by grouping pre and post drawings and then analysing them for positive and negative changes. These findings were also confirmed by the aforementioned mathematics education faculty member.

## Results

*Initial Drawings*

Through the drawings and writings, teacher candidates expressed a variety of experiences and impressions of mathematics. A majority (32) of the experiences were negative. However, there were nine that were positive and twenty-one were neutral. All the positive drawings related mathematics to the content, real world examples, and puzzle. Most negative drawings related to the teacher candidates' emotions and experiences in school (see figure 1 and 2). For example, three people drew themselves at the board with question marks. Question marks seemed to be a common expression for teacher candidates to show their feelings of confusion. Also, many drew textbooks and jumbled ideas in their drawings.

*Figure 1*

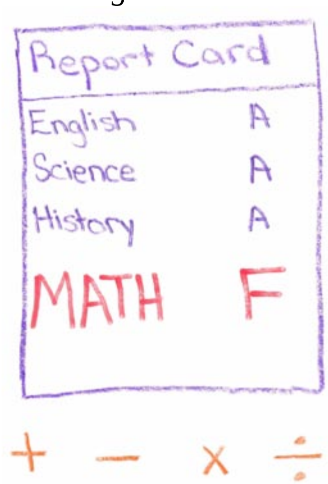

*Figure 2*

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

Table 1 shows the positive, neutral, and negative emotions connected to the drawings. A common thread for many of the negative drawings was the struggle that teacher candidates felt in school mathematics. One teacher candidate explained, "I never understand it. I always feel stupid and like what the teacher says is a foreign language." Several wrote sentences expressing the desire to change these emotions in order to avoid negatively impacting future students.

Table 1
*Categories of Drawings*

| | Pre-test | Post-test |
|---|---|---|
| Positive | 9 | 38 |
| Neutral | 21 | 24 |
| Negative | 32 | 0 |
| Particular Experience | 33 | 19 |
| General | 29 | 43 |
| Classroom Setting | 28 | 22 |
| Read World Setting | 7 | 11 |
| Abstract | 27 | 29 |

After analysing the emotions in the drawings, were categorized based on if they referred to particular experiences or were more general (see table 1). Thirty-three drawings displayed a particular point in time. For example one teacher candidate drew tears and question marks around an illustration of herself. In her writing she explained that she remembers her fifth grade math teacher being angry with her. She went on to describe a time she was at the board in fifth grade and had no idea how to solve the problem. She described this situation as representative of her feelings of math. Twenty-nine drawings were math symbols or items related to math, rather than a specific memory related to math.

The final category evaluated if the images related math to the classroom setting, real world setting, or were more abstract (see table 1). Many teacher candidates drew content images such as shapes, numbers, and equations. The abstract images had a mix of written responses varying between positive, negative, and neutral emotions. The teacher candidates who drew themselves cooking, shopping, or building all expressed a passion and conceptual understanding of connections, real world meaning, and reasoning essential to mathematics.

*Drawings of Change*

The experiences of teaching mathematics to fourth grade students during the methods course as well as exploring content in the methods course from a Standards-based approach (NCTM 2000) were positive for the teacher candidates. Fifty-eight teacher candidates reflected in the final writing, that they now saw the connections between the real world and the content they were teaching. While five were still hesitant and concerned about their own understanding, they expressed growth and a more positive perception of math. Thirty-eight of the final drawings and writings showed a new perception that math is fun, meaningful, and makes sense. Teacher candidates expressed more confidence in teaching mathematics, but also more confidence in their own personal mathematical abilities.

> I always thought I was bad at math and dreaded this course, but now I see that math isn't just memorizing stuff the teacher says. It is talking about stuff, exploring different ways of doing things, and thinking about what makes sense.

I am actually good at it, now that I understand that.

When the emotions attached to the final images were compared to the initial drawings a positive growth in emotional affect and reduction of anxiety was seen (see Table 1). The drawings that showed positive emotions in mathematics contained images of collaboration, manipulatives, real world connections, and discussions. There were no changes towards negative emotional connections to mathematics in the drawings. Those that initially drew positive drawings kept these, but several included more images of collaboration and simplified the mathematics in the drawings to match the mathematics that they will use in the elementary classroom. In the final drawings the images of specific classroom experiences were positive, rather than the negative images initially drawn. In addition, drawings displayed more collaboration and meaningful learning (see figure 3).

*Figure 3*

## Implications

These findings contribute to the body of research on perceptions of mathematics held by elementary teacher candidates. Several key findings provide insight into teacher candidates' perceptions and have implications for teacher education programs.

This study provided further evidence of the negative experiences teacher candidates bring to the classroom (Swars, 2006). It goes deeper than simply recognizing these negative emotions and experiences. It examines how teacher candidates view the concept of math. The details in the images provide visual understanding of the anxiety experienced by many. One interesting finding was the discovery that the negative experiences are often related to the classroom rather than real world math. This aligns with the work of Nicol, who suggests this lack of real world connection negatively impacts their students (2002). When teacher candidates connected math with real world experiences, they viewed math in a positive light and displayed confidence in the content.

When teacher candidates changed their depiction of mathematic to a more positive image, this included images of discussions, manipulatives, understanding, and connections to the real world beyond the classroom. Even when classroom images were the focus of the drawing, the writings on the back referred to the importance of making connections. Those who expressed math in a positive light at either the beginning or the end did not make references to textbooks, isolation, or working problems on the board. Instead meaningful, connected, and engaging math was the focus. By exploring the methods for teaching elementary content within a context connected to working with students, teacher candidates expressed a change in beliefs about the concept of mathematics as displayed in their drawings.

The connection between teaching children and reduction of mathematics anxiety aligns with Harper and Daane's study (1998). Because conscious reflections on attitudes can alter negative complexes (Hillman, 1992), the attitudes may have been changed through the symbolic analysis, which was both a part of the unique methodology of the study and a conscious reflective process. This is one of the reasons that the images can be analyzed, but assumptions about why they changed cannot be made. By having teacher candidates draw their perception of math initially, they were more aware of this throughout the course. Their emotions attached to math were a natural part of the conversations about methods and their experiences with students. These teacher candidates were challenged to draw their own perceptions of math and many used this opportunity to express their own problems they encountered in math as a student. This in turn made them more aware of problems students might have throughout the semester.

Teacher educators need to allow time for teacher candidates to reflect upon the perceptions and beliefs they bring to the classroom. This reflection allows teacher candidates to acknowledge their biases and begin to explore how to create more meaningful experiences for students (Rule and Harrell 2006). In addition time for teacher candidates to make real world connections between math concepts should be an essential portion of elementary methods courses (Chappell & Thompson, 1994).

While this study offers insight into the perceptions that elementary teacher candidates hold, further studies are needed. Continuing this activity by having teacher candidates at the end of internship and inservice teachers draw math could show how these perceptions change and are refined as they progress in their development as teachers as well as the sustainability of the newfound positive perceptions. In addition, it would be interesting to compare the images of inservice teachers with the students they teach in order to see the correlation of perceptions. Asking teacher candidates to draw, write, and explain their conceptions of math can further understanding into the mathematics anxiety that many experience, the pedagogical stances they bring into teacher preparation courses, and their understanding of connections between concepts and real world uses of school mathematics. These understandings can provide insight into supporting teacher candidates as they develop positive affect, effective pedagogical strategies, and content knowledge for teaching mathematics. These are all critical areas of development to increase student achievement and end the cycle of mathematics anxiety.

# TEACHING MATHEMATICS FOR UNDERSTANDING: THE SOCIAL CULTURE OF THE CLASSROOM

Cynthia P. Edgington
North Carolina State University
cpedging@ncsu.edu

*The purpose of this study is to examine the mathematics teaching cycle of two kindergarten teachers who took part in a professional development project that promoted culturally relevant pedagogy and teaching mathematics for understanding. The study examines if and how the teachers' lesson planning practices and their enacted lessons are consistent with the ideologies associated with culturally relevant pedagogy and teaching for understanding. This paper will focus on the social culture of the classroom, in particular how the teachers encouraged their students to develop their own strategies for sharing fairly and how those strategies were valued in the classroom.*

## Background

Recent reform efforts in mathematics education stress teaching mathematics for understanding in an environment that is accessible to all students (NCTM, 2000). Literature on the nature of teacher planning in light of reform efforts to change the teaching and learning of mathematics is sparse (Simon, 1995; Simon & Tzur, 1999). The majority of research on teacher planning is not specific to mathematics nor does it address how teachers attend to the cultural aspects of teaching and learning or what teachers need to do to promote learning mathematics for understanding (McCutcheon, 1980; Yinger, 1980; Zahorik, 1975). Additionally, research has not addressed how teaching mathematics for understanding and attending to students' cultural backgrounds can effectively be incorporated into teachers' lesson planning practices (Eisenhart, et al., 1993; Gutstein, Lipman, Hernandez & de los Reyes, 1997; Ladson-Billings, 1995; Putnam, Heaton, Prawat & Remillard, 1992).

In light of this gap in the research, this study aimed to examine the lesson planning practices and enacted lessons of two teachers who participated in a year long professional development project which promoted the development of culturally relevant pedagogy (Ladson-Billings, 1994) and teaching for understanding (Heibert, et al., 1997). The purpose was to examine if and how the teachers incorporated the ideologies associated with culturally relevant pedagogy and teaching for understanding into their lesson planning practices as well as their enacted lessons.

## Conceptual Framework

Due to the nature of the professional development project in which the teachers in this study participated in, this study is framed theoretically by tenets of culturally relevant pedagogy (Ladson-Billings, 1994) and Hiebert et al.'s (1997) dimensions of classrooms that promote teaching for understanding. Since the focus is on teacher planning in addition to classroom practices, Simon's (1995) mathematics teaching cycle will be used as a lens through which to view this phenomenon. This section provides details about each construct.

### *Culturally Relevant Pedagogy*

Research has emerged to examine the pedagogy of teachers that are successful at teaching students of color without disregarding their home culture. Ladson-Billings (1994) has coined the term culturally relevant pedagogy (CRP) and defines it as "a pedagogy that empowers students

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

intellectually, socially, emotionally, and politically by using cultural referents to impart knowledge, skills, and attitudes" (p. 17-18). CRP does not adhere to an explicit list of behaviors that if performed will ensure the success of all students, but rather is an ideology that may look different in different classrooms. CRP is supported by three general tenets: (1) academic success is experienced by all students; (2) students nurture and sustain cultural competence; and (3) students develop critical sociopolitical conscientiousness (Ladson-Billings, 1995).

*Teaching for Understanding*

Learning mathematics with understanding can be described as the ability to make sense of new knowledge by relating it and connecting it to what we already know. By drawing on the research of four large projects that focused on students' conceptions of multidigit addition and subtraction, Hiebert, et al., (1997) were able to characterize classrooms that promote students' mathematical understanding. Hiebert, et al. (1997) calls these critical characteristics *dimensions* of classrooms that support mathematical understanding and they are: (1) the nature of classroom tasks, (2) the role of the teacher, (3) the social culture of the classroom, (4) mathematical tools as learning supports, and (5) equity and accessibility. This paper will focus on the third dimension, the social culture of the classroom, in particular how students are encouraged to develop and share strategies and if these strategies are valued in the classroom.

*The Mathematics Teaching Cycle*

The mathematics teaching cycle was chosen because it is grounded in the constructivists' view of learning, and as such, is consistent with CRP and teaching for understanding. The framework design for this study utilizes the three major components of the mathematics teaching cycle: planning (drawing on teacher knowledge and the creation of a hypothetical learning trajectory), teaching (the enactment of classroom activities) and assessment (formative). In each of these components, the researcher used tenets of CRP and dimensions of teaching for understanding as the lens through which to analyze the data (see Table 1 and Figure 1).

Teachers whose beliefs are consistent with CRP and teaching for understanding will draw on these constructs during each phase of the mathematics teaching cycle. For example, during the planning phase, one might expect that a teacher would draw on students' prior knowledge, students' out of school knowledge as well as the teachers' own mathematical knowledge. During the teaching phase, one might expect to see a classroom culture where students are encouraged to choose and share their own methods for solving problems and where those methods are valued. In addition, there would be evidence of high academic success by all students and students would be communicating about mathematics in ways that are consistent with their cultural ways of expression. During the assessment phase, one might expect to see teachers' attend to how students are communicating and reflecting on mathematics and how student learning informs the teachers' own knowledge. This framework was used to drive the design of the study as well as direct the analysis of the data to answer the research questions.

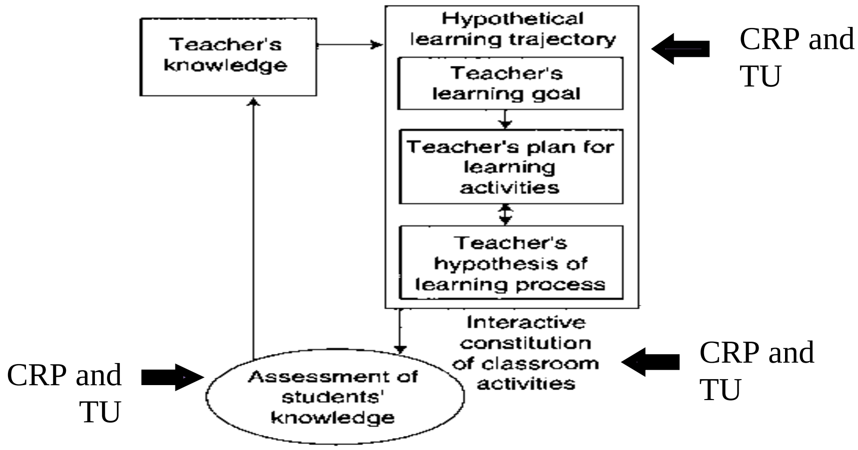

*Figure 1.* Mathematics Teaching Cycle (Simon, 1995).

**Research Questions**

1. What does a kindergarten teacher attend to in each phase of the mathematics teaching cycle?

2. Is there evidence of the ideologies associated with CRP and teaching for understanding with in each phase of the teaching cycle?

**Methodology**

*Context for the Study*

Participants in the current study were involved in Nurturing Mathematics Dreamkeepers (NMD), a professional development project for kindergarten through second grade elementary school teachers (for more information, see Marshall, 2008). Three cohorts of teachers from six local elementary schools were chosen to participate in the project. Each cohort of teachers attended professional development retreats for varying lengths of time (cohort I for three years, cohort II for two years, and cohort III for one year), where participants took part in various mathematical tasks aimed at improving not only their content knowledge and own mathematical understanding, but also their pedagogical content knowledge. In addition, teachers participated in a variety of activities where they were asked to engage in critical reflection on issues related to culture in the teaching-learning process.

*Participants.* This study involves two kindergarten teachers who were participants in the third cohort of teachers. Sarah is a white female in her twenty-ninth year of teaching kindergarten and pre-kindergarten. Pamela is a white female who has spent both of her two years of experience teaching kindergarten. Both teachers held undergraduate degrees in elementary education and had not received any specific training in mathematics instruction other than the curriculum training that was required by the county in which they teach.

*Sources of data.* Four sources of data were collected: a lesson planning interview, an observation of a lesson planning session, video-recordings of two consecutive math lessons, and a post-lesson reflective session. The lesson planning interviews as well as the lesson planning observation was audio recorded and transcribed. The lesson planning interview questions asked the teachers to describe and discuss what they attend to when planning their mathematics lessons. Questions were specific to content, types of activities, resources, assessment (both formative and summative), and student knowledge.

The math lessons and post-lesson reflective session were video recorded. The math lessons were described in five minute increments and portions were transcribed. The post-lesson reflective session was transcribed verbatim. The videotaped math lessons took place in the teachers' classrooms during their regularly scheduled math times for two consecutive days. On the first day, Sarah's math lesson was recorded first while Pamela observed, and then Pamela's math lesson was recorded while Sarah observed. On the second day, Pamela's math lesson was recorded while Sarah observed and then Sarah's math lesson was recorded while Pamela observed.

The reflective session took place four days after the second videotaped lesson. In the reflective session, the teachers discussed how their lessons supported or hindered their students' conceptual understanding of the mathematics and were asked questions regarding their students' out-of-school and in-school knowledge as well as if their enacted lessons followed the lessons they had planned.

*Analysis of Data*

The data was analyzed to describe what the teachers attended to in their lesson planning and what parts, if any, of their lesson planning and enacted lessons were consistent with culturally relevant pedagogy and teaching for understanding. In addition, the enacted lessons were compared to the lesson planning observation to determine if the lessons were consistent with what was planned. The four sources data were analyzed in three separate phases.

*Phase 1: Teaching planning.* First, the three transcribed sources of data (interviews, observation, and reflective session) were organized with respect to Simon's (1995) Mathematics Teaching Cycle and each piece of data was coded for instances of teacher knowledge, hypothetical learning trajectory (HLT), and assessment. Any parts of the data relating to teacher knowledge were then combined into one document. Similarly, new documents were created for parts of the data pertaining to HLT and assessment. The researcher then analyzed and coded each new document for what each teacher focused on in their lesson planning such as objectives, content, activities, materials, etc.

*Phase 2: Teaching for understanding and CRP.* During the second phase, each new document was analyzed for teaching for understanding and CRP. First, the documents for teacher knowledge, HLT and assessment were coded for evidence of teaching for understanding using Hiebert, et al.'s (1997) dimensions of teaching for understanding.

In order to analyze the data for evidence of CRP, the researcher initially coded with respect to the three tenets of CRP: high academic achievement, cultural competence, and sociopolitical consciousness. Once the data were coded, the initial codes did little to answer the research questions. More specific codes were created as sub-codes of the three tenets of CRP. Since CRP is an ideology, it may not be readily observable in a kindergarten classroom.

*Phase 3: Video-taped lessons.* In addition to the documents, the video-taped lessons were also coded for teaching for understanding and CRP. The lessons were viewed several times and then they were described in five minute increments. The lessons were viewed again and critical events were identified and transcribed. Then, the lessons were coded for evidence of teaching for understanding and CRP. The transcriptions included dialogue by the teacher and students as well as a description of any actions that were visible on the video recording. Lastly, the videotaped lessons were compared to the lesson planning observation to determine if the enacted lessons were consistent with what was planned.

## Findings

For the purposes of this paper, a specific dimension of teaching for understanding, the social culture of the classroom, will be described with respect to the teachers' mathematics teaching cycle due to the fact that this aspect of teaching for understanding was readily observed in the teachers' lesson planning and in their enacted lessons. Because of the nature of this dimension, one would expect to find evidence of classroom culture in teachers' lesson planning and in their enacted lessons. Therefore, this section will provide evidence of the teachers' social culture of the classroom first with respect to their lesson planning, and then with respect to their enacted lessons.

### *Lesson Planning*

*Planning for "fair shares"*. Sarah and Pamela did not plan collaboratively on a regular basis; however, because of the nature of data collection for the NMD project, they chose to plan their video-taped lessons together. The content they chose came directly from the North Carolina Standard Course of Study (NC DPI, 2003) for kindergarten: "The learner will share equally (divide) between two people; explain." This concept was also referred to by the teachers as *sharing fairly*. The teachers chose this content based on the fact that it was listed as an objective from the Standard Course of Study for the current quarter.

During the lesson planning session, the teachers began by stating the objective they wanted to cover. Sarah referred to a previous activity where her students struggled with the concept of equality and states, "So that's why I feel like we really need to do this." Sarah conveyed to Pamela the story *The Doorbell Rang*, by Pat Hutchins and stated that she had used the story in previous years and felt like it was relevant to the chosen objective.

The story is about a mother who offers her two children a plate of 12 cookies to share between themselves. After the children decide they will get 6 cookies each, the doorbell rings and in comes two more children. Now they must decide how to share the 12 cookies between four children. The story continues this way until each person has only one cookie and the doorbell rings one last time. Thankfully, it is Grandma with more cookies.

The teachers discussed using pretend cookies and plates to act out sharing the cookies fairly as in the story. Through their discussion, the teachers talked about how their students would learn fair shares and how to emphasize the idea of equality. They also discussed how to extend the activity for students who they believed could understand how to share an odd number of cookies. In thinking about strategies their students might use to share fairly, Sarah stated "…they'll be somebody…that will say 'Six? Oh that's three each. Eight? That's four each.' I have some that will do that." Other than this comment about students using known facts, they did not discuss specific strategies they would emphasize or other strategies they thought their students would use during the lesson.

### *Enacted Lessons*

*Day 1*. During the first day of the two day lesson, both teachers read the story *The Doorbell Rang* to their class and had the children act out the story by sharing 12 cookies between 2, 4, 6 and then 12 children.

Both Sarah and Pamela created a classroom culture where the focus was on students' methods for determining fair shares and not just the answer. Sarah and Pamela emphasized wanting to know students' strategies, frequently asking their students "What can we do to make it fair?" and "How did you know…?" However, neither teacher encouraged her students to reflect upon chosen strategies or how they were thinking about the mathematics involved.

The students in both Sarah's and Pamela's classes were encouraged to come up with their own strategies for sharing fairly and some students had the opportunity to share their strategies with the class during the first lesson. However, in Sarah's classroom, it was apparent that she did not value all of these strategies as she continually emphasized (and tried to get her students to emphasize) dealing out one cookie at a time until they were all gone, and then counting the cookies to determine how many each person had and if the amounts were equal. Sarah listened to the ideas offered and acted on some of them, but she was not content until a student suggested passing out one cookie at time.

For example, at the beginning of the story, Sarah's class is trying to determine how to share 12 cookies among two people. A student suggests giving each person three cookies. After Sarah passes out three cookies to each of two students, the class determines that there are still 6 more cookies left to share. Sarah asks her class "So how do we figure out how many more they can have? Who has an idea how we could figure out how to share it fairly?" Three different students suggest giving three of the remaining six cookies to each student to share the cookies fairly. Sarah verbalizes that this is correct, but continues to probe the class to find out "[What can I do] if I didn't know if there was enough for three and three? Is there another way we could do it?" Once the strategy of passing out one cookie at a time was offered, she was willing to continue on with the story.

In addition, Sarah did not ask her students to reflect on any of the ideas offered by their classmates. In one instance, a student suggested a strategy whereby she was able to count the cookies and determine how many each person should get. Sarah explained what she *believed* to be the student's thinking, however she did not attempt to have the student explain her strategy nor did she ask the class what they thought of this strategy. She continued to question the students and even put all the cookies back in the middle, until another student suggested giving one cookie to each person.

Pamela, too, encouraged her students to come up with and share their own strategies, yet she emphasized passing out one cookie at a time as well. Despite this, Pamela was more accepting of other strategies offered by her students than Sarah. Pamela was willing to act on students' strategies as long as they were correct. For example, when Pamela's class was trying to determine how to share 12 cookies among 4 students, a student suggested giving each person 3 cookies. Pamela modeled this strategy and even asked the student "How did you know to say give three to Adarian and three to Ally?" However, Pamela did not ask the class to reflect on the strategies suggested by students or the strategies she chose to model during the story. It was not clear if Pamela valued all of the ideas suggested by her students and in fact, only gave verbal praise to a student who suggested passing out one cookie at a time.

*Day 2.* On the second day, both teachers had their students work in pairs to share a set number of cookies between two people and then represent their answers in a table that they provided. In both classrooms, students were completing the activity, but they were not encouraged to discuss their strategies or explain how they determined fair shares.

## Discussion

In the context described by Hiebert, et al (1997), the social culture of a classroom that supports teaching and learning mathematics with understanding provides opportunities for students to choose methods that are meaningful to them. Additionally, Hiebert et al. (1997) state that "ideas, expressed by any participant, have the potential to contribute to everyone's learning and consequently warrant respect and response" (p. 9). By examining and reflecting on students' chosen strategies, teachers are valuing students' ideas and using these ideas as opportunities for learning. In this way, a mathematical community is created where students collaborate and communicate about important mathematics, thereby fostering mathematical understanding.

Both Sarah and Pamela created a classroom culture where the focus was on students' methods for determining fair shares and not just the answer. The teachers wanted their students to come up with strategies to solve problems and to communicate their ideas. During the planning phase, the teachers hypothesized about the importance of understanding equality and how their students might approach the chosen activities. Throughout the first lesson, both teachers encouraged their students to share their ideas and at times, both teachers acted on their students' suggestions about how to share the cookies.

However, the teachers did not appear to be open to the idea that all of their students strategies, both correct and incorrect, had value in the classroom. Both Sarah and Pamela focused on dealing out one cookie at a time when their students were in fact using more sophisticated strategies such as dealing out by two's or three's. Although it is unclear why the teachers did not choose to focus on the more sophisticated strategies their students came up with, during the post-lesson reflection they did state that they wanted to emphasize passing out one cookie at a time in order to explicitly offer a strategy for students who struggled with determining fair shares. Nonetheless, with respect to the strategies that were offered by their students, neither teacher encouraged their students to reflect upon and evaluate the strategies they used. In this way, the teachers did not appear to value the strategies offered by their students.

On the second day, the focus was less on the strategy that students were using and more on determining the correct answer when a certain number of cookies were shared fairly and filling out the table correctly. Although both Pamela and Sarah worked with individual groups of students to make sure they were sharing fairly, as students worked in their pairs, they used whatever strategy was meaningful to them and they were not asked to communicate about their strategies, only the answers.

*Implications*

With respect to the current study, it can be hypothesized that if the teachers had been more aware of the different types of sharing strategies appropriate for their students, they first may have been able to identify strategies other than dealing out by one at a time, and then secondly, may have been more accepting of those strategies. The findings from this study highlight the importance of teachers' knowledge on how students think about and develop mathematical concepts. Teachers can use literature on how students learn to inform their instruction. For example, in an article by Sally Roberts (2003) from the NCTM journal, *Teaching Children Mathematics,* teachers are offered ideas on how to teach fair shares and what strategies are typical of kindergarten students such as estimating, dealing out by ones, or grouping by twos or threes.

Furthermore, it should be emphasized that by merely having students share ideas, teachers are not necessarily valuing them. Teachers can allow students to not only share, but to also explain their ideas and use both correct and incorrect ideas as opportunities to develop students' understanding. By reflecting on and evaluating different strategies, students can build mathematical reasoning and extend their problem solving skills.

Teachers can choose appropriate classroom activities or tasks when they have information about how students may think about concepts and how those concepts can be developed over time. Through preservice methods courses and inservice professional development, teachers can gain insight into how students learn mathematics in order to accurately develop lessons that are meaningful and accessible to all students and that increase students' mathematical understanding. In addition, teachers can build on students' chosen strategies, encourage students to evaluate ideas, and use mistakes and misconceptions as learning sites for all students.

# A CROSS-CULTURAL CURRICULUM STUDY ON U.S. ELEMENTARY MATHEMATICS TEXTBOOKS

Hyun Jung Kang
Arizona State University
Hyun.kang@asu.edu

*The purpose of this paper is to report how U.S. elementary mathematics textbooks differ from other international curricula, specifically Korean national curricula. This paper further investigated the characteristics of the U.S. curricular within two opposite spectra, traditional and standards-based curriculum and extended the comparison with Korean textbooks. This study found that the Korean national curricula mostly emphasized on number and operation and both U.S. curricular was more advanced in geometry and measurement. The major difference between the U.S. curricula was its major focus on story and strategy based problems in standards-based textbook and more practice problems in traditional textbook.*

## Background

The findings from the TIMSS study brought considerable concern about the mathematics achievement of the U.S. students. One of the responses was the comparative curriculum studies with international textbooks in order to understand how the U.S. mathematics curricula differ from international averages. The textbook was a focus for two reasons. The first is teacher's high dependency of using textbooks in mathematics classrooms (Weiss, 1987 and Tarr et al 2006). The other reason was the importance of curriculum in terms of opportunity to learn, which means it is not taught unless it is introduced in the textbooks (Flanders, 1994; McKnight et al., 1987; NCTM Standard, 2000; Reys et al., 2004; Tarr, 2006).

## Theoretical Framework

Recognizing the need for the international curricular study, a number of research scholars examined the U.S. curricula in relation to students' mathematical achievement based on SIMS and TIMSS (Frase, 1997; NRC, 2001; Peak, 1996; Schmidt, W., McKnight, C., & Raizen, S.A., 1997; Reys, B.J., Reys, R.E., & Chavez, O., 2004). These researchers compared the mathematical content of textbooks on what content was introduced across participating countries. One major distinction found in these curricular analyses was that the U.S. curricular were not determined at the national level, as it was in most TIMSS countries (Frase, 1997). The above research scholars reported several problematic aspects of the U.S. mathematics curricula. Schmidt et al. (1997) described the U.S. textbook was 'a mile wide and an inch deep' (Schmidt et al. (1997)), which means the U.S. textbooks deal with too many topics in each grade with little emphasis on particular and strategic topics. He criticized covering too many topics as not facilitating students' higher achievement with deeper understanding. Flanders (1994) and Tarr et al. (2006) criticized the U.S. textbook focused less and late on algebra and geometry than international average. Another weakness was that the same topics were revisited repeatedly in the U.S. textbook (NRC, 2001 and Schmidt, 1997). They reported that in the U.S. curricula, multidigit computations were introduced over several years with one digit added each year, meanwhile, high performing countries introduced and develop such topic for students to master it within a specific grade level. These studies negatively valued this repetition because it defers students' mastery of concepts at a certain grade level. However, a Korean research paper which comparing the Korean national curriculum and Everyday Mathematics stated that repetition had a positive point. Seo et al (2003) argued that in Korean textbooks, mathematical concepts and skills were usually introduced once with little relation to the previous year, thus, the focus is placed on students' mastery of the concept at a specific grade level. They also criticized that this curriculum did not provide students with enough time and opportunities to learn important mathematical concepts and skills.

Other comparative studies criticized that in the U.S. textbooks, the topics persist over grade levels (Fuson et al (1998)). She reported that both the simplest and the most difficult multidigit addition and subtraction appeared and disappeared late (from 1 to 3 years) in the U.S. textbooks than other countries such as Japan, China, Taiwan etc. However, if extended this comparison to a Korean textbook analysis (Kang et al, 1998), even though Korea excelled in TIMSS, there was no difference between Korean textbooks and the U.S. textbooks, in terms of the first introduction time of multidigit number operation (Korean has 3.5 average grade level versus the U.S. has 3.4 grade level).

This comparative analysis implies that some factors other than the first instruction time possibly play a role in students' mathematical learning. Hence, there is a need for looking at how the concepts are developed within the chapter as Stein et al (2007) argued in his paper. He criticized that the previous curriculum studies primarily focused on what content was covered but rarely compared how the content was developed within the concept. He argued how the content was presented was also important because they set into motion different pedagogical approaches and different opportunities for students learning. For example, the organization of textbooks will be different depends on whether the developers believe that mathematics is best learned through student constructions or direct instruction and skill practice.

Along with above stated considerable critiques of the U.S. mathematics curricula, a number of mathematics educators developed elementary mathematics curricular to incorporate the ideas of the NCTM standards (1989, 1990, 1995). Even though the release of NCTM standard produced an entire new set of curricula there is not enough data analysis that compares international textbooks to the U.S. standards-based textbooks. The characteristics of the U.S. curricular described so far stood out more in the traditional U.S. textbooks. This brings an attention to the need for extending comparisons to both curricula, and to its organizations as well. Furthermore, it is necessary to broaden the comparisons cross culturally in order to evaluate the strengths and weaknesses of the U.S. curricula from an international perspective.

## Research Questions

In this paper, I extended the international curricula comparisons to Korea, which is one of the highest performing countries on TIMSS and made deeper comparisons with both the U.S. traditional and standards-based curricula. In addition to the topic placement in the textbooks, I also examined how three different textbooks - the Korean national, the U.S. standards-based and the U.S. traditional - were organized under three guiding questions. 1) What topics are placed in each textbook for both 1$^{st}$ and 4$^{th}$ grade? 2) How those topics are developed within the mathematical concept? 3) What is the main focus of the problems in the chapters (e.g. procedure based or strategy based)?

## Methodology

This paper investigated two mathematics textbooks currently being used in the U.S. elementary classrooms and the Korean national curriculum. One of the U.S. textbooks is research-based, developed through NSF funding and structured around the NCTM standards (standards-based). As a standards-based textbook, I selected the most recent edition of the Investigation series (2008) from Pearson: Scott Foresman, The other textbook is not research-based (traditional) and I chose 2007 Harcourt Math series which are widely used in the U.S. elementary schools. I considered it as traditional because although it references the NCTM standards, its structure is similarly to textbooks prior to the standards. As an extension of previous comparisons, I chose two fairly different US textbooks in terms of their characteristics and broadened the comparisons to the Korean national textbook which is dissimilar to the localized U.S. curricula. In order to analyze both lower grade levels and upper grade levels in elementary school I compared 1st grade and 4th grade of all three textbooks.

This comparison consists of three parts: 1) topic placement, 2) topic organization and 3) problem focuses. In topic placement analysis, the proportion of topic was main focus. In topic organization, I investigated the order of sequence of two major topics of elementary level, which were number and operation and geometry, and examined its highlighted mathematical ideas. In problem focus analysis, I classified all the problems as either 1) computation or procedure based problems when the problem asked for the answer or procedures without justification, or 2) story or strategy based problems when the problem was introduced with word problems and asked to the answer with reasoning or strategy. For the analysis of optic organization and problem focus I selected the multidigit addition and subtraction chapter for 1st grade and multidigit multiplication and division chapter for 4th grade because multidigit number operations are one of the most fundamental mathematical concepts for students.

## Result

Topic placement and organization of curricula differed from textbook to textbook across grade levels. There were unique features that stood out the most in each textbook and these features were somewhat different across grade levels. This paper reported the major differences among textbooks first and illustrated in depth comparisons later.

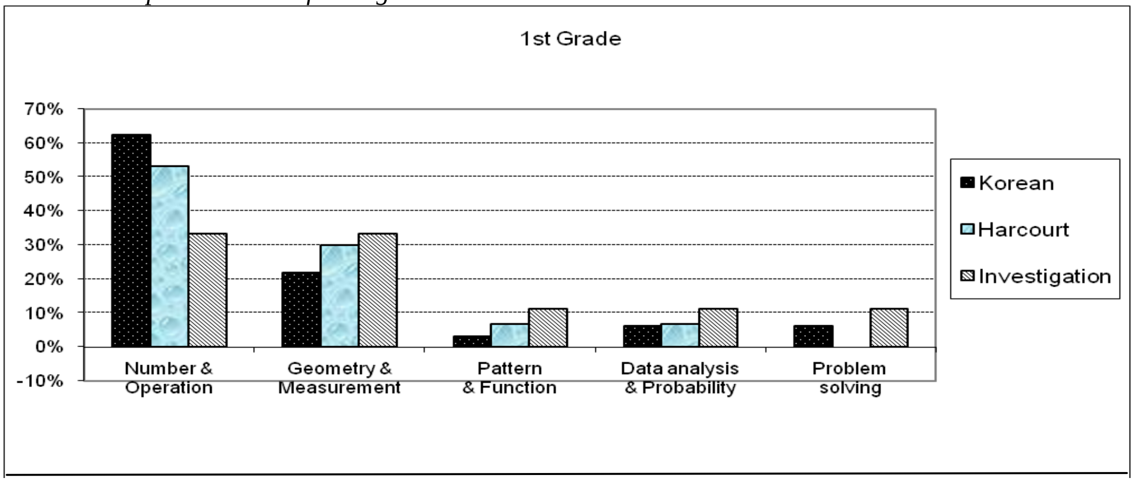
The most fundamental difference of the Korean textbook was its emphasis on the number and operation in both grade levels. It is not only because the Korean textbook dealt with the largest numbers across the grade levels, but also the Korean textbook highlighted the place value and number operations the most. For example, the Korean textbook included the activities such as counting objects, making groups of ten, and decomposing and composing numbers focusing on the combination of ten in 1st grade. Furthermore, in 4th grade, only the Korean textbook developed number sentences that contained all four operations (addition, subtraction, multiplication, and division) at the same time.

The highlighted features of Harcourt were first, the biggest number of topics observed from both grade levels. For instance, only Harcourt contained the fraction and probability concept for 1st grade and measurement of volume and circumference for 4th grade textbook.
The other was the emphasis of practice of number and operation. As shown in the table 2, Harcourt included the most number of practice problems for both grade levels.

In Investigations, activity based lessons and group discussion were the primary emphasis. In general, each chapter of Investigations started with student activities that included the mathematics concepts of that chapter and those activities were composed of group work. Another major focus of this curricular was the largest portion (about 35 %) of story based problems and the most flexible approach of using strategies.

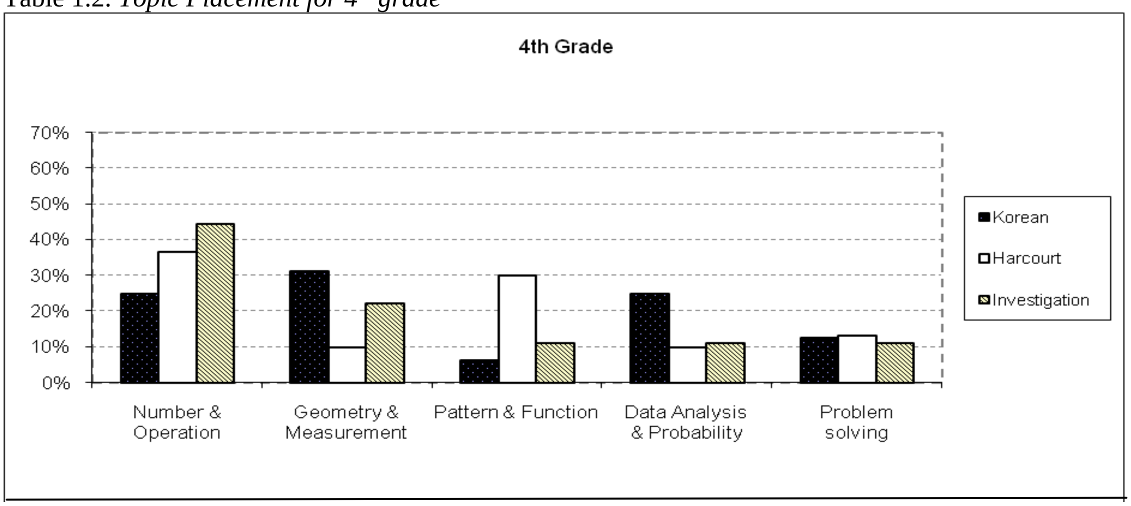
For in-depth analysis, the placement of topics was firstly examined. This section examined two aspects; what topics existed and the portion of such topic in each textbook.

Table 1.1. *Topic Placement for 1st grade*



This table illustrated that in the 1st grade curriculum. The Korean textbook focused the most on number and operations (62.5 %) than the U.S. textbooks (Harcourt - 53.3 % and Investigations - 33.3 %). This contrasted with the least emphasis of geometry of Korean textbook (21.8 %) than the U.S. curricular (Harcourt -29.9 % and Investigations - 33.3%). The critiques from the previous studies, less emphasis of geometry, stood out more in the U.S. traditional and Korean national curricula. However, the comparison was the opposite for the 4th grade curricular.

Table 1.2. *Topic Placement for 4th grade*



As shown in the table 1.2, Korean textbook included the least portion of number and operations (25.0 %) than Harcourt (36.7 %) and Investigations (44.4 %) at this grade level. The contrasting result by grade level continued to the geometry. The Korean textbook contained the most amounts of geometry (31.3 %) than both of the U.S. curricula (Investigations - 22.2% and Harcourt - 30.0 %) at 4th grade. The differences within other topics were not obvious at both 1st and 4th grade. The analysis of topic placement illustrated the proportion of each topic but it is necessary to examine in what order the topics were organized for deeper analysis.

Topic organization was examined focused on the sequence and the highlighted mathematics ideas under number and operation and geometry. In the analysis of the sequence, the central focus was how the same concepts were closely connected each other within the textbook especially when the same topics were revisited. First, the order of sequence was reported from 1st grade followed by 4th grade and key mathematical ideas were noted as the same order.

For the 1st grade, the Korean textbook included the least gap between number and operation concept and introduced such concept the earliest among three textbooks but it contained the least geometry concept. On the contrary, there was a largest gap in number and operation in Harcourt for this grade level but this textbook introduced the most advanced contents in geometry. Investigations was placed in between. For example, in Harcourt, chapter 20 introduced the addition and subtraction sums up to 20 but fraction came at chapter 21, then chapter 22-28 was all measurement. The similar leap was observed in Investigations. In this textbook, the number and operation concept was re-introduced five chapters later since it was introduced first time. This type of structure may be more difficult for the students to build number sense.

In the order of senesce of 4th grade, Investigations was placed in between Harcourt and the Korean textbook in terms of its distance. There were no significant gap different in number and operation but Investigations had the least gap among three textbooks. But when compared the content of number and operation, some major differences were observed. The first standing out feature was that only Harcourt included the concept of addition and subtraction of whole numbers (Chapter 1 – 4) at this grade level. Such concepts were not presented in other two textbooks.

Even though both of the Korean textbook and Investigations presented multiplication and division of multidigit number, there were differences between those two. Korean textbook dealt with multi-digit operations of multiplication and division as a mastery level, hence, such operations disappeared after chapter 1 and 2.On the other hand, both U.S. curricular introduced the concept of multiplication and division as a beginning level. This concept was introduced even later in Harcourt, which is in the middle of the book. Another difference within number and operation comparison was both Korean and Investigations began with multiplication first and related them to division later but Harcourt combined two concepts first and then introduced multiplication and division separately.

When compared the sequence of geometry in 4th grade, Investigations included the least gap than the other two. However, when compared the geometry concept of Harcourt and Korean textbook, the distance was bigger in Korean curricula. Chapter 17 through 19 of Harcourt covered lines, angles and plane figures and the chapters 28 to 30 covered measuring perimeter, area and volume of polygon. Harcourt provided explanation of general polygons first then moved to the measuring them at the end. On the contrary, Korean textbook explained learning angles and triangles first (chapter 4 & 5) and introduced quadrilaterals and other polygons at chapter 12. This structure provided less information to learn the relationships among polygons. Overall, Korean textbook introduced geometry concepts with least connection and relatively later compared to the U.S. curricula.

In addition to these differences, the highlighted mathematical concepts of each textbook were also dissimilar each other. This section was reported as the following order: 1) 1st grade number and operation, 2) 1st grade geometry 3) 4th grade number and operation 4) 4th grade geometry.

Firstly, the grouping number around 10 was highlighted the most in Korean textbook. When counting numbers, Korean textbook contained the activities to make a group of 10 and introduced only counting by ones and tens. Meanwhile, both the U.S. curricular introduced counting by twos, fives and tens equally without emphasis of grouping of tens. This pattern was repeated to the fact family. In Korean textbook, only the combination of 10 was introduced as a fact family but the U.S. curricular included fact family of 10 as one of other fact families.

How such concept was developed was dissimilar each other. Harcourt emphasized number operation the most than any other number concept hence it introduced the vocabulary and symbol first than the concept. However, both in the Korean textbooks and Investigations, number recognition, counting and composing numbers were explained first without symbols. In addition, Harcourt was composed of more operational problems than the conceptual problems, which will be discussed later in this section.

In Investigations, multiple strategies and conceptual problems stood out the most. This textbook introduced the highest numbers in counting (up to 200) and contained the smallest number of addition and subtraction (sums less than 20). It contrasted to the Korean textbook and Harcourt, which consisted of the same operation (sums up to 100) at this grade level. However, Investigations pushed more various strategies with the small number operations.

Yet, the different tendency was observed under the geometry. Compared to both of the U.S. curricular, Korean textbook included the least geometry contents and explained such concept limitedly. For example, Korean curricula only introduced three 3-D shapes (cylinder, cube and sphere) and three 2-D shapes (square, triangle and circle). However, both Harcourt and Investigations introduced more shapes such as cone, pyramid, hexagon etc. The central focus of geometry in Korean textbook was recognizing shape, and any other contents did not exist. On the other hand, both the U.S. curricula introduced geometric terms such as vertex, faces, sides and symmetry etc. and they also engaged with further geometric activities such as moving shapes. Within the U.S. curricular, the contents were pretty similar to each other.

Thirdly, in 4$^{th}$ grade comparisons, the difference among geometry concept was more significant than number and operation. Only Korean textbook contained separate chapters entitled 'order of operation (Ch 6)' which consisted of number sentences with mixture of all four operations (addition, subtraction, multiplication, and division), but none of U.S. curricular contained the same number sentences. Estimation related problems were placed separately under this chapter in Korean textbook, but in both U.S. curricular, the same concepts were embedded within the number and operation chapters. Even though Korean textbook contained the smallest portion of number and operation, those concepts seemed to be more advanced than the U.S. textbooks. However, the result was the opposite in geometry comparison.

The geometry comparison for 4$^{th}$ grade demonstrated the similar results as 1$^{st}$ grade but the difference became greater. For instance, Korean textbook did not contain the transformation of shapes and finding area of polygons but both the U.S. curricular were composed of measuring angles, perimeters, areas, volumes. Harcourt further added circumferences. No measurement was placed in Korean textbook and such concepts were introduced in 5$^{th}$ and 6$^{th}$ grades, which was 1 or 2 years later than the U.S.. Among the U.S. textbooks, Harcourt included the most number of topics such as congruent & similar figures, tessellation, circumferences, and diameter etc. which were not represented in Investigations.

A further comparable finding was that the U.S. curricular classified polygons based on the relationships across the shapes. Meanwhile, Korean textbooks tended to explain the properties of polygons limitedly connected the relationships among polygon. There was another dissimilarity that observed only at this grade level comparison, which was the different mathematical focus within geometry concept. The Korean textbook emphasized the angles of polygons hence it asked how to prove the sums of inside angles of triangle and quadrilateral but neither of the U.S. textbooks contained the similar problems.

The last analysis was to investigate the problem type of number and operation of each grade level. The result of each textbook was shown in table 2.

*Table 2. Analysis of Addition Problem Types for 1st and 4th Grade*

| | 1st Grade | | | 4th Grade | | |
|---|---|---|---|---|---|---|
| (N=total number of problems in the chapter) | Harcourt (N=220) | Korean (N=53) | Investigations (N=49) | Harcourt (N=145) | Korean (N=53) | Investigations (N=56) |
| Computation or procedure based problem | 200 | 36 | 31 | 129 | 49 | 36 |
| Story or strategy based problems | 20 | 17 | 18 | 16 | 12 | 20 |
| Percentage of story problems out of total number of problems | 9 % | 32 % | 36 % | 11 % | 22 % | 35 % |

Overall, for both grade levels, Investigations most often included story/strategy based problems and the U.S. traditional textbook had the largest number of practice problems but included the least number of story based problems. In the meantime, the number of problems was similar between the Korean and U.S. standard based textbook.

## Discussion and Conclusion

The results of this study brought some similar findings from the previous studies and dissimilar findings at the same time. Similar to previous studies (NRC, 2001; Schmidt, 1997), I found that the U.S. textbooks tended to revisit same topics in the previous year. Both in U.S. textbooks, multidigit addition and subtraction problems were represented in 4th grade textbooks, but, in the Korean textbook, the concept was introduced and disappeared only within the assigned chapter. Number sense and operations persisted across grade levels (NRC 2001) in the U.S. curricula but the U.S. reform curricula contained the most flexible way of number operation. Unlike the previous critique, both the U.S. textbooks were more advanced than the Korean textbook in geometry. Furthermore, the in-depth analysis of the textbook organization brought worthwhile educational implications in addition to the analysis of placement of topics.

The findings here highlight the demand of detailed comparisons of curricula from the opposite end of spectrum in U.S. and the need of broadening the study to cross cultural comparisons in order to improve written curricula. However, I believe it is also critical to develop the intended and implemented curricula for teachers who use traditional textbooks. This is urgent for teachers because it takes a long time and a lot of money to scale up reform curricula, even though researchers agree that reform curricula is more effective for students' mathematical understanding. How to use traditional textbooks is also effective if teachers can teach concepts with traditional textbooks. Therefore, research studies beyond the written curricula would help curriculum developers and researchers understand how curricula play out differently in student's mathematical learning and their achievement.

# PROPORTIONAL THINKING: A CASE OF STUDY

Elena Fabiola Ruiz Ledesma
Instituto Politécnico Nacional
efruiz@ipn.mx

Patricia Camarena Gallardo
Instituto Politécnico Nacional
pcamarena@ipn.mx

*a teaching proposal on ratio and proportion. A group of sixth-grade students (eleven years old,) of elementary education in México participated in the implementation of the proposal. The child of the case study was representative of those students in the group who had a lot of recourse to handling algorithms mechanically and whose elaborations made no sense at all, according to their answers to an initial questionnaire. A didactical program, developed in a problem-solving context for the research study, helped the child widen his qualitative thinking and strengthen his quantitative thinking about proportion.*

## Research Problem

The case study we present in this report was part of a research study carried out for a doctoral dissertation (Ruiz, E.F. 2002). Previously, other aspects and activities of that research have been presented and reported in various communications. The case study of our research is about a boy, Emilio, who solved ratio and proportion problems by having recourse to algorithms which made no sense and had no meaning at all.

By other hand, the topics of ratio and proportion beginning in the Primary School (Secretaría de Educación Pública, 2001 a y b, and NCTM, 2003), and they are the support for the other concepts, ( Clark, Berenson y Cavey, 2003).

We designed a teaching proposal embedded in this situation, with the aim of strengthening his establishing of solid connections between qualitative and quantitative thinking about proportion[1], so that he could improve his handling of algorithms by situating them into meaningful applications. The following question guided our research about Emilio´s case.

## Research Question

Does the extensive handling of qualitative aspects of ratio and proportion allow the student to widen quantitative relationships of these concepts as well as to improve the handling of her algorithms?

## Hypothesis

Enriching Emilio´s qualitative thinking -by using integrated verbal categories, recognizing the compensations posed between these categories, and involving the corresponding empirical and perceptual data- favors the significance processes he has developed by using algorithms for solving ratio and proportion problems.[2]

## Some Theoretical Antecedents

Piaget and Inhelder (1978a) pointed out, as a result of their experimental researches in education, that children acquire qualitative identity sooner than quantitative conservation. Thus, these authors made a distinction between qualitative comparisons and true quantification. According to Piaget and Inhelder (1978b), the acquisition of the notion of proportion always starts in a qualitative by using categories or classes of words. Our own interpretation of what is qualitative refers to what is based on linguistic recognitions by creating comparison categories such as big or small. Our interpretation is that what is qualitative consists of intuitive and empirical aspects as well, which are provided by our senses.

Piaget (1978) pointed out that the idea of order emerges during transition from the qualitative to the quantitative realm, although the idea of quantity is not yet present.

Piaget called these situations intensive quantifications. For us, this is what makes the transition from qualitative to quantitative thinking stand out.

On their part, Van den Brink and Streefland (1979) agreed with Piaget as to their research findings that qualitative aspects of thinking occur sooner than quantitative ones. However, Streefland usually had recourse to these findings in teaching contexts. In our approach for the designing of the didactical program as well as in the development of interviews for the case study of educational research we present in this report, we used that contribution by Streefland.

Research findings reported by Streefland (1984; 1985) emphasized that the early teaching of ratio and proportion topics must depart from qualitative levels of recognizing them. For that purpose, Streefland made use of didactical resources, which strengthen the development of perceptual patterns for supporting the corresponding processes of quantification. Streefland stated that qualitative reasoning evolves as the thinking of the child advances and he or she is capable of incorporating more elements for an analysis, which will allow him or her to consider different factors simultaneously.

Thus, since Piaget and Streefland took into account qualitative and quantitative thinking about proportion exhibited by their subjects under research, the rationale for our case study was strongly based on Piaget´s and Streefland´s findings. We based the didactical approach developed for our research on Streefland´s realistic mathematics approach.

Hart (1988) and her collaborators had reported results of their research studies on proportional thinking as well. They found out that most students who participated as subjects in their researches considered that it was difficult to solve mathematics problems that involved proportion. However, Hart and her team analyzed collected data and evidenced that younger students as well as pupils in secondary school with less success had a certain sense of “what is seen right” or of “what seems to be a distortion”. Hart designated the latter as a regulation from “common sense”, which we recognized as intimately involved in “qualitative thinking”. Moreover, Hart pointed out that the most advanced level of proportional thinking occurred in those subjects who had already constructed certain concepts.

We based the didactical context of our research on realistic mathematics education referred to by Streefland (1993). Realistic mathematics education has become a theory since reality is, in first instance, a source of information and the context for the application of teaching models, schemata, and notations-school productions that have an influence in social practice. This theory favors the development of research and practice of the teaching and learning of mathematics. Analogously, according to this realistic theory it is essential to link students’ learning periods by resorting to the “strategy of change in perspective”, which is characterized by the exchange of part of the information in the problem-situation being approached. Consequently, the possibilities for the reconstruction and production of problems become explicitly recognized by students, without losing their multifaceted conceptual richness, (Gueudet, 2007).

## Methodology

The research process of the case study of included integrating results from analyses of data collected from (a) his answers to an initial questionnaire, (b) a teaching program designed under a constructivist-didactical approach, (c) a final questionnaire, and (d) interviews of “didactical nature". The research instruments were tested in a pilot study of a one-year school cycle and definitively implemented during a ten-month period of fieldwork. In this case-study report we present relevant examples of the use of the research instruments.

*Participants*

Twenty-nine students of sixth-grade of elementary education in México, who were eleven years old, solved the initial questionnaire. We choose a child (Emilio), for a case study because he was representative of those students who, in the initial questionnaire, had a lot of recourse to handling algorithms that made no sense and who simultaneously exhibited few elaborations in the qualitative context. Throughout the development of the teaching experience, Emilio exhibited enrichment of his qualitative thinking and, in spite of making a lot of progress in the numerical context, he did not abandon the qualitative context of proportionality. He achieved a close harmony of both contexts.

*The Initial and Final Questionnaires*

The initial and final questionnaires were integrated by the same tasks, although their application had a different aim. The first questionnaire was applied for exploratory purposes, whereas the second one focused on evaluating the implementation of the teaching program. Eight months elapsed between the applications of both questionnaires: Thus, there was no influence of the first questionnaire on the students' answers to the second one.

The tasks included in the questionnaire did not involve the use of quantities for their solution: it comprised comparison activities that allowed the student recognize similarity relationships between figures.

*Didactical Program*

Figueras, Filloy, and Valdemoros (1987) defined *model* as a collection of teaching strategies which include meanings –of both technical and common languages–, didactical program, according to that definition, we designed several situations associated to "teaching models" so that Emilio could link his qualitative and quantitative thinking processes on proportion. We worked with those models at different stages of the research experiment, similarly to what Streefland (1993) pointed out in his realistic theory as to the "change strategy in perspective": We created a model and tried to get the best out of it in the light of an idea, so that we could retake it and use it for another idea.

## Analysis of Emilio's Progress by Comparing his Answers in the Initial and in the Final Questionnaires

In the initial questionnaire, Emilio exhibited a preference for using algorithms mechanically and very little work in the qualitative context. We observed that he almost did not use his common sense or visualization.

From the thirteen tasks posed in the initial questionnaire, he solved nine of them correctly.

The first two tasks in the questionnaire were designed so that Emilio could give justifications of his answers by strongly resorting to qualitative appreciations and not taking into account explicit quantities associated to the given relationships of proportionality. We employed squared paper in the next three tasks of the questionnaire to favor a transition toward quantification. The remaining tasks in the questionnaire involved quantified situations of ratio and proportion. In these last tasks, we provided Emilio with certain numerical values and asked his for new values. In some of these tasks we used a table of numerical values as a mode of representation for the recognition of external and internal ratios.

Now we present an analysis of two tasks Emilio answered incorrectly: task 1 and task 4. In task 1, the drawing of a car was presented and the student was required to select the correct reduced sketching of the original drawing (see figure 1). Emilio selected a sketching that did not correspond to the original drawing and he argued that his choice was the car C because it resembled best the original drawing. However, in the final questionnaire Emilio based his choice of the reduced drawing by having recourse to his intuition first and then by measuring each part of this drawing to obtain the ratios with corresponding magnitudes of the original drawing, although in his new explanation he mentioned again that "car B looks like the original car" and added that "it is similar, that is, proportional". Thus, we observed that, from the initial questionnaire to the final one, the expression "looks like" underwent a change of meaning for Emilio: he exhibited an understanding of the term "proportion" as the relationship of equivalence between two ratios (but he did not abandon his common sense, which was exploited throughout the teaching program).

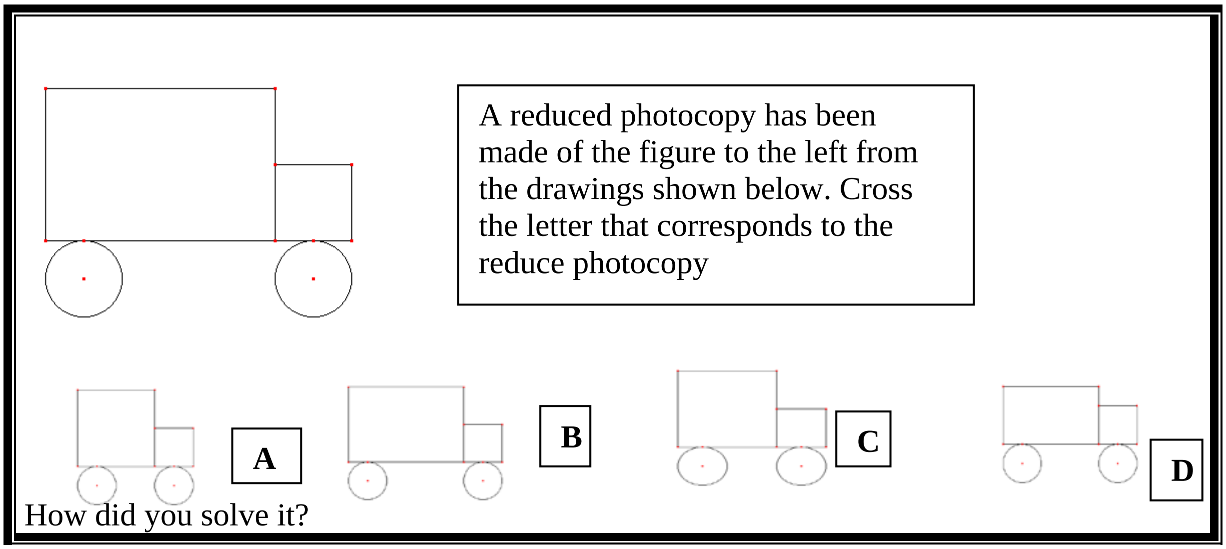

*Figure 1.* Task 1 of the initial and final questionnaires solved by Emilio.

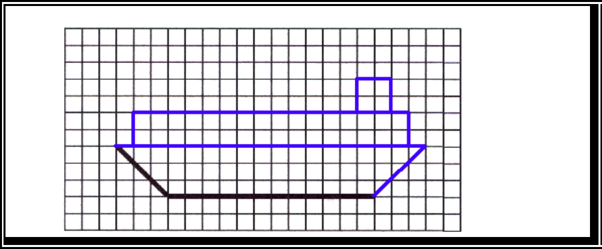
The answer that Emilio gave in the initial questionnaire was: “*The car C is the one which best resembles the original one”*, and the one he gave in the final questionnaire was*: “Car B looks like the original car. It is similar, that is proportional.”*

We can ascertain this based on other collected evidence: for instance, Emilio did not solve correctly task 4 in the initial questionnaire, but he did in the final one. It is important to make the explanations he elaborated stand out in this research study; they are included in figures 2 and 3. In the task 4 we asked students to make amplification the original drawing, and we give them a portion of the amplified drawing.

As shown in figure 2, Emilio completed the drawing but he did not notice that he had amplified it twice and not thrice. As seen from figure 3, Emilio showed the establishing of equivalence between two ratios that were obtained from comparing two corresponding magnitudes from the middle portion of the ship.



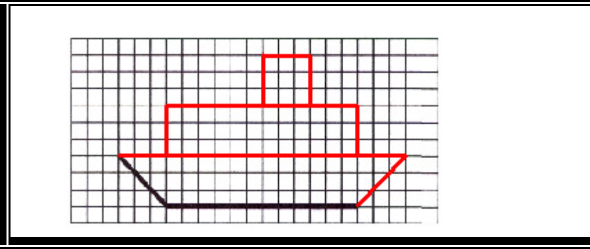


*Figure 2.* Task 4 solved by Emilio questionnaire.

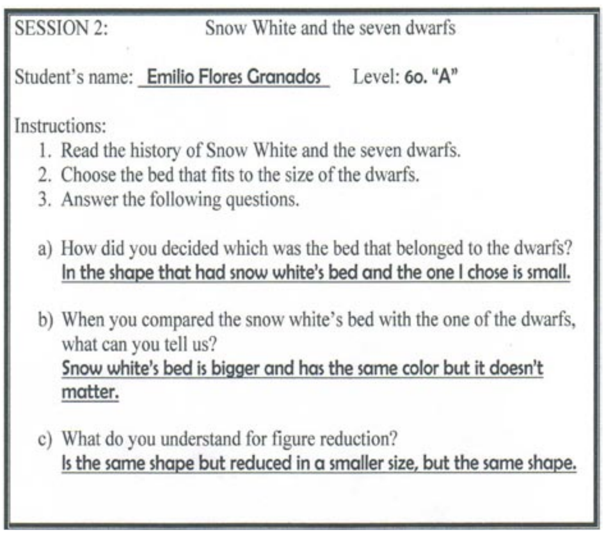
*Figure 3.* Task 4 solved by Emilio in the initial the final questionnaire.

**Analysis of Emilio's Progress during the Development of the Teaching Program**

The solution of different tasks employed during the development of the teaching program, such as comparison activities, involved using quantities. These activities allowed Emilio recognize—by using very intuitive terms such as reduction and amplification—similarity relationships between figures and he could enrich his qualitative thinking. We worked with those notions by referring to concrete situations of the type of the experience of reproducing a drawing to scale and of the idea of using a photocopier. In the figures 4 and 5, we show two activities that are part of the Didactical Program and that Emilio solved them. In those activities is shown the notion that Emilio has about the proportionality, after some working sessions and the relation between magnitudes to establish ratios, as well as equivalences relations between ratios.



SESSION 2: Snow White and the seven dwarfs

Student's name: Emilio Flores Granados Level: 6o. "A"

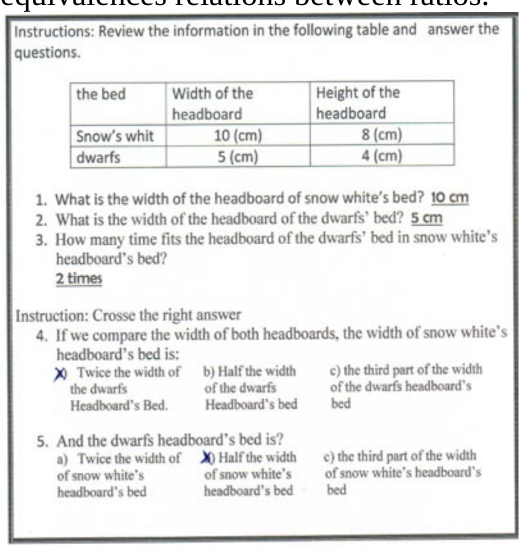
Instructions:

1. Read the history of Snow White and the seven dwarfs.
2. Choose the bed that fits to the size of the dwarfs.
3. Answer the following questions.

a) How did you decided which was the bed that belonged to the dwarfs?
In the shape that had snow white's bed and the one I chose is small.

b) When you compared the snow white's bed with the one of the dwarfs, what can you tell us?
Snow white's bed is bigger and has the same color but it doesn't matter.

c) What do you understand for figure reduction?
Is the same shape but reduced in a smaller size, but the same shape.



Instructions: Review the information in the following table and answer the questions.

| the bed | Width of the headboard | Height of the headboard |
|---|---|---|
| Snow's whit | 10 (cm) | 8 (cm) |
| dwarfs | 5 (cm) | 4 (cm) |

1. What is the width of the headboard of snow white's bed? 10 cm
2. What is the width of the headboard of the dwarfs' bed? 5 cm
3. How many time fits the headboard of the dwarfs' bed in snow white's headboard's bed?
2 times

Instruction: Crosse the right answer

4. If we compare the width of both headboards, the width of snow white's headboard's bed is:
X) Twice the width of the dwarfs Headboard's Bed. b) Half the width of the dwarfs Headboard's bed c) the third part of the width of the dwarfs headboard's bed
5. And the dwarfs headboard's bed is?
a) Twice the width of snow white's headboard's bed X) Half the width of snow white's headboard's bed c) the third part of the width of snow white's headboard's bed

*Figure 4.* Activity solved by Emil about proportionality using verbal categories.

*Figure 5.* Activity solved by Emil using quantities to establish ratios and equivalences relations between ratios

During the transition from qualitative to quantitative thinking, Emilio produced an ordering when comparing: he used the phrases "bigger than and smaller than". This finding agrees with what Piaget (1978) pointed out. Later on, Emilio took measures to make comparisons. First, he compared different objects by placing one figure over another and then by using a measure instrument. In terms stated by Freudenthal (1983), the resources exhibited by Emilio at this development stage of her thinking are called "comparers." After that, Emilio established relationships between magnitudes. He worked with natural numbers and employed fractions as well. Thus, at a very elementary level, he introduced his elf to the field of rational numbers. The boy of this case study could designate a ratio as a relation between two magnitudes and a proportion as an equivalence relation between two ratios. This designation agrees with definitions given by Hart (1988).

When the working sessions ended, Emilio showed he had achieved a close relationship between his qualitative and quantitative thinking. This relationship implied the sense she made of her work in the numerical context, which was not revealed at the beginning of his work. Eventually, when the teaching experience ended and the final questionnaire was applied. Emilio's meanings and quantification processes had been enriched. Now he could use a technical language in the designation context. He achieved a generalization stage in which new situations related to ratio and proportion were favored.

## Analysis of Emilio's Progress during the Interviews

Emilio was interviewed in three different occasions, once a week, after the teaching program ended and the final questionnaire had been applied. The main purpose of the interviews was to asses the teaching program. The interviews consisted of asking to solve new tasks which aims were similar to that of the didactical program and of the questionnaires. Additionally, the development of the interviews gave feedback to Emilio.

With the first tasks we posed Emilio during the interviews, through his solution processes we could observe how he kept qualitative aspects to the light of having worked quantitative aspects, and how important it was for his to use visual images as well as his perception ability. Through the next tasks in the interviews, we also investigated how he handled numerical tables to recognize ratios and express these as fractions. During the interviews he exhibited his use of internal and external ratios, his transition from one symbolic system to another, and his posing of a situation where the use of proportions would be necessary to solve it this first interview was closely related to the Snow White and the seven dwarfs teaching model. Next, we show the development and analysis of that interview. Emilio measured the length and the width of Snow White's wardrobe as well as the length and the width of each of the four drawings shown in the figure so that he could choose the required reduction. Once Emilio had chosen a wardrobe, he obtained the ratios between magnitudes of some of its parts and the corresponding parts of the original wardrobe. Now we show part of the interview with Emilio.

Interviewer: What did you base your choice of the dwarfs' wardrobe on?

*Emilio: I took measures and found out that wardrobe B is proportional to Snow White's because all their ratios are equivalent. (Emilio pointed to what she had written, "12/8 = 6/4=3/2.").*

*Interviewer: Will you please tell me how you obtained the ratios?*

*Emilio: By comparing measurements of Snow White's wardrobe with those of the dwarfs'.*

The numerator of each fraction measures certain part of Snow White's wardrobe: for instance, 12 is the length of the height, 8 is the length of the base, 3 is the length of one little window (she pointed to one of the drawings representing a decoration of the wardrobe), and 1.5 is the width of this little window. The denominators of the fractions are the measurements of the corresponding parts of the dwarfs' wardrobe. (The measurements Emilio mentioned are given in centimeters.)

Thus, Emilio established links to determine ratios based on taking measures. In another part of the same interview we could observe how he had recourse to his perception ability when he said, "*Wardrobe A is too long, C is very wide, and D is very little. Although I did take measures, I noticed that those three wardrobes did not seem proportional to Snow White's."*

Emilio exhibited that his handling of conceptual aspects was meaningful since he identified ratio as a relation and proportion as an equivalence relation between ratios. Moreover, we could notice that Emilio did not abandon the qualitative context, since he also used verbal categories and common sense to verify that his choice of the wardrobe was the right one. To this respect, he wrote that Snow White's wardrobe was equivalent to that of the dwarfs, and that as to their form they were equal although one was small and the other was big.

## Conclusions

Emilio exhibited a strong progress in relation to two important aspects:

1. The development of her qualitative thinking in relation to ratio and proportion.
2. The signification he gave to his using of algorithms.

During the processes of solving different tasks, Emilio exhibited how strong perceptual data became for his as well as how important it was for his to rely on his own experience. This is evidence about his achievements in the qualitative context of proportionality. The algorithmic work allowed us to explore the tacit recognition of the operators about which Emilio was thinking. These operators were natural numbers as well as fractions. The latter were used implicitly when multiplying certain value by a number and then dividing the result by another number, or vice versa, first dividing and then multiplying. In the context of what is now considered the construction of meanings, these—together with the processes of signification—were enriched. As to their designation, Emilio could eventually use the appropriate mathematical terms. Finally, he reached the point of constructing the concepts of ratio and proportion. This achievement was evidenced by the applications he made of those concepts in different contexts as well as by using their different modes of representation.

## Footnotes

1. The qualitative thinking is supported by linguistic recognition creating comparison categories such as big, small. In the qualitative is included the intuitive that is the supported in the experience, the empiric, in the senses. The quantitative refers to activities that allow the student to count, to measure, to use quantities in the procedures

2 According to Benveniste (1971), meaning is a “dictionary entry” and “a universal semantic category”; and sense is a semantic content, which is associated to particular constructions of language, it does not shape universal categories and usually keeps a close relation to specific modes of articulating them. Moreover, it is proper to emphasize that there is not a chronological sequence, or of precedence, in the development of sense and meaning. They are different semantic components, which complement each other.

# TENSIONS OF ADOPTING ELEMENTARY MATHEMATICS CURRICULUM MATERIALS IN A DIVERSE DISTRICT

Corey Drake
Iowa State University
cdrake@iastate.edu

Michelle Cirillo
University of Delaware
mcirillo@iastate.edu

How do school districts make decisions about the adoption of new elementary mathematics curriculum materials? Although these decisions are made annually at school districts across the country, little is known about the questions district leaders ask when adopting new materials, the kinds of evidence they consider, or the tensions and challenges involved in the decision-making process. In this paper, we present a case study of one district, River City (pseudonym), adopting new curriculum materials. We claim that the issues, questions, and tensions experienced in River City can inform the work of districts adopting new materials in the future.

River City is a district of 38 elementary schools serving approximately 14,000 students (~55% eligible for free and reduced lunch). In this district, textbooks are seen as just one among many tools teachers might draw on in designing instruction. The district mathematics leader articulated this vision of the relationship between teachers and curriculum materials and its relationship to the adoption process in the following quotation:

> I want teachers to have the freedom to make professional decisions based on their students and yet, I understand the need for that additional task to be taken off someone's plate who just doesn't have the time, the energy, or the knowledge….but I feel as if we were to purchase *a* material, then why would teachers ever read *Teaching [Children] Mathematics*? Why would they ever go to the NCTM web site? It almost appears as if we're turning our backs then on other things that could be valuable supplements, enhancements, or replacements.

The materials evaluation and adoption process initially proceeded quite smoothly. Without significant debate, the committee agreed on three programs for more in-depth consideration: *Investigations* (TERC, 2008), *Math Expressions* (Fuson, 2008), and *Math Trailblazers* (TIMS Project, 2008). It was in the process of considering these three programs that two key tensions arose. The first tension involved identifying a single set of curriculum materials that would meet the diverse needs of all of the *teachers* in the district. The second tension involved the levels of professional development and teacher learning required by each program and whether it would be best to adopt a high risk (in terms of demands on teacher learning), but also high reward (in terms of moving the district forward) program (*Investigations)* or to adopt a program (*Math Expressions*) that would represent more incremental and less risky change for most teachers, with the assumption that more teachers would be likely to implement a program that required less of them. It is important to note that members of the committee were not necessarily making judgments or assumptions about the willingness or the capacity of individual teachers for change, but instead about the capacity of the district and the curriculum programs to support the significant change that would be required. In the poster, we present more details about the process, as well as the eventual outcome.

# TRANSITION FROM ARITHMETIC TO ALGEBRA: A TEXTBOOK ANALYSIS FROM AN ASIAN PERSPECTIVE

Tingting Ma
Texas A&M University
ting@tamu.edu

Mathematics educators and researchers have increasingly recognized the gatekeeper role of algebra in preK-12 schooling (Carraher & Schliemann, 2007). Previous research highlights the importance of integrating arithmetic and algebra in early grades (Carpenter, Franke, & Levi, 2003). In Asian countries, students are exposed to algebraic thinking in textbooks much earlier than their U.S. peers (Cai et al., 2005). To investigate the transition from arithmetic to algebra, this study examined the features of introduction to algebraic thinking in selected Asian elementary mathematics textbooks.

The textbooks chosen for this study consist of two series of new *Standards*-based elementary mathematics textbooks in China and one series of widely adopted elementary mathematics textbooks in Singapore. Through the theoretical lens of Kieran (2004), this study adopted qualitative methods to examine and analyze the selected textbooks.

The main findings of the study include: First, introduction of algebra in Chinese and Singaporean textbooks is characterized by patterns and generalization. For example, in one Chinese textbook, students are asked to generalize from a popular Chinese nursery rhyme, *Count Frogs*, by filling in "n frogs, ____ mouths". Second, Chinese and Singaporean textbooks address difficulties and misconceptions of the equal sign and variables as a unidirectional operator and placeholders, respectively. Chinese textbooks present equations with numbers on both sides of the equal sign, followed by equations with one variable on one side of the equal sign. For example, 5=5, 5**+2**=5**+2**, and x=10, x**+5**=10**+5**. Singaporean and Chinese textbooks also present various forms of the multiplication sign. For instance, an expression of 3p can be written as 3×p or 3·p. Third, by emphasizing such topics as relating equations containing numbers alone with equations containing numbers and variables, and interpreting and simplifying algebraic expressions, Chinese and Singaporean textbooks help students make adjustments and transit from arithmetic to algebra.

This study extends our understanding of transition to algebra in early grades and has implications for curriculum development in algebra in the U.S.

# PRE-SERVICE TEACHERS' KNOWLEDGE AND ATTITUDE PROFILES: RESULTS OF A MIXED METHOD DESIGN

Immaculate K. Namukasa
The University of Western Ontario
inamukas@uwo.ca

Kinful Aryee
The University of Western Ontario

*There is a growing trend in mathematics teacher education on researching the nature of pedagogical content knowledge required for teaching. In what unique ways can rich mathematics problem-solving experiences contribute to pre-service teachers' understanding of subject matter and pedagogy? We research an elementary pre-service program that since 2004-2005 added a rich mathematics problem-solving component to its mathematics methods course. Specifically, we will report the results of a survey that studied elementary school pre-service teachers' cognition and affective responses at the end of the program. The conference poster will show case knowledge and attitude profiles of pre-service teachers. These profiles created from mixed methods survey data.*

There is a trend in mathematics teacher education on researching the nature of mathematics required for teaching (Ball, 2002). Many elementary pre-service teachers' classroom experiences have been negative, even when positive, have left the pre-service teachers with a narrow understanding of what doing mathematics involves (Cooney, 1999). Many researchers conceive that re-organization is one of the major roles of teacher education courses. They present varied tasks as forms of intervention and preparation. The program which we research uses rich mathematics problem solving. Teachers and students need to experience a *better, re-conceptualized* mathematics. "The underlying premise is … to allow them [teachers] to understand and reconstruct what they know with more depth and meaning" (p. 230, Ponte & Chapman, 2008). In our work we focus on ways to get teachers to engage in doing *warm* mathematics, specifically non-routine problem solving (Namukasa, Gadanidis & Cordy, in press). The study is guided by complexity research in education. In a manner consistent with most research on mathematical affect, complexity research asserts that the cognitive and the affective are closely interwoven. Complexity research also recognises the need for mixed methodologies (Day, Sammons, & Gu, 2008). The methodology for the study combines interpretive and survey study. Beginning 2004 we collected qualitative data from students' written work interview transcripts. In 2007, in an attempt to corroborate our methodology we designed a survey questionnaire on mathematical knowledge and beliefs. The survey is descriptive and explanatory. In 2008-2009, 150 candidates completed the pre-program and post program questionnaire for instruction and evaluation purposes. This poster illustrates pre-service teacher's knowledge and attitude profiles that were created from data from a small preliminary study with 20 participants carried out in 2007-2008. The profiles are an example of results from a mixed methods research and assessment design.

# AFFECT AND RACIAL/ETHNIC ACHIEVEMENT DISPARITIES

Michael H. Davis
University of California Berkeley
micdavis@berkeley.edu

*This paper reports on an exploratory study on the role of affect in mathematics achievement disparities. Qualitative data was used to develop a survey (N = 513) to examine relationships between students' emotional experiences during class and their perceptions of group work, relationships with teachers and mathematics achievement. Analyses were conducted by racial/ethnic group. Results for African American students were significantly different than those for students from other groups, including: negative emotions were more associated with lower grades, and less frequent negative emotion was more associated both with positive views of group work and stronger relationships with teachers.*

## Introduction

Affect influences how students perceive assignments, relate to teachers, participate in class, and ultimately their achievement. This paper reports on exploratory research into how affective issues may contribute to achievement disparities in mathematics. More specifically, the study reported here considered negative emotions and analyzed how these emotions relate to students' perceptions of group work, relationships with teachers, and math grades.

The research was conducted at a medium-sized, urban, public high school with a diverse student body (no racial/ethnic group was in the majority). The school had a mathematics department that in many ways matched the ideals promulgated by leaders in the field of mathematics education. Teachers were predominantly mathematics majors from top schools and credentialed by leading programs. They worked collaboratively on developing norms across classrooms and improving teaching practices and materials. They were involved in professional organizations and maintained connections with the higher education community. They used high quality mathematical tasks for their courses and emphasized group work, multiple representations, and conceptual understanding. In addition, they made serving all their students a priority. Their classes were untracked. They had a block schedule. Extra help from teachers was available daily, before school, during lunchtime, and after school.

However, analyses of achievement trends found that African American students, males in particular, had not benefited to the same degree as students from other groups from their otherwise successful implementation of reforms. Differences in SES cannot account for these differences because the student population is from working class homes across races.

Department leaders reached out to the research community for help understanding and addressing the observed achievement inequity. The paper reported here is part of a larger project to help in these efforts. This school site and its mathematics department provide a particularly rich context to explore issues related to equity in education. It differs from the more commonly documented under-resourced schools, where there is often a lack of will or skills to address the challenges of promoting equity.

The initial focus of the research was to understand the school and the mathematics classrooms as social spaces. Toward that end 300 hours of observations were conducted over a three-year period, primarily in mathematics classes, but also in other courses, extracurricular and social contexts within the school. At the conclusion of each academic year interviews were conducted that explored students' views of themselves, their school, their attitudes toward mathematics, and their experiences in their mathematics classrooms (N = 60; African American N = 45). All data sources were open coded. This qualitative research had several important findings. First, literally, all the African American students interviewed reported caring about their grades and viewing mathematics as important for their lives (Davis, 2008). (Consensus on the importance of mathematics may be related to departmental norms regarding communicating mathematics' value to the students.) Additionally, students uniformly showed disappointment or dejection with low marks and protested when they thought they deserved higher grades. Despite their commitment to achievement the students frequently did not engage in mathematical activities as expected by their teachers. Many students reported and were observed experiencing and expressing intense negative emotion during mathematics class, including physical rage and crying.

Anger and frustration frequently emerged when students confronted assignments they could not understand. Also, many students spoke about fear of exposing incompetence. These reports fit with observational data. Students were often reluctant to share their approach to a problem unless they were confident it was correct and became agitated when pressed by their teachers and peers. Importantly, some factors seemed to be associated with less intense negative emotions. Students who understood and endorsed group-learning practices and had stronger relationships with teachers appeared to experience less negative emotion. It also seemed that these students engaged more frequently in group work activities as expected by their teachers. For example, one such African American student commented that he volunteered to present his work on problems when he was confused because he knew that he would get the support of his classmates in understanding the problem.

Our qualitative data (referred to above) focused heavily on African American students. It seemed that similar issues were playing out for students across racial/ethnic groups. However, it also appeared that African American students more frequently confronted the types of negative emotions described above. Moreover, we suspected that these emotional experiences might contribute to disparities in mathematics achievement and be alleviated by particular pedagogical approaches. Therefore, we investigated the role of negative emotions in student achievement across racial/ethnic groups and the degree to which students' perceptions of group work, personal connections to teachers, and mathematical identities were related to these negative emotions. We also examined how these relationships varied across racial/ethnic groups.

## Literature Review and Theoretical Perspectives

The focus of this study cuts across several different bodies of research. As is often the case with exploratory research, there is not an established body of directly relevant research. This review considers relevant studies on affect in mathematics, stereotype threat, and reform mathematics. It concludes with some theoretical considerations about emotion and cognition.

Research on affect in mathematics education has focused primarily on beliefs and attitudes and has not attended as much to more "hot" emotions, such as anger, fear, and shame (McLeod, 1994). Studies that do consider emotion have been mostly limited to the investigation of math anxiety. Although these studies have consistently found significant relationships between levels of anxiety and performance, they have either not considered race or found no differences between racial/ethnic groups (Ma, 1999). McLeod (1994) argues that researchers in this field have not attended sufficiently to the characteristics and experiences of their subjects. This limitation, in conjunction with investigating an insufficiently broad range of emotions may have contributed to finding no differences across racial/ethnic groups.

Other research suggests that there may be interactions between race, context, emotion, and cognitive performance. Stereotype threat research has shown that increasing the salience of an identity that is stigmatized in the domain tested can have detrimental effects (Aronson & Steele, 2005), including African Americans in mathematics (Steele & Aronson, 1995). Although research on causal mechanisms for these findings, has been inconsistent, anxiety-related emotions appear to be a contributor (Smith, 2004). However, stereotype threat findings are limited to specific populations and conditions, namely domain-identified individuals being tested in controlled settings on material that is at the edge of their skill level. In contrast, this study considers students' experiences in natural learning environments. Further, it explores how negative emotions operate in classrooms where race is salient on a day-to-day basis. Moreover, it looks at reform mathematics classroom that are highly social in nature where issues of identity, racial/ethnic identities included, are pushed to the forefront.

The public and social nature of mathematical activity in reform-based courses makes them interesting contexts to consider affect. Some researchers studying reform mathematics have found that these curricula foster achievement supporting affective changes (Boaler, 2002; Nichols et al., 1990; Stipek et al., 1998). However, these studies did not conduct analyses by race/ethnicity. Other researchers (Lubienski, 2007) have argued that issues of diversity have not been adequately addressed in the implementation of reform curricula. More specifically, some studies have found that teachers of African American students have difficulty establishing the desired discourse norms for these courses (Martin, 2000; Murrell, 1994). It is unclear what role negative emotions might have in the challenges observed.

There are several aspects of reform curricula that may make considerations of affect important for addressing equity concerns. First, these curricula employ problems that lower-achieving students have had more challenges with (Jordan, Kaplan, Nabors Olah, & Locuniak, 2006). Models of affect suggest that past experiences cumulatively precipitate relatively stable beliefs and attitudes that come to shape perception and behavior (Marshall, 1989; Schumann, 1994). Thus, students with histories of low achievement in mathematics (and by extension those students from under-served social groups) may have negative affective responses to the types of problems that are the focus in reform mathematics. Also, these curricula focus on types of mathematics most associated with math anxiety (Hembree, 1990). Finally, students are expected to share answers and justifications, which increases opportunities to expose not only miscalculations, but also misconceptions. Students who view these experiences as creating a risk of appearing incompetent may avoid participating in ways could help them learn (Covington, 1992). Negative emotions may also lead to prolonged deficits in the ability to complete assignments even when students re-engage (Carver & Scheier, 2005)

Studying the role of affect in learning, particularly emotion, presents methodological challenges. However, isolating affect from intellect is of questionable utility for developing an understanding of human behavior (Eder et al., 2007). Vygotsky (1986) wrote, "Their separation as subjects of study is a major weakness of traditional psychology" (p. 10). More recently other scholars have pointed out that education research in particular tends to treat affect as separate from cognition, which has limited a thorough understanding of affect (Malmivuori, 2006). We can make theoretical distinctions between cognition and emotion but the boundaries between them are not clear (Schoenfeld, 1994). Even while engaged in purely analytical processes our thoughts have an emotional valence (Schumann, 1994). These feelings influence our behavior and thinking and are connected to our identities and beliefs. We advocate a distinctly sociocultural view of emotion that seeks to understand how beliefs and identities are interrelated with affect and participation (see Evans, Morgan, & Tsataroni, 2006 for a related approach). Our model moves beyond looking at affect as an aspect of personality and the subject experiencing the emotion as the prime cause of that experience. Instead, it considers the ways contexts afford and support different beliefs and identities (Greeno, 1994) and how these are related to emotions.

## Research Questions

1. Are there differences across racial/ethnic groups in the frequency of negative emotion during mathematics class?
2. What is the relationship between negative emotion and mathematics achievement? Are there differences across racial/ethnic groups?
3. Are students' positive perceptions of group work, stronger connections with teachers, and identification with mathematics associated with less frequent negative emotion during mathematics class? Are there differences across racial/ethnic groups?

## Methodology

We investigated these questions through a survey that allowed us to make comparisons across broad segments of the population (N = 515; African American N = 115). The survey was administered to all students taking mathematics during a single semester. Participation in many classrooms was 100%. The survey contained four Likert questions about emotion that asked students to rate the frequency that they experienced the following during mathematics: worry about looking stupid, anger when confused, frustration when confused, and headache or stomach aches due to difficulty in mathematics. The content of these items was derived from interview transcripts and observation notes. Other scales included mathematical identity, which asked students about their commitment to the subject and sense of skill in it, and interpersonal connections with teachers, which asked about care and respect in student-teacher relationships (Marks, 2000). In addition, we asked students to provide five reasons why their teachers ask them to work in groups. Answers were coded into three categories: providing instrumental support for learning mathematics (IM), providing instrumental support for social learning (SL), and negative comments about group work (N). An additional pair of Likert questions asked students to report the degree to which they found working in groups helped them learn mathematics.

## Results

*Question 1*

Our results indicated that students from all racial/ethnic groups experience some negative emotions during mathematics class. There were no statistically significant differences in the levels of negative emotion reported between racial/ethnic groups

*Question 2*

Correlations between negative emotion and math grades for the entire sample were significant $r(470) = -.215^{**}$. African American females showed no correlation between negative emotion and math grades, $r(56) = .015$, while African American males showed a significant correlation, $r(50) = -.345^{*}$.

Breaking down the negative emotion variable into individual survey items we found two items contributed more strongly to the significant correlations for African American males, fear of looking stupid in mathematics class, *r*(51) = -.478** and frustration when unsure of what to do, *r*(51) = -.345*. White females (N = 20) were the only other group with significant correlations on both of these variables.

To investigate whether the relationship between math grades and 'fear of looking stupid' for African American students was significantly different from that found for the general population we tested the slopes of the regression lines for parallelism for math grades on 'fear of looking stupid' and found that the slope for African Americans was significantly steeper (*t* = -2.752, *p* = .003). To ensure that this significant finding was not confounded by gender differences, we also compared the slopes of the regression lines for African American males to the slope for all other males for these same variables. The difference between these slopes was also significant (*t* = -2.149, *p* = .033).

*Question 3*

Turning to the relationship between negative emotions during mathematics class and perceptions of group work learning exercises, we did not find significant correlations when examining the sample as a whole. However, analyzed by race/ethnicity, African Americans were the only group that displayed significant correlations between two of these variables, instrumental social (IS) *r*(103) = -.235* and negative comments (N) *r*(103) = .267**. These findings indicate that for African American students the awareness of teachers' intention to promote social learning through group learning activities was associated with less negative emotion and critical views of group work were associated with higher levels of negative emotion. A test for the parallelism of the slopes of the regression lines for African American students and non-African Americans students for negative emotion on IS found a nearly significant difference, with the regression line for African Americans having a steeper slope (*t* = -1.853, *p* = .064).

In the general population, higher levels of mathematics identity (MI) were associated with lower levels of negative emotion (MI *r*([513] = -.251**). Analyzed by race/ethnicity students from all groups displayed significant correlations between these variables, such that less negative emotion was experienced by more domain-identified students.

In the general population, there was a weak but significant negative correlation between interpersonal connection (IC) and negative emotion, *r*(513) = -.108*. Analyzed by racial/ethnic groups, only African American students showed a significant correlation between IC and negative emotion *r*(106) = -.269**. Analyzed by gender and race/ethnicity we find only African American and Latino male students showed significant correlations between these variables, but results for African American females were approaching significance (AAM: *r*[50] = .335*; LM: *r*[83] = -.244*; AAF r[56] = .252, *p* = .069). A test for parallelism of slopes for African-American students and non-African American students for the regression of negative emotion on interpersonal connection was approaching significance (*t* = -1.846, *p* = .065).

Group work support and interpersonal connection were both associated with lower levels of negative emotion for African American students. We also found that African American males showed the strongest correlations between these variables. Comparisons of the slopes for African American males and all other students for the regression of group work support on interpersonal connection found that African American males showed a steeper slope (*t* = 3.034, *p* = .002).

## Discussion

Not surprisingly, students from all racial/ethnic groups reported experiencing negative emotions in mathematics class. Although there were no significant differences in the amounts of negative emotion reported, there was divergence in how negative emotions were related to achievement across racial/ethnic groups. It is unclear if differences between groups are related to variation in how readily students acknowledge social anxiety, how they define negative emotions as expressed in the survey, and/or different responses to these emotions (or some combination). For example, fear of looking stupid can be experienced as a gripping anxiety or merely as something unpleasant to avoid. Also, some students may manage this anxiety (whatever its strength) by trying to take good notes and ask questions so as to insure that they master the material, whereas others may be motivated by this emotion to attempt to get recognized for some socially valued identity, such as class clown. In addition, we suspect that prior histories of difficulty with mathematics may be related to the strength of negative emotion experienced and how it is responded to. Longitudinal research that can disaggregate the role of factors related to race/ethnicity from achievement history is needed.

African American students showed a stronger relationship between negative emotions and perceptions of group work than students from other groups. Due to the prevalence of stereotypes about African Americans and intelligence (Steele, 1997) and students' awareness of the social consequences of school failure (van Laar, 2000) there may be more at stake and thus more negative emotions for African American students in school contexts where race is salient and emotional safety is lacking. Therefore, perceptions of learning exercises and their purpose may have a greater influence on African American students' emotions. That is, believing that teachers assign group work to promote learning or social development may help students view risk exposure as having an instrumental value, which in turn may lead to experiencing lower levels of negative emotion. Endorsing the learning practices may provide a much-needed proximal reason for engagement for those students who lack certainty about the distal value or likelihood of school achievement. Seeing group work as instrumentally valuable may help also students cognitively restructure interpretations of events in ways that down-regulate negative emotions when they emerge (Gross, 2002). Domain identification with mathematics and interpersonal connections with teachers may help students in similar ways. For example, believing that your teacher respects you and is committed to your learning may provide ways of framing struggle that decreases arousal and supports engagement and persistence.

Findings indicated that higher levels of mathematics identification were associated with lower levels of negative emotion. These results contrast with stereotype threat research that finds that only domain-identified individuals are subject to the performance-reducing effects of racial priming. This contrast suggests that perhaps the kinds of negative emotion measured in this study are not related to stereotype threat effects. Alternatively, these effects may play out differently *in situ*.

## Conclusion

This study suggests that negative emotions may play a role in achievement inequity in high school mathematics. It also offers promising results. More specifically, this study suggests that when students view the learning practices as having instrumental value and have interpersonal connections with teachers, they may experience less negative emotion. Further research is needed to develop validated measures for the kinds of emotions investigated in this study and to better understand the variability observed in the relationship between negative emotions and achievement across racial/ethnic groups. Additional qualitative research that adds needed complexity to the limited fixed categories of racial/ethnic identities used in these analyses is called for. It will be valuable to examine the different ways racial/ethnic identity is constructed and how these variations relate to the ways emotion influences participation in mathematics.

# MATHEMATICS EDUCATION IN THE PUBLIC INTEREST: PRESERVICE TEACHERS' ENGAGEMENT WITH AND REFRAMING OF MATHEMATICS

Laura Jacobsen Spielman
Radford University
lspielman@radford.edu

*Equity and social justice agendas in mathematics education are becoming increasingly central to researchers and educators. The Mathematics Education in the Public Interest*[i] *project implemented a mathematics course for preservice elementary and middle teachers where mathematical units are placed in contexts encouraging critical analysis and exploration of the world and connections between mathematics and students' lives. Preservice teachers' views about mathematics and mathematics teaching changed over time. Mixed-methods research indicated mechanisms supporting their engagement with and reframing of mathematics included: (1) Learning the relevance of mathematics; (2) Developing interest in mathematical applications; and (3) Changing prior assumptions and instructional goals.*

## Introduction

Projects such as the Dartmouth *Mathematics Across the Curriculum* project and the Indiana University *Mathematics Throughout the Curriculum* project have suggested the need for greater indisciplinarity and a strengthened mathematical infrastructure in the undergraduate curriculum. Quantitative literacy projects such as *Quantitative Reasoning in the Contemporary World* at the University of Arkansas have strong potential to help students make connections between quantitative information and their lives and interests outside the classroom. These projects help students to understand the relevance and interconnectedness of mathematics with other subjects and with the real world.

In recent years, an increasing number of mathematicians and mathematics educators have begun to ground mathematical investigations in meaningful personal and social contexts. Teachers and researchers have begun to document students' experiences and learning from this process, as well as their own experiences and learning. For example, teaching in a middle school classroom in a diverse Chicago school, Gutstein's class included mathematical studies of the distribution of the world's wealth, possible racism in housing data and mortgage loans, and random drug testing (Gutstein & Peterson, 2005). Based on his research, Gutstein (2007) suggested, "Students learned mathematics and began to develop sociopolitical awareness and see themselves as possible actors in society through using mathematics to understand social injustices" (p. 420). Turner and Strawhun (2005) described New York City middle school students' mathematical investigations of overcrowding at their school, concluding, "Not only did opportunities to engage in responsive action support students' sense of themselves as people who can and do make a difference, but using mathematics as a tool to support their actions challenged students' view of the discipline" (p. 86).

Consortiums such as the Center for the Mathematics Education of Latinos/as (CEMELA) have been extremely important to advancing equity and social justice agendas in mathematics education. CEMELA involves parents, school administrators, and teachers in a collaborative effort to improve the mathematical education of low-income Latino students by focusing on the interplay of the language, social and political issues affecting Latino communities. Thus far, little has been done in teacher education programs to prepare preservice teachers, in particular, for centering their future mathematics practice on equity and social justice agendas. In May 2008, the NSF-funded "Connecting Mathematical Funds of Knowledge Conference" held in Tucson, Arizona helped teacher educators consider what it means to support preservice teachers to connect children's mathematical thinking with children's and community funds of knowledge in the context of elementary mathematics methods courses. Such emphases, while still very uncommon, are beginning to take root in a small number of mathematics methods courses across the country. However, mathematics *content* courses engaging preservice teachers in learning mathematics in support of equity and social justice emphases, with an eye toward the relevance of mathematics in local and global communities, have been nearly non-existent.

The *Mathematics Education in the Public Interest* (MEPI) project initiated at Radford University has implemented a mathematics course designed for preservice elementary and middle school teachers where mathematical units are placed in contexts encouraging critical analysis and exploration of the world and connections between mathematics and students' lives. Based on mixed-methods research in the junior-level *Elementary and Middle Grades Mathematics for Social Analysis* (*Math for Social Analysis*) course, this article communicates changes in preservice teachers' views about mathematics and about mathematics teaching and mechanisms supporting preservice teachers' engagement with and reframing of mathematics.

## Theoretical Foundation for MEPI

> Democratic access to powerful mathematical ideas for social justice requires that students have comprehension of global conditions that are driving the global society and how mathematical and technical knowledge can be tools used to develop a more just world. (Malloy, 2008, p. 29)

For many years now, various forms of classroom or knowledge management, instruction, opportunities, and so forth, have been suggested as stratified across social classes (e.g., Anyon, 1980; Bowles & Gintis, 1976; Knapp & Woolverton, 1995, 2003; Moses & Cobb, 2001; Oakes, Joseph, & Muir, 2004; Secada, 1992; Tate, 1997). Among other things, content and pedagogies weak or lacking in cultural relevance for some students or stemming from Eurocentric perspectives (e.g., Atweh, Forgasz, & Nebres, 2001; Ladson-Billings, 1995; Lubienski, 2002; Rodriguez & Kitchen, 2005; Tate, 1995) have been offered as contributing to race and class divisions in access to knowledge. As a discipline, mathematics, "often regarded as the most abstract subject removed from responsibilities of cultural or social awareness" (Boaler & Staples, 2005, p. 32), has additionally been associated with such stratification. Historically, school mathematics is isolated from other subjects and from students' lives and interests outside of school. Mathematics is treated as independent from important social, political, and economic issues facing our communities and our world.

Regarding student learning, research has yielded largely positive support for reform practices of the kind supported in the U.S. by the NCTM *Standards* (1989, 2000). In an extensive, three-year comparative study of two schools in England, Boaler (1998) suggested that students who receive project-based instruction learn more, and different, mathematics than students receiving traditional skills-based instruction. In the U.S., relatively consistent evidence also exists that students using reform-based curricula perform equally well on tests of mathematical skills and procedures as comparison students using traditional curricula, and perform better on tests involving mathematical concepts and problem solving (Schoenfeld, 2002; Senk & Thompson, 2003). Schoenfeld further explained, "Reform appears to work when it is implemented as part of a coherent systemic effort in which curriculum, assessment, and professional development are aligned. Not only do many more students do well, but the racial performance gap diminishes substantially" (p. 17). Also, both male students and female students in reform-based school programs in the U.S. outperformed their counterparts in traditional programs; and for female students, all performance differences by program were statistically significant (Riordan & Noyce, 2001).

Equity and social justice agendas in mathematics education have become increasingly central to a growing number of researchers and educators in recent years. Recommendations for how to achieve equity goals almost always include requirements for setting high expectations and providing strong support for all students (e.g., Moses & Cobb, 2001; NCTM, 2000). But despite many great strengths, reform documents such as the NCTM *Standards* (1989, 2000) still do not go far enough.

Lubienski's (2002) criticism of *Standards*-based reforms (NCTM, 1989, 2000) focuses largely on multicultural considerations of discourse and the NCTM's general oversight of such considerations. Others have focused more on the absence in the *Standards* of a critique of societal inequities (e.g., Apple, 1992; Gutstein, 2003, 2006). Gutstein (2006) indicated the *Standards* embody a relatively narrow perspective on equity, discussing equity in terms of opportunity to learn, but not critiquing societal inequities behind the lack of those opportunities for many segments of the population both in the U.S. and abroad.

Social justice agendas help students to clarify issues, to understand the structure of society, and to justify or refute opinions, increasing learners' capacity to understand and also challenge oppressive social structures and power relations that perpetuate over time and across the globe (cf., Frankenstein, 1989). In a world where educational inequities and other inequities persist, the treatment of school mathematics as abstract, as independent of students' lived experiences, and as independent of moral and social obligations is short-sighted. We can do better.

Gutstein (2006) proposed an exploratory orientation toward building mathematics curriculum with integrated components of community knowledge, critical knowledge, and classical knowledge. The twelve characteristics of the Connected, Equitable Mathematics Classroom proposed by Goodell and Parker (2001) also support similar emphases in the rethinking of mathematics. The MEPI project foundation rests on an assertion that mathematics curriculum and instruction can be improved by maintaining overlapping objectives that, for example: (1) incorporate NCTM *Standards*-based reform practices, (2) are more culturally responsive, (3) make use of individuals' and groups' funds of knowledge, (4) engage learners' more fully, more meaningfully, and more responsibly with their communities, and (5) explicitly aim to achieve social justice locally and globally.

## *Math for Social Analysis* Course

In Radford University's Department of Mathematics and Statistics, we created a junior-level course for elementary and middle school preservice teachers, *Math for Social Analysis*. *Math for Social Analysis* is the third course in a three-course sequence of mathematics content courses for preservice teachers, each offered out of the Department of Mathematics and Statistics. All elementary and middle grades preservice teachers at Radford University are required to take *Math and Human Development I and II*, both of which are prerequisites for *Math for Social Analysis*. *Math for Social Analysis* is required for elementary education majors and recommended for middle school education majors—likely to become required for that group in the future as well. The course, and related research project "Mathematics Education in the Public Interest," maintain overlapping emphases on mathematics content, social critique, and community relations and actions. After completing this mathematics sequence, students later take a mathematics methods course in the education program.

In *Math for Social Analysis*, the connection between mathematics and the world emerges as students critically analyze social issues using mathematics. For example, one curriculum unit speaks to environmentalism, which includes topics on global warming, mountaintop removal in Appalachia, rainforest depletion, and water conservation. Students learn and raise questions about their own and global contributions to these problems. Another curriculum unit tackles the global economy, where students explore and mathematize such topics as poverty, the distribution of wealth, and sweatshop labor. Class activities, readings, guest speakers, and videos help connect students to the social issue, which promotes dialogue, and deepens their mathematical understanding as they grapple for solutions.

Additionally, our students complete a semester-long project, choosing between a research/teaching project option and a service learning project option. The research/teaching option is a small group project. The group raises an authentic question about the world and they research answers to their question. The group produces a research paper and several age appropriate mathematics lessons based on the research, and the project culminates with the group teaching one of the lessons to their classmates. The service learning option is an individual project in partnership with a local community-based organization's after school programs. Our students provide mentoring and tutoring assistance for 3 hours each week. This option requires the students create and teach five mathematics activities, two based on social issues, and they write reflections detailing their experience. The project culminates with a presentation to their classmates, reflecting on their experiences.

## Research Methods

This paper is based on mixed-methods research conducted with 77 preservice elementary and middle school teachers enrolled in three sections of *Math for Social Analysis* in 2007-2008. Three participants were male, and 74 female; 75 identified themselves as "Caucasian/White" on the survey. Further, 70 of the 77 participants were in elementary education, 3 in middle school education, 3 in special education, and 1 in early childhood education.

Data collection included:

- Pre- and post-surveys with all participants on their views related to the relevance of mathematics in understanding and solving social issues and to connections between mathematics and students' families and communities. Surveys included demographic items, Likert-type items, and open ended response items.
- 18 interviews (with 16 participants) conducted in the latter half of the semester to learn preservice teachers' background experiences with mathematics, views and attitudes about mathematics and its relevance, and learning and experiences in *Math for Social Analysis*
- Introductory journal reflections from all participants to learn their background experiences with mathematics, views and attitudes about mathematics and its relevance, and goals and expectations in *Math for Social Analysis*
- Final project assignments from all participants, including reflection papers addressing their attitudes toward mathematics, their experiences and learning in *Math for Social Analysis*, and the relevance of the course for their future teaching of mathematics

The author of this paper and colleague Jean Mistele each teach one or more sections of the *Math for Social Analysis* course each semester. For ethical reasons and to limit bias, we interviewed each other's students rather than our own. Data analysis involved coding and recoding the qualitative data, using categories such as “Math Anxiety/Confidence,” “Interest in Math,” “Views on Math and Social Issues,” and “Goals for Math Teaching.” We triangulated multiple quantitative and qualitative data sources to arrive at conclusions regarding the nature of preservice teachers’ experiences and learning in *Math for Social Analysis*. As we reviewed data and heard preservice teachers almost universally describing very different, and mostly very positive, experiences and learning in this course than in all previous mathematics courses, we became interested in how and why they characterized the course as they did. Our results section documents changes in preservice teachers’ views about mathematics and about mathematics teaching from the pre-survey to the post-survey and communicates mechanisms supporting preservice teachers’ engagement with and reframing of mathematics.

## Supporting Student Engagement with and Reframing of Mathematics

> My attitude about mathematics for a long time has been dread and confusion…I feel that by teaching math in this new method, people may better understand math because they will be able to learn by relating it to real life…This may also better people’s attitudes toward math by showing them its importance and relevance to their future. By using this method of teaching math, we have the opportunity to greatly change the way the world sees math for the better. (Mary, 12/11/08)

Students universally label this course as their first extended experience with learning mathematics in connection with multiple meaningful real-world applications and social issues. Many of our preservice teachers enter *Math for Social Analysis* describing high levels of mathematics anxiety. We have previously reported ways that preservice teachers’ mathematics anxiety levels subsided as a result of their engagement with social issues in the course (Mistele & Spielman, 2009). Survey results also provide evidence that preservice teachers’ views about mathematics and about mathematics teaching changed over the semester. They come to see mathematics as: (1) Increasingly useful for understanding and engaging with important issues and (2) Increasingly connected to home and community experiences.

*Using Mathematics to Understand and Engage with Important Issues*

One set of pre/post survey items measured preservice teachers’ views about the ways mathematics is, or can be, used to understand and engage with important issues. These items were measured on a 4-point scale ranging from strongly disagree to strongly agree. The 10-item scale (Scale reliability, Cronbach’s $\alpha = 0.80$) included items such as, “Having an understanding of mathematics makes people more powerful as citizens” and “It is my job as a math teacher to help students see connections between mathematics and social issues.” A t-test comparing pre- and post-survey means on this composite yielded a significant difference ($t = -5.229$, $p < 0.001$). At the end of the semester, preservice teachers reported significantly stronger agreement with scale items such as these, or respectively, disagreement with negatively worded items.

*Connecting Mathematics to Home and Community Experiences*

A second set of pre/post survey items measured preservice teachers’ views about the ways mathematics is, or can be, connected to students’ home and community experiences. These items were likewise measured on a 4-point scale ranging from strongly disagree to strongly agree. The 9-item scale (Scale reliability, Cronbach’s $\alpha = 0.81$) included items such as, “Getting to know students’ families and becoming familiar with their communities is useful for teaching mathematics” and “Home and community activities are good contexts for posing and solving mathematical problems.” A t-test comparing pre- and post-survey means on this composite yielded a significant difference ($t = -3.203$, $p = 0.002$). At the end of the semester, preservice teachers reported significantly stronger agreement with scale items such as these, or respectively, disagreement with negatively worded items.

*Mechanisms Supporting Engagement*

Overall, student responses thus far have been very positive and supportive of the *Math for Social Analysis* course, although to appropriately characterize in detail students' experiences and learning in the course would require greater depth than may be included in a conference paper. Based on qualitative data analysis, interwoven mechanisms supporting preservice teachers' engagement with and reframing of mathematics included: (1) Learning the relevance of mathematics to something they care about; (2) Developing interest in mathematical applications and in supporting their future students' interest and learning in mathematics; and (3) Shifting their perspectives on mathematics by changing prior assumptions and instructional goals. See Figure 1.

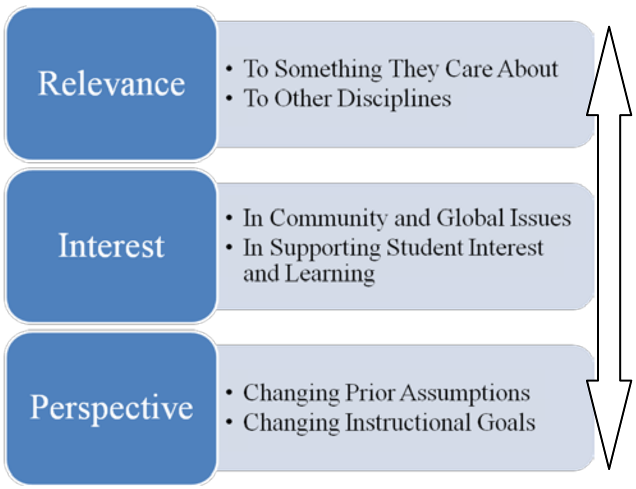

*Figure 1*. Mechanisms supporting engagement.

Classroom experiences helping preservice teachers connect mathematics to other disciplines and to social issues helped them develop a foundation for constructing new connections and applications in the future. Once preservice teachers started making connections between mathematics and other disciplines and social issues, they found it much easier to make additional new connections. Preservice teachers had often never considered relationships between mathematics and the things they cared about. By learning examples of how mathematics is related to social issues, this spurred many new possibilities for how to teach math using social issues. They saw a whole array of new possibilities for their future classroom practice. As teachers increasingly saw mathematics as relevant and important in social issues, they developed new teaching goals to help students integrate math with other subjects and the world outside of school.

Preservice teachers also re-examined their assumptions about the (ir-)relevance of mathematics as they learned mathematics in ways they had never before experienced. They used their new learning of interdisciplinary and social issue connections to mathematics to rethink their futures in mathematics teaching and reframe math as a discipline children can become excited to learn. Further, they developed a new sense of agency to create mathematical learning opportunities that students will find interesting and relevant. Preservice teachers' own interest and confidence in teaching mathematics in the future was tied to their knowledge of different ways to get students interested in the discipline. Their interest in mathematics was related to the ways they understood connections between mathematics, other disciplines, and their own lives and interests. The mathematics came alive to them in the context of meaningful applications.

## Implications and Future Research

Results from mixed-methods research in *Math for Social Analysis* are sufficiently positive to suggest the need for continued implementation and testing over time, on a larger scale, and at additional sites. Further research is also needed to learn more about the ways the *Math for Social Analysis* course, or similar courses, impact preservice teachers' mathematical understandings, as that has not yet been rigorously examined.

*While research has shown the effectiveness of representational technologies in mathematics education, barriers to broad use remain. The Scaling Up SimCalc project has begun to address these barriers by considering the role of technology within a wider "curricular activity system." In this paper we discuss how we leveraged the representational and communicative infrastructure of SimCalc to meet the needs of a diverse student population, while we also met the needs of key stakeholders in the wider education system. This resulted in increased learning for a diverse group of students. We also discuss possible improvements to our intervention.*

## Introduction

Research has shown the effectiveness of using representational technologies in mathematics to scaffold and support student learning (Mayer, 2005; Marzano, 1998). However, there have been barriers to broad use, such as the perception that technology is too difficult to implement in diverse classrooms (Becker, 2001), and inconsistent findings on the benefits of educational technology in mathematics (Dynarski et al., 2007; National Mathematics Advisory Panel, 2008).

In this paper we report on a study that leveraged the effective aspects of representational technology while overcoming existing barriers to broad use. The study evaluated a particular instantiation of the SimCalc approach, which integrates interactive representations with paper curriculum and teacher professional development to increase students' opportunity to learn advanced mathematics. In designing the Scaling Up SimCalc study, we incorporated the perspectives of different stakeholders –students, teachers, and school districts– to minimize barriers to implementation and increase the chance of having the intervention used. We addressed teacher and district concerns regarding current policy demands (e.g. NCLB and accountability testing) and the need to meet local standards. We considered multiple teaching styles and designed materials so teachers with a wide variety of mathematical and technological backgrounds could use them. And, through representational technologies and scaffolded curriculum we met the cognitive, linguistic, and social needs of a diverse student population. At the heart of this approach is a refinement of our conceptualization of the use of innovative technology in the classroom. Whereas earlier work focused primarily on the representational and communicative infrastructure of SimCalc, the concept of a "curricular activity system" has emerged as being vital to successful scale up (Roschelle et. al., in review).

Scaling Up SimCalc makes an important contribution to the literature by providing very strong evidence that embracing these diverse perspectives increased student learning of advanced mathematics with a diversity of teachers in a wide variety of settings.

## Background

For over fifteen years the SimCalc project has had the goal of ensuring that all learners have access to complex and important mathematics, as expressed in the SimCalc mission statement "democratizing access to the mathematics of change and variation" (Kaput, 1994). The mathematics of change and variation emphasizes the concepts of rate and accumulation as thematic content that can be developed across many grade levels. A foundational belief of the SimCalc Project team is that reconceptualizing middle school and high school mathematics in light of the broader mathematics of change and variation developmental strand can yield a more coherent and fruitful mathematical experience for all learners, including those that have not traditionally been successful in mathematics (Kaput & Roschelle, 1997).

This view of how mathematics can be structured stands in contrast to the traditional mathematics curricula, which was laid out in the $17^{th}$ and $18^{th}$ centuries, and hasn't changed much since (Kaput & Roschelle, 1997). This is, in part, because the curriculum has "worked" to train a workforce where most jobs require little more than arithmetic, and few require deep understanding of advanced mathematical concepts. Today, the picture is different. Not only are there economic arguments for preparing more young people, of different races and backgrounds, to use complex mathematics on the job (National Advisory Mathematical Panel, 2008), but participation in society as an empowered citizen requires understanding the mathematics of change (Kaput & Roschelle, 1997), and increasing the number and diversity of those in the field of mathematics may even be vital in advancing the field itself (Gutierrez, 2007).

While the SimCalc research program has considered restructuring the mathematics curriculum as a way to achieve its goal of democratization, strict adherence to this goal in the short term may stand in the way of necessary reforms that can help many of the students who need this access the most—those in low-performing schools who are already likely to get worse instruction and less access to high-level content than their peers at high performing schools. In this study, guided by a curricular activity systems approach, we built upon the past successes of SimCalc, while taking an incremental approach to addressing what is taught.

In this paper, we will use *SimCalc* to refer to the Scaling Up SimCalc study (2005-2008) and the system of curriculum, software and professional development developed therein. The software, SimCalc MathWorlds® (hereon referred to as MathWorlds), is a simulation environment in which the user and the software co-construct mathematically meaningful objects and relationships. MathWorlds moves beyond simple interactivity and animations of math, and instead provides students with access to complex mathematics, and allows students to quickly conjecture, test, and iterate while preserving mathematical relationships and structures. This is very difficult to replicate in static media, where students may unintentionally violate mathematical principles in an investigation (Hegedus, 2005).

We next describe the results from the Scaling Up SimCalc study, and then report on those features of our intervention that most likely resulted in its success in helping a wide variety of students learn important mathematics.

## Results from the Scaling Up SimCalc Study

The Scaling Up SimCalc study found the SimCalc approach to be successful in meeting the needs of a diverse set of students and teachers. Ninety-five seventh grade teachers and their students across varying regions in Texas participated in a randomized controlled experiment in which they implemented a SimCalc-based three-week replacement unit. An analysis of the results showed a large and significant main effect with an effect size of 0.8 (Roschelle et al.,

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

2007; Roschelle et al., in review). This effect was robust across a diverse set of student demographics. Students who used the SimCalc materials outperformed students in the control condition regardless of gender, ethnicity,[1] teacher-rated prior achievement (we will discuss possible remedies for the trend of higher achievement students having slightly higher gain scores in the *Conclusion and Discussion*), and poverty level[2] (Figure 1). We provide a comparison of students in one particular region in Texas, Region 1, to other students in the study. Region 1 is in the Rio Grande Valley adjacent to the Mexican border, is predominantly Hispanic, and is one of the poorest areas in the United States. Consistent with our other data, we see that the students in Region 1 who used SimCalc had greater learning gains than students in the control condition.

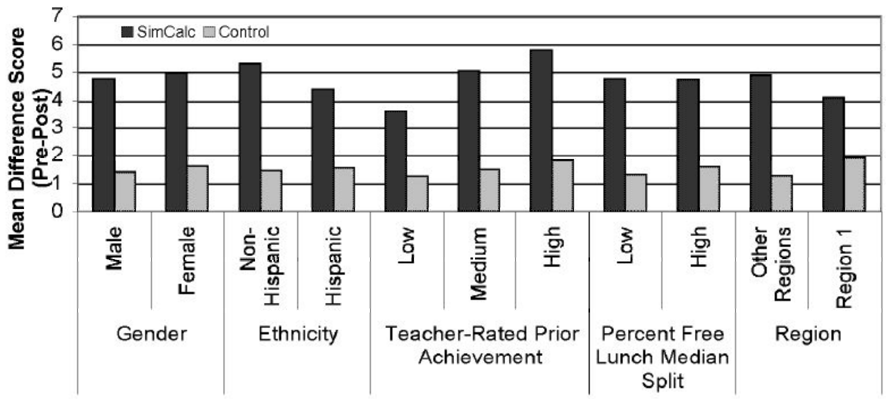

*Figure 1.* Mean student-learning gains by subpopulation group.

In the remainder of this paper we report on those aspects of the SimCalc curricular activity system that most likely led to these robust findings. In particular, we leveraged those features of the SimCalc environment that are consistent with the literature on under-achieving students (particularly those from non-mainstream backgrounds), while also meeting the needs of key stakeholders in the education system. We also discuss ways the integrated system could be improved to further close the gap for particular subpopulations.

## Research Foundations

In this section we describe some of the key features of SimCalc as a representational and communicative infrastructure. These features of SimCalc relate directly to what we know about effective instruction for all student populations, including students from non-dominant cultural and language backgrounds and other students who traditionally underperform in mathematics (e.g. Moschovitch, 2007b; Kaput and Roschelle, 1998).

SimCalc builds on students' existing competencies and experiences. The SimCalc approach differs from the traditional pre-algebra approach in several ways. Perhaps the most important is that SimCalc places motion phenomena at the center of learning (see Figure 2), enabling students to build on their existing cognitive and social competencies. Research with urban students (Monk & Nemirovsky, 1994) has shown that students tend to engage in "interval analysis" of motion simulations and interpret motion in a piecewise manner (e.g. "First the boy was going slowly, then he was running really fast, and then he stopped"). Further, all students, including traditionally low-achieving students, are capable of constructing rich stories about motion over time and can use narratives as a resource for interpreting graphical and tabular representations of motion as they build a qualitative understanding of calculus (Stroup, 2002). SimCalc allows students to play and replay a simulation of motion as many times as they wish, allowing more students to access these fundamental resources than is possible using traditional static media.

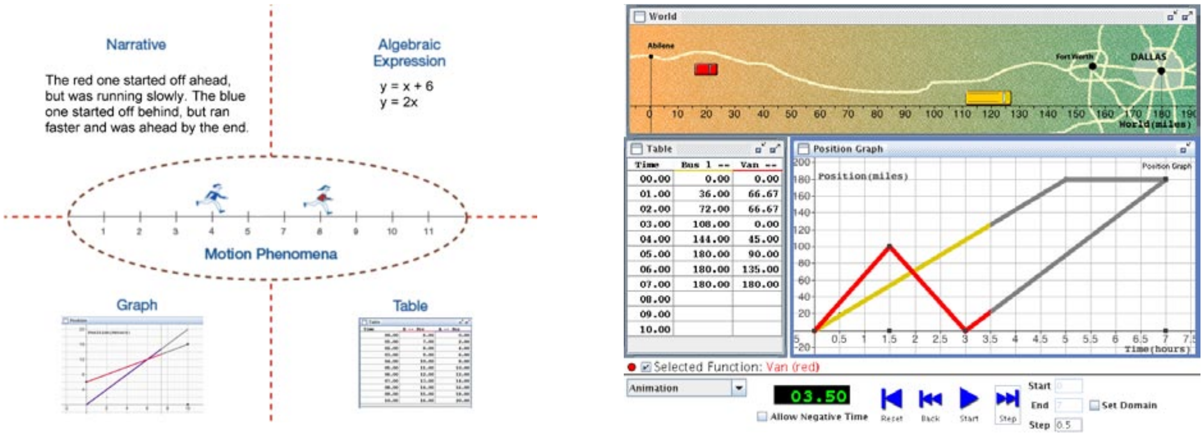

*Figure 2.* SimCalc linked representations (left); MathWorlds activity screenshot (right).

SimCalc supports multiple forms of representation and expression (see Figure 2). In SimCalc students study functions through linked motion, graphs, tables, and symbolic expressions. Research has found that complex mathematics is more learnable when students are not reliant on symbolic forms or dense textual descriptions, but can interact directly with a mathematical representation such as a graph, and immediately see the effects on other linked representations (Roschelle et. al., 2000). Moreover, providing access to multiple representations means that symbols can be introduced *after* students have experience with motion, narratives, tables, and graphs. In this way the symbols are *about* something, and can be understood as a compact and precise way of describing phenomena. By waiting to introduce the symbolic form, SimCalc is also not held hostage by what is symbolically or computationally simple. For instance, piecewise linear functions are quite complex to represent symbolically, and so are not introduced in most middle- and high-school curricula. However, interpretations of piecewise motions can help students understand the mathematics of change, and the narrative of an exciting race can provide exactly the context students can use to engage in deep mathematical thinking.

SimCalc supports communication and discourse. Making mathematical connections across different representations has social and communicative advantages. The four linked representations provide a shared set of referents for students and teachers to explore by replaying the motion or making changes in one representation to see the changes in the others. Students have opportunities to use a wider range of verbal and nonverbal communication acts, such as pointing: “See, right *here* the boy starts running faster.” Students also have opportunities to use the language of academic mathematics for a communicative goal (e.g., Does *going longer* refer to *time* or *distance*?). This goal- and meaning-oriented approach is consistent with best practices for learning language and with recommendations for supporting mathematical discourse (Moschkovich, 2007b; Swain, 2001) and is in contrast to traditional approaches to teaching academic language that rely on memorization of vocabulary lists.

## Scaling-Up: Meeting the Needs of the Educational System

Taking these research findings to the classroom on a large scale was a new challenge for the SimCalc project. Previously, the SimCalc approach was taught directly by either researchers or teachers who had been involved in long-term professional development or collegial arrangements with the researchers. In order to reach a larger audience of teachers and students, we needed a robust combination of curriculum, technology, and minimal professional development to leverage the benefits and while minimizing the chances of lethal mutations (Brown, 1991). This resulted in the emergence of a curricular activity system approach (Roschelle et al., in review), which helped us to address teacher, district and state constraints and realities while extending the SimCalc mission.

We designed a curriculum sequenced in a way that would be comfortable to most American teachers: breaking complex concepts into small pieces, starting with the smallest piece, and culminating with complexity. This approach differs from the “historical” SimCalc approach, where students are presented with a fairly complex problem, are asked to generate solutions for it, and through this process, learn concepts of rate and function—and other calculus related ideas. What we retained from the SimCalc approach built up over the years was a reliance on motion as a context for understanding function, and function as a way to think about rate. This, fortunately, aligned with Texas state-advocated approach. And of course, the curriculum is tied to the MathWorlds software, in which students are able to control simulations of motion and representations of graphs, equations, tables and actions are related.

We also focused on a small number of important activity structures, and provided supports for these in the written curriculum materials. For example, we incorporated the SimCalc tradition of having students predicting a motion by interpreting a graph, running the simulation to check their predictions, and explaining verbally differences or coincidences between prediction and simulation. This “predict-check-explain” model was not only discussed in trainings, but also written into each lesson in the student workbook, as one way to ensure students were exposed to the SimCalc approach, regardless of the teachers’ approach.

We used a fairly typical “week in the summer” model of professional development that met the time (and funding) constraints of a large number of districts and teachers. All teachers in the study received TEXTEAMS training, a two-day workshop on rate and proportionality developed by the Dana Center. SimCalc teachers received 3 additional days of professional development on the SimCalc curriculum. Over these three days, teachers became familiar with the SimCalc units and MathWorlds, and planned when they would teach the SimCalc units. The SimCalc pedagogy was modeled by the facilitator and included in the student workbook.

Deciding what mathematics to include in the units was a task of finding the intersections between the mathematics of change and existing national and state standards for 7$^{th}$ and 8$^{th}$ grades. The Texas Education Authority, through the Dana Center, was advocating an approach to teaching proportionality that was consistent with the SimCalc approach. Rather than presenting three numbers, and a procedure for finding the fourth, embedded in the equality among ratios ($a/b = c/d$), the advocated approach was to teach proportionality as a linear function of the form $y = kx$ (Stanley et. al., 2003). This provided the SimCalc project with the opportunity to connect the multiplicative constant *k* in the algebraic expression $y = kx$, the slope of a graphed line, the constant ratio of differences in a table comparing y and x values, and the experience of rate as “speed’ in a motion.

To ensure that students engaged with the mathematics in a variety of contexts, we grounded the unit in an overarching story framework–managing a soccer team. While use of real world contexts was consistent with prior SimCalc work (which has always been grounded in modeling the real world and students’ own experience of motion), having a single story framework was a departure from past research. This decision enabled us to start the units with typical linear and piecewise linear motions, and extend into non-motion contexts, such as mileage and money (oft used contexts in traditional math curricula and standardized tests). Though the units had overarching contexts, they were “context-light” in that the problems and software presented a highly simplified model of the real world, and these simplifications were made apparent to students. Knowledge of soccer, for example, was neither an advantage nor a barrier to understanding the problems. All the clues and grounding experiences necessary for solving the problem were contained in the simulation, so that all students regardless of cultural or socioeconomic background have the same opportunities to engage with the materials. Because SimCalc provides the phenomena to be studied, we leverage student knowledge of the “real world,” while avoiding inappropriate uses of their real world knowledge

## Conclusion and Discussion

In this paper we have shown how the Scaling Up SimCalc project integrated multiple perspectives to meet the needs of diverse student and teacher populations. Our focus on the representational and communicative infrastructure of SimCalc allowed us to create materials that were effective for students who are considered among the most at-risk for academic failure. By also incorporating a focus on the larger educational system, we were able to create materials that were used by a wide variety of teachers in a wide variety of settings. We believe that, as more innovations attempt to make a difference on a large scale, this focus on the overall curricular activity system will become crucial to successful scale-up.

We also note that, while our instantiation of SimCalc was successful in its goal of helping a wide variety of students learn important and complex mathematics, we believe that more can be done to further meet the needs of a diverse student population. We recognize that the data shown in Figure 1 indicates that there may be some disparities in learning among sub-populations of students who used the SimCalc intervention. For instance, students who were rated by their teacher as having low prior achievement had smaller gains than those who were rated as having high prior achievement, and there is a non-significant trend that Hispanic students had smaller gains than non-Hispanic students.

Detailed analysis of classroom interactions of a subset of the SimCalc teachers shows the importance of specific teacher moves that were used to scaffold discourse. Teachers who incorporated student ideas into their explanations (called “responsiveness”) and who engaged students in tasks that required cognitively complex intellectual work (similar to “cognitive demand”, Stein et al., 2000) had greater student gains than those who did not use such moves (Pierson, 2008). Providing additional professional development and support to allow all teachers to engage in these high-impact moves is likely to increase student achievement for underperforming sub-populations, as students with low prior achievement and students from non-dominant cultures and languages are those most likely to have impoverished classroom discourse. An additional component of discourse support is aiding students in acquiring an appropriate vocabulary (Moschkovich, 2007a; Olivares, 1996) including highlighting those words that have register-dependent meanings (Halliday, 1978; Pimm, 1987). Future work will consider creating a visual glossary of mathematical terms as well as general academic words (e.g. “predict,” “evidence”) to support students in using academic language appropriately.

To further aid in supporting productive discourse for our target students, we will investigate strategies that allow a reduction of the language load while maintaining the rigor of mathematical discourse. A productive strategy has been that of making expectations explicit, and providing scaffolding that aids students in meeting these expectations (Lee, 2005). This strategy is based on the finding that much of academic discourse is based on implicit norms (Gee, 2001; Lee, 2005), and students who are not aware of, or have cultural norms that are in conflict with, academic discourse norms are at a disadvantage (Ladson-Billings, 1995). By making norms and expectations explicit, *all* students will be able to more fully participate in the classroom discourse, while also engaging in rigorous academic thinking.

## Acknowledgements

## Endnotes

1. We focus on Hispanic students because they consisted of a majority of our student sample, there were negligible numbers of other minority groups in the study, and Hispanic students have traditionally underperformed in measures of mathematics achievement (Education Trust, 2003).
2. We take as our measure of poverty the percentage of the campus eligibility for the free and reduced price lunch program.

# BECOMING A "LIBERAL" MATHEMATICIAN: EXPANDING SECONDARY SCHOOL MATHEMATICS TO CREATE SPACE FOR CULTURAL CONNECTIONS AND MULTIPLE MATHEMATICAL IDENTITIES

Lisa M. Jilk
University of Washington
jilklisa@u.washington.edu

*This case demonstrates how a multidimensional construction of secondary mathematics afforded Amelia, a young Latina immigrant, opportunities to participate in her mathematics classrooms in ways congruent with her cultural knowledge and salient identity as a "liberal." Additionally, this expanded version of school mathematics positioned Amelia's "liberal" ways of knowing as valuable tools for learning and provided her with opportunities for genuine self expression, motivating her continued engagement. This research contributes to the literature about culture and mathematics learning that is aimed at building from diverse forms of knowledge and cultured ways of being in an effort to support students who are often marginalized by traditional curricula and pedagogies.*

## Background

There exists a grave and immediate concern about how to encourage and support diverse students to engage more in school mathematics, to be academically successful with mathematics and to enroll in more upper-level mathematics courses. Some responses to this problem are the use of Culturally Relevant Pedagogy (Ladson-Billings, 1995), Culturally Responsive Teaching (Gay, 2000), pedagogy for social justice (Gutstein, 2006), Complex Instruction (Cohen, 1994; Cohen & Lotan, 1997), and Funds of Knowledge (Moll, Amanti, Neff & Gonzalez, 1992) as researchers and practitioners advocate for making connections been students' cultural knowledge and the knowledge needed to be mathematically successful and simultaneously create classrooms and use mathematical content that reframes cultural knowledge as necessary for the learning of school mathematics.

One mathematical success story has been explored in the research of Boaler and Staples (2007) and Horn (2002) and explained by the department's collaboration as a learning community and the use of Complex Instruction as a primary pedagogical tool in its mathematics classrooms. Many Railside students are achieving in mathematics and choosing to enroll in upper-level courses after they have met their graduation requirements. Previous research at Railside has used the Complex Instruction program, teachers' practices, and classrooms as the units of analysis. This work takes a different perspective by starting with students, specifically young immigrant women who achieved mathematical success at Railside. The goal of this work is to expand and build from what is already known about Railside High and Complex Instruction while changing the focus to students, their perspectives and experiences.

## Theoretical Framework

Research in mathematics education has recently begun using identity as a research construct in an effort to better understand the relationship between learning and culture within mathematical communities of practice (Boaler, 1997; Boaler & Greeno, 2000; Boaler, 2002; Cobb & Hodge, 2002; Cobb & Hodge, 2007; Martin, 2000; Nasir, 2002; Sfard & Prusak, 2005). This is important work, as attention to the identities students create within the local cultures of

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

their mathematics classrooms has the potential to illuminate how students make sense of their school mathematical experiences and then make choices about how to act in relation to them. Additionally, understanding learning as a process that encompasses the construction of new ways of being provides for a unique balance between personal agency and influences from the broader communities in which students participate. This perspective prevents us from completely attributing students' failure or achievement to cultures located outside of school and simultaneously recognizes the role of the individual in academic pursuits.

The research that has been done about identity and mathematics learning has determined a reciprocal relationship between identity and practice. That is, within any learning community, inside or outside of school, students construct identities in practice. They shape self-understandings relative to the cultural activities afforded them, meaning that their participation affects the construction of their identities (Wenger, 1998; Nasir, 2002). Simultaneously, identities affect participation. Students come to a practice with ideas about who they are and their purposes for engagement which were situated in specific cultural contexts. Students understand practices and are motivated to practice in particular ways because of these identities (Nasir, 2002; Boaler & Greeno, 2000; Jilk, 2007; Sfard & Prusak, 2005).

However, there is little research about identity and mathematics learning that considers the multiple out-of-school communities in which students participate which shape ideas for how one thinks about herself and then acts. Martin's (2000) attention to the intersection of ethnic identity with students' mathematical identities is significant, because it acknowledges the culture inherently created in of all communities of practice (Cobb & Hodge, 2002). Ignoring culture means ignoring a critical component of students' lived experiences, which they use to shape their identities, and simultaneously contributes to the homogenization of young people by presenting an incomplete and inaccurate portrait of their lives.

This paper builds on and expands previous research about identity and mathematics education by foregrounding the life story of one young woman and her self-understandings relative to her lived experiences in Mexico, the United States, and her secondary mathematics classrooms. It considers the communities outside of school in which she participated as critical sites for identity construction and the ways in which identity is privileged and supported within the context of learning mathematics.

The research questions that framed this study were:

(1) What are the salient identities created by Latina immigrants who were academically successful in their secondary mathematics classes, and in which communities of practice were they shaped?

(2) How do Latina immigrants who were academically successful in secondary mathematics interpret their experiences with Complex Instruction through the lenses of their salient identities?

## Methods

*Context and Participants*

This case is part of a larger one-year ethnographic project focused on the cultural interpretations of secondary mathematics classrooms by Latina immigrants who attended a large urban high school as English Language Learners and successfully completed four years of college preparatory mathematics, including Advanced Placement Calculus. There was no specific site for this study. The stories the young women shared spanned time and contexts, both inside and outside of school, and both inside and outside of the United States.

Railside High School, however, was the one community that all participants had in common. They attended Railside during the 2000-2001 school year, the same year in which both Boaler (2002) and Horn (2002) conducted their research. During this school year Railside had approximately 1500 total students. Of these students, 35% were Latino, 25% African American, 21% White, and 18% Asian or Pacific Islander, and 1% American Indian. In 2000-2001, 12% of all students at Railside received English language services, and of these 68% were Spanish speaking (Education Data Partnership, 2007).

Additionally, these young women experienced four years of mathematics instructions steeped in the program of Complex Instruction. Based on the work of Elizabeth Cohen and Rachel Lotan at Stanford University, Complex Instruction (CI), is a framework that “enables teachers to teach at a high intellectual level” (Cohen et al., 1999) through the use of collaborative groups in heterogeneous classrooms. At the core of CI is an awareness of the structural inequities that are generated both in the larger society and within schools and classrooms, which often translate into an assumed hierarchy of competence. Complex Instruction aims to eradicate these hierarchies and to promote equal-status interactions amongst students, creating opportunities for all students to engage with and learn from rigorous mathematical tasks within a cooperative learning environment.

*Data Collection and Analysis*

Narrative methods (Lieblich, Tuval-Mashiach, & Zilber, 1998) were used to collect life stories told by these young women about experiences in their home countries, in the United States, and in their secondary mathematics classrooms. Other data included focus group meetings and parent interviews.

Narrative inquiry was used to shift the research focus away from teachers, programs and classrooms as the units of analysis and foreground individual students and their stories as primary data sources. This shift helps to dispel common views of Latina immigrants as a homogenous group and simultaneously affords access to the “self-understandings” (Holland et al., 1998, p. 8) and “representations of self” (p. 29) as described by the young women. Second, narrative inquiry is not often utilized in mathematics education research, therefore this frame expanded available information about students’ inner realities and the meanings assigned to them. Finally, in this work I am responding to a call by many to attend to out-of-school contexts as sites that influence students’ beliefs about self and mathematics in order to better understand the range of sociohistorical forces affecting students’ mathematical learning (Martin, 2000; Reyes & Stanic, 1988; Weis & Fine, 2000).

I analyzed the data by using a “content-oriented approach” (Lieblich, Tuval-Mashiach & Zilber, 1998), in which I dissected the original stories and analyzed smaller narrative sections aimed at uncovering the implicit content by asking about the meaning conveyed by the narrative, which traits or motives of the individual were portrayed, and the relevance of the images invoked by the author. I considered the distribution of themes across the story as a while and attended to emphasis placed on particular words or phrases and considered the emotion with which the young woman spoke.

Case studies provided me with the opportunity to examine the “local particulars” (Dyson & Genishi, 2005, p. 3) of each young woman’s identity and experiences as related to the more abstract phenomenon of learning mathematics. As a research design, case study emphasizes “the role of organizations, communities, crucial events, and significant others in shaping subject’s evolving definitions of self and their perspectives on life” (Bodgen & Biklen, 2003, p. 57). This focus coincides with my multi-level framework that includes multiple communities of practice in which each woman participated as important sites for identity formation.

## Results

Although her identities as a young woman and Mexican were important to Amelia, her identity as “liberal” was most salient to her. Amelia emphasized her “liberalness” in her decisions about the people with whom she associated and how she participated in the world. Amelia’s “liberal” identity did not have any political connotations. The meaning she assigned to “liberal” focused on voice and authority. Amelia felt that she acted “liberally” when she verbalized her ideas and opinions and made decisions that determined the trajectory of her life. Amelia constructed this salient “liberal” identity as she participated in both local communities in Mexico and as she moved across geographical and emotional borders throughout her life.

When Amelia described her secondary mathematics experiences at Railside High, she focused on the “multidimensional” (Boaler, 2004) nature of mathematics, especially the myriad ways to think, talk, and reason mathematically that were available to her. For Amelia, being a mathematics learner at Railside meant that she could discuss ideas, explore and justify alternative solutions, argue and reason. In these spaces where school mathematics was broadly constructed, Amelia’s “liberal” identity was useful and necessary. Her communication skills and desire to verbalize her opinions became strengths in these mathematical communities that required students to put forth ideas and justify reasons. Amelia’s “liberal” desires to determine her life decisions and paths were necessary skills when her mathematics teachers asked for multiple strategies for solving a problem. Indeed, Amelia’s “liberal” ways of being in out-of-school communities supported her mathematical participation, and her “liberal” identity became an intellectual resource for participating with and learning mathematics.

## Discussion

Amelia’s case demonstrates that the identities most salient to young people are not always constructed relative to major social structures such as ethnicity and gender. Identities are extremely nuanced and particular to an individual and her lived realities. It is therefore not useful and simultaneously potentially harmful to assume that all Latina immigrants fit into a homogenous group. While brown skin, long dark hair and a Spanish accent may place Latinas from the same continent, varied experiences intertwined with unique issues of immigration, bilingualism, religion, and generational status shape the identities created by Latinas.

Additionally, this case illuminates the cultural connections Amelia made between her salient identity as “liberal” and her participation in secondary school mathematics. Amelia’s focus on the multidimensionality of Railside’s mathematics program, framed by the use of Complex Instruction, argues for the expansion of secondary school mathematics such that students have opportunities to negotiate their use of cultural knowledge in service of learning mathematics. The knowledge and skills that young people cultivate while constructing salient identities become necessary resources for learning.

Finally, the opportunities available for Amelia to participate “liberally” in her mathematics classrooms helped her to engage authentically. As opposed to those who assert, “I am not a math person,” or students who claim that the norms for participation available in their mathematics classes do not coincide with the ways in which they think of themselves as young people (Boaler & Greeno, 2002), Amelia maintains that she could “be herself” in her mathematics classes. She could simultaneously be “liberal” and a mathematics learner. In fact, through her participation in four years of high school mathematics at Railside, Amelia created a new identity by bringing and using her "liberal" identity in the mathematics classroom and becoming a "liberal" mathematics learner in the process.

# CURRICULAR REDESIGN, COFLECTION, AND DEMOCRATIC MATHEMATICS EDUCATION

Lecretia A Buckley
Jackson State University
lecretia.a.buckley@jsums.edu

*In this paper, I examine teachers' tacit notions of equity as they engage in several efforts to reform their department's curriculum. Their efforts are examined for insights to implement equity-centered reform. Coflection, or joint inquiry, is a construct with four components: collective, deliberative, critical, and transformative. Coflection is offered as a means to promote equity-centered reform which encompasses teachers' professional development, curricular design, and construction of placement policies.*

## Introduction

Equity is a longstanding issue in mathematics education. For decades, equity has gained more attention with increasing prominence. In spite of gains in achievement on low cognitive demand items among students who traditionally underperform (American Institutes for Research, 2005; Tate, 1997), a significant achievement gap remains (Lubienski & Crockett, 2007). The achievement gap can be partially attributed to students' access to content or the curriculum. At the high school level, students' access to advanced mathematics content or courses is influenced by course offerings and policies such as tracking. When departments offer fewer and more rigorous courses, students experience higher performance (Lee, Smith, & Croninger, 1999).

In the face of low performance which is typically worse among underrepresented students, mathematics departments have engaged in various reform efforts to mitigate the problem. While some departments have been identified as *Organized For Advancement* (Gutierrez, 1999), others have implemented detracking (Oakes, Wells, Jones, & Datnow, 1996) to address the problems associated with the achievement gap. Still, others have sought reform through professional development programs (e.g., Silver & Stein, 1996). Each of these approaches has provided insights to the field. Yet, there remains a need to examine reform as a dynamic process in which assumptions about equity are explicitly addressed and challenged.

In this paper, I examine teachers' tacit notions of equity as garnered through a research study of department level curricular design. In particular, I consider the impact of their conceptions of equity on the curricular redesign that was implemented. The teachers' conception of equity comprise their expectations for underrepresented students as well as their expectations for how and for what students would use their mathematical understanding. Afterwards, I analyze how equitable the resulting mathematics program is as well as the barriers which contributed to inequitable outcomes. Finally, coflection is offered as an alternative approach to implementing equity-centered reform.

## Theoretical Framework

The teachers' conceptions of equity are informed by Secada's (1989) notion of equity as comparative, qualitative, and dynamic. In order to gauge equity, comparisons are made between two entities in order to judge what is fair or just. Equity is different from equality in that comparisons employed to evaluate equality consider if there is sameness or parity. The comparisons that are made are a matter of what is just; consequently, there is an

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

acknowledgement that the comparisons are value-laden (Gutierrez, 2002). Equity is a dynamic construct and is context specific requiring ongoing and periodic evaluations. Additionally, what is characterized as equitable mathematics education comprises inputs (e.g., access to courses), processes (e.g., pedagogical approaches), and outputs (e.g., achievement scores). This approach to gauging equity was employed by Rousseau and Tate (2003) as they evaluated a mathematics program and identified barriers that impeded teachers' reflection on their practices.

The research reported here is also informed by Skovsmose and Valero's (2001) work which posits coflection as a means to promote democratic mathematics education and the work of Carol Malloy (2002). Coflection is a knowledge generating process and consists of four components – collective, deliberative, critical, and transformative. Coflection refers to the "thinking process by means of which people, together, bend back on each other's thoughts and actions in a conscious way, that is, people *together* [emphasis added] consider the thoughts, actions, and experiences they live as part of their collective endeavor, and also adopt a critical position toward their activity (Skovsmose & Valero, 2001, p. 48, 2001). Democratic education is characterized as education that is concerned with providing access and mathematical literacy (Malloy, 2002). Malloy outlines three benefits of democratic mathematics education - inclusiveness, mathematical understanding, and the ability to apply mathematics to problems.

With this framing in mind, I identify barriers that inhibited the design of a more equitable mathematics program. The resulting curriculum is evaluated to gauge how equitable or democratic it is. Then the barriers are investigated as I discuss how equity-centered reform focusing on coflection may have minimized their influence and yielded different, more-equitable outcomes.

## Research Design

The research was conducted in a secondary mathematics department in a small town in the Midwest. The department served 1500 students and consisted of 13 teachers with 12 participating in this study. The department implemented several efforts to reform its curriculum focusing specifically on low level classes which were disproportionately populated by underrepresented students. The data sources include field notes from a year of department meetings; field notes from classroom observations of five sections of low-level mathematics courses taught by three teachers; up to three interviews with each of 12 participating members of the department, administrators, and a guidance counselor; and school documents.

Constant comparative analysis (Strauss, 1987) was employed as I identified emergent themes. A list of initial codes was informed by the research literature and was used for the initial coding. The list of codes was revised as iterations of analysis were completed.

## Findings

The teachers held a one-dimensional conception of equity that focused primarily on providing students with access to content. They added and eliminated courses; however, they did not evaluate the pedagogical practices that were employed or how specific courses limited or increased students' access to advanced mathematics. The teachers' expectations were low and led them to eliminate content they classified as rigorous from courses. The efforts in which the department engaged did not produce a more equitable mathematics program. Rather, the department designed a new program of course offerings that limited students' access to advanced mathematics, perpetuated tracking, and neglected conceptual understanding.

The course offerings which resulted from the department's efforts yielded a mathematics program that was, perhaps, less equitable than the one they sought to reform. First, the new course offerings included two additional low-level courses. These courses were intended to provide students with opportunities to increase their fluency with skills and procedures or to prepare them for the first mathematics course for which a student could receive mathematics credit towards graduation. Second, the new course offerings included Modified Algebra, a course that by design, covered concepts in algebra with *less depth* than the traditional algebra course. Third, a Modified Geometry course was added; however, it excluded formal proof writing, thereby, limiting students' opportunities to engage in deductive reasoning.

While the new course offerings provided more opportunities for students to take more remedial courses, the course offerings also increased tracking, and stricter placement policies were implemented. Together, the Modified Algebra and Modified Geometry course constituted an additional track for students in the low level courses targeted by the department's efforts. Although this track permitted more students to take a geometry course, the track itself consisted of courses that were deemed, by the teachers in the department, as less rigorous and unlikely to prepare students for advanced mathematics course taking.

Moreover, the curriculum did not promote conceptual understanding. The Modified Algebra course addressed concepts with less depth, and the Modified Geometry course lacked formal proof writing and did not seek to improve students' ability to reason.

Two significant barriers to designing a more equitable mathematics program existed in the department's dynamic reform processes. The first barrier was the teachers' failure to examine their own beliefs and expectations for underrepresented students. Their conceptions of equity were narrow and reflected many commonly held and low expectations. Their low expectations were evidenced by their rationale to exclude formal proof writing; their rationale was that this was the *harder* content in the course. The goal became designing a course that students *could* pass. They did not examine their expectations for what their students could learn or how their own teaching might influence student performance.

The second barrier was the teachers' views about the purpose of mathematics. The teachers did not envision their students as users of mathematics far beyond arithmetic. They sought to prepare their students for everyday tasks that were restricted to purchasing and banking oriented tasks. They did not design courses that sought to prepare their students for college entrance examinations or mathematics- or science-based majors or careers. Nor were the students' preparation aimed at preparing them for decision-making and analysis needed to participate in a democratic society. The answer to the question that Secada (1989) asked about the intended ends of the students' mathematics education was that it would not to prepare them for advancement or economic or democratic participation.

## Discussion

In this section, I summarize how this research aligns with previous findings and outline how coflection employed as a knowledge generating process embedded in professional development might have minimized the negative, unintended outcomes. An exploration of how the four components of coflection promote democratic mathematics education is provided. The insights gained from this inquiry highlight the need for equity-centered professional development and reform efforts that explicitly confront teachers' conception of equity.

This study addresses areas that already have been studied. The curricular redesign efforts in the department revealed that the teachers held low expectations of their students. The students affected by the changes were primarily students of color and poor students, and the teachers holding low expectations aligned with previous research (e.g., Irvine & York, 1993). Analysis of student performance on national assessments reveal that despite some gains, the gains made by students of color are typically on low cognitive demand items. The focus of the department to design remedial courses and to improve procedural fluency yielded a program that did not promote conceptual understanding. The addition of more lower level courses may restrict the number of students who would take more higher level courses and stifle their performance since research higher performance is associated with a narrower more rigorous curriculum.

The department sought to improve students' performance in the low level courses and to have those students to take more mathematics. While a small percentage of the students would take geometry as a result of the new course offerings, the mathematics education that they received fell short of democratic education. Indeed, more students would take geometry. This access to new content speaks to inclusiveness – the first benefit of democratic mathematics education (Malloy, 2002). However, mathematics understanding and the ability to apply mathematics, the second and third benefits, were not foci or outcomes of the reform efforts.

Despite these disheartening outcomes, the challenge to create more equitable mathematics programs must not be abandoned. As mathematics teachers, mathematics educators, and mathematics teacher educators forge ahead, we must evaluate prior efforts and offer alternative approaches. Coflection is an alternative that I propose.

The four components of coflection speak to the barriers of equity-centered reform that I identified in the department's efforts. Coflection is collective; it takes place within a community with a shared endeavor. In this case, the community is the mathematics department, and the endeavor is reforming its mathematics program to address high failure rates amongst students of color and poor students. Coflection is deliberate with community members engaging in discourse aimed at solving the problems they have identified. Members of the department met frequently, at least once per month, and smaller groups of teachers met to discuss issues specific to particular courses. Thus, meeting to deliberate would be an unlikely problem for this department to employ coflection. The critical component of coflection, however, is essential and was missing from this department's efforts. While the members of the department met frequently and had a shared goal, they did not engage in critical analysis of the courses they designed or their rationale for such. Rather, their notions about the nature of mathematics, who can learn advanced mathematics, and the role of teaching in student learning were unchallenged. The absence of this critical component facilitated reform that was not more equitable. The goal of coflection and democratic education is also the fourth component of coflection – transformation. Transformation that advances equity, however, did not result. Yet, coflection appears to be an alternative that may have yielded more equitable outcomes had it been included as part of the reform process.

## Conclusion

Teachers who engage in reform must be willing to be critical of existing ideologies, practices, and policies. This study demonstrates that in order to create more equitable mathematics programs, having teachers who are willing to devote time, discuss problems, and make changes are insufficient conditions. Rather, reform must be equity-centered challenging long held notions about who can learn powerful mathematics and re-envisioning students' possibilities and how mathematics opens or closes the doors of opportunity. Coflection, with its goal of *transformation* that results from *deliberation* from a *critical* perspective to solve a shared endeavor by a *collective,* presents an alternative to equity-centered reform efforts that have been unsuccessful.

# SEEING MATHEMATICAL LITERACIES IN AN AFRICAN-AMERICAN PARENT-CHILD INTERACTION

Amy Noelle Parks
University of Georgia

Sarah Bridges-Rhoads
University of Georgia
sbridges@uga.edu

*This paper provides an analysis of the mathematical ways of thinking present in a 15-minute interaction between an African American mother and her preschool son during a craft project as a way of opening up notions about the competence of young minority children and their parents.*

## Introduction

Much of the news reported about the achievement gap in mathematics is pretty bleak, even for young children. Studies have shown that while 66 percent of European American kindergarteners pass tests on reading numerals, counting past 10, sequencing, and comparing; only 42 percent of African American and 44 percent of Hispanic children pass similar tests (NRC, 2005). Similarly, other research has shown that poor children have a harder time solving problems mentally than well-off children do (Jordan, Huttenlocher & Levine, 1994).

Historically, researchers have attributed this gap at the start of school to a variety of factors, including inadequate preschool education (e.g., Graham, Nash & Paul, 1997) and inadequate support from parents (e.g., Starkey & Klein, 2000). The National Research Council (2005, p. 173) summed up this line of work in this way: "overall, the research shows that poor and minority children entering school do possess some informal mathematical abilities but that many of these abilities have developed at a slower rate than in middle-class children."

More recently, some mathematics education researchers have argued that the gap in performance between minority and low-income students and their majority peers may result from different mathematical values and practices in homes and schools as well as educators' inability or unwillingness to capitalize on the mathematical strengths children bring from home (Anderson & Gold, 2006; Baker, Street & Tomlin, 2006).

The purpose of this paper is to build on this later work by providing an in-depth analysis of the mathematical ways of thinking present in a 15-minute interaction between an African American mother and her preschool son as they worked together on a craft as part of a family involvement activity. To do this, we draw on the theoretical frame of multiliteracies (New London Group, 1996), which has been used by reading and language researchers to diversify notions of what it means to be literate. We believe this theoretical frame can be used within mathematics education to highlight the diverse practices involved in competent mathematical performances.

## Literature Review

A number of researchers concerned with the mathematical development of low-income and minority preschoolers have written about interventions that were designed to teach parents successful ways of developing the mathematical thinking of their children (Baker, Piotrkowski & Brooks-Gunn, 1998; Bryant, Burchinal, Lau & Sparling, 1994; Starkey & Klein, 2000). Although these studies demonstrated some success improving preschoolers' performance on mathematics assessments, the studies also began with the assumption that the research community and teachers had little to learn from low-income and minority parents. For example,

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

Bryant, Burchinal, Lau and Sparling (1994) compare children from "better" home environments to those in "poorer" home environments. The line between these two kinds of homes was determined by a survey, which asked about things like number of books in the home, organizational schedules, and family activities. Families that came out lacking in these measures were not seen as having alternative resources that had not been addressed by the survey. The authors of the study conclude that "determining how to improve the quality of Head Start child care and home environments are major challenges that still need to be addressed" (Ibid, p. 306). This notion that researchers must work to "improve" family lives makes it difficult to think about low-income and minority families as having strengths that researchers and teachers might tap.

Anderson and Gold (2006, p. 262) challenged this line of thinking with a study that examined the mathematical practices of low-income, minority children in informal settings, such as game-playing at home and school. They wrote: "Too often, teachers and schools fail to recognize or credit the knowledge, skills, and strategies that children bring with them from home – especially when a child comes from a family background that differs from that of the teacher's in social class, race, or ethnicity." Researchers are only just beginning to identify home-based knowledge, skills, and strategies that may be useful in early mathematical learning. Recent studies have identified some funds of knowledge (Gonzalez, Andrade, Civil & Moll, 2005) that families in some communities possess that may be drawn on in mathematics classrooms, such as knowledge of gardening (Civil, 2001). More work needs to be done that looks not only at the particular knowledge and skills that families in communities may have as a result of their work or home lives, but also how ways of speaking to and interacting with children in non-majority communities can be seen as sites for building mathematical competence, rather than as deficits.

A number of researchers have noted differences between the speaking patterns and norms of interaction of African American students and their majority teachers (e.g., Delpit, 1995; Heath, 1983). These differences have been explored in a number of ways. For example, Orr (1987), who studied the failure of African American students in mathematics and science at a private, progressive school, concluded that Black Vernacular English prevented students from thinking in mathematical ways. She suggested that this dialect, used by many African-American students in the school, did not have adequate vocabulary or grammar structures to support high-level quantitative thinking. This was harshly critiqued by linguists, in particular Baugh (1994); however, the notion that adult-issued commands and non-standard English inhibit mathematical thinking lingers. Other researchers have suggested that the rich, linguistic traditions in the African American community could be taken up and used in productive ways to further school learning (e.g., Delpit, 1995); however, much of this work has focused on language literacy learning. This paper seeks to bring this line of work into mathematics, examining the ways that an African American, low-income mother's comments, questions, and directions to her son can be seen as supporting his mathematical thinking and reasoning.

## Theoretical Framework

To contribute to the literature described in the previous section, this paper draws on the notion of multiliteracies to identify mathematical literacies present in a parent-child interaction. The goal is to name particular language and communicative practices that could be studied in other settings with attention to mathematical thinking and reasoning.

Multiliteracies, first articulated by the New London Group (1996), was intended to address both the multiplication of modes of literacy (visual, print, computer, etc.) and the increasing cultural and linguistic diversity present in many countries around the world. The theory was intended to expand notions of literacy beyond language and traditional representations of language to include the many ways that literacy is used by people in the world. In some ways, this work is similar to work in mathematics that has sought to identify and to value the ways that mathematics is used by people in informal situations (e.g., Lave, 1988). However, with the term “multiliteracies,” the New London Group made a conscious effort to include these alternative practices in the definition of what it meant to be literate in the world today. In particular, research drawing on multiliteracies has emphasized the visual aspects of language and has criticized definitions that focus only on the decoding and meaning-making of written words. Using this framework, literacy researchers have found that children identified as “struggling” in literacy classrooms often are capable of complex literacy practices when the definition of literacy is broadened (e.g., Cumming-Potvin, 2007).

## Modes of Inquiry

The data reported in this paper comes out of a larger study located within interpretive ethnographic traditions (Eisenhardt, 1988; Geertz, 1973). For the last two years, we have been studying the mathematical learning of children in a preschool classroom located in one of the most rural counties in Georgia. Oliver County Public School is a PK-12 school with fewer than 300 students. Most of the students are African American, and, because so many students qualify for free lunch, the school decided not to charge any of its students for meals. These characteristics make it an ideal setting to study the mathematical learning of underrepresented students in a *rural* (as opposed to the more-commonly studied urban) context.

Over these two years, we have visited the classroom weekly to observe both formal instruction and center time, where children engage in more open-ended play. During these visits, we wrote fieldnotes, audio-recorded conversations, took digital pictures, and collected student work. To supplement the written fieldnotes, all audio tapes have been transcribed. For this paper, we chose to focus on the fieldnotes and transcripts of a 15-minute interaction between a mother, Patrice, and her four-year-old son, Markus. In order to promote family involvement, one of the high school classes occasionally organizes activities for the preschool children and their parents. This activity, which involved making a paper plate scarecrow, was held just before Thanksgiving in the second year of the project. Although here we focus on just this interaction, our analysis was informed by our experiences in the classroom over two years as well as our analysis of the larger corpus of classroom fieldnotes for other purposes.

Little (2002) did similar work when she chose a short segment of conversation to analyze in her study of collaborative learning in teacher study groups. She notes that “there is crucial strategic value in looking closely at bounded segments of text” (p. 920) because the “mundane exchanges” of any moment reveal interaction patterns, ways of speaking, and shared values and expectations. The goal of this analysis is not to generalize to all of Patrice and Markus’s interactions and certainly not to all interactions between African American mothers and their children. As Geertz (1973, p. 23) has written, the point of ethnographic work is not to show “the world in a teacup.” Rather, the goal here is to provide an analytic model for examining informal conversations in order to identify mathematical literacies.

To meet this goal, we began our analysis by asking the following research question: What mathematical literacies did Markus engage in during this craft-making experience and how did his mother support this engagement? For this preliminary analysis, we did a content analysis of the mathematical knowledge and skills represented in the focal transcript as well as a discourse analysis of the conversational moves used by the mother and child.

## The Conversation

Due to the space limitations, we present the first seven minutes of transcript below in as much detail as possible (although we analyzed the entire interaction). To save space, markers of pausing have been eliminated, some parts of the conversation have been summarized instead of quoted, and some unrelated conversations with other children and parents have been removed. Although we could not present the whole interaction, we wanted to present a significant chunk in because there are few examples of parent-child interactions around mathematics in the literature. Many claims about parents' abilities to support their students in mathematics are based on interviews and surveys, rather than observations.

As stated above, this conversation occurred around an activity that asked parents and children to make a scarecrow out of a pre-packaged craft, which included paper plates, colored foam cutouts, and written directions. These directions included a black-and-white diagram of what the finished product was supposed to look like. Some of the foam cutouts were irregular, while others were triangles, circles, and rectangles.

*Patrice showed Markus the black-and-white paper with the directions on it. He looked at it in her hands as she talked.*

*Patrice:* "See this page?" *He nodded*. "See what's supposed to go at the top? See that triangle?"

*Patrice pointed to the drawing of the triangle on the paper. Markus looked at it and then at the foam pieces spread out in front of him. He reached for the large brown triangle that was the biggest part of the hat and was supposed to be glued on top.*

*Patrice:* "You see how that goes at the top*?" She pointed at the picture in the directions. Markus put the piece on the top of the scarecrow's head. Patrice picked up the piece that was supposed to serve as the brim.* "And this." *She held up the brim piece.* "This goes like that." *She pointed first to the picture on the diagram and then put the brim onto the scarecrow.*

*Patrice then picked up a rectangle of perforated yellow foam*. "See this? This is the hair. We got to take these apart. I guess." *She looked back at the diagram and then pulled one of the pieces off.* "Here, you can help me." *Patrice handed Markus some of the foam.*

*Markus:* "Where the hair go?"
*Patrice:* "Look on the picture and see." *She handed him the diagram.* "You see? Up under there?" *She pointed to the hair. Markus put down the foam and picked up the diagram and studied it.*
*Markus:* "Under the hat?"
*Patrice:* "Yeah. I'll take it apart for you and you can put it on." *She took back the foam and quickly ripped it apart, while Markus laid three pieces of foam down over the forehead of the scarecrow and tucked up under the hat, just like in the picture. He sat back.* "That's all the hair you want?"
*Markus*: "Uh-uh." *He started to put more pieces on.*

*Patrice put the strips she had separated into two piles in front of Markus.* "They got long hair and short hair." *She picked up the directions.* "You can use them so it can look like this, with the short hair in the front and the long hair can go on the back." *Patrice noticed that they had forgotten to put glue down on the paper plate. She took off the hair that Markus had put on, got a glue stick, and spread glue on the top. She then started to replace the hair.*

*Patrice*: "You see. You do the rest of them." *Markus started to lay down more strips of foam across the forehead of the scarecrow.* "Make sure it sticks now. Press it down." *Markus pressed on the hair.* "Can you get one more on there?" *Markus picked up another strand of hair and placed it in line* *next to the others.* "Now, you're going to put the long hair on the sides, but you need more glue."

*While Patrice got glue from another parent, Markus picked up the paper with the directions on it and traced the long hair on the sides with his finger. Then he looked back at his own scarecrow. Patrice took the glue stick and spread it on the sides and then put more glue on the top of the plate above the hair that had already been glued downed.*

| | |
|---|---|
| *Patrice:* | "Look at your picture. Remember." *Markus picked up the directions and studied them.* |
| *Markus*: | "The triangle goes on top?" |
| *Patrice:* | "Uh-huh. How?" *Markus pointed to the top of the scarecrow.* |
| *Markus:* | "Like that." |
| *Patrice:* | "Uh huh. You show me." *Markus picked up the triangle top the hat and placed it on the scarecrow to match the picture.* |
| *Patrice:* | "And then … this." *She picked up the brim of the hat. Without prompting, Markus picked up the directions and looked at them. After a moment he pointed to the bottom of the hat.* |
| *Markus*: | "It go right there." |
| *Patrice:* | "Okay." *She put glue on the bottom of the hat and then Markus put the brim on.* |
| *Patrice:* | "What else we got there?" *She picked up the directions*. "We need a nose, don't we? You got a nose?" *Markus looked at the directions* |
| *Markus:* | "Uh-huh." |
| *Patrice:* | "What kind of nose*?" Markus picked up the triangle piece that matched the black-and-white drawing in the directions.* |
| *Markus*: | "Orange." |
| *Patrice*: | "Okay. And what kind is it? … What it look like? … Shape." |
| *Markus*: | "That way." *He held the triangle so it was oriented the same way as in the picture.* |
| *Patrice*: | "Triangle, right?" *Markus nodded*. |

*Patrice put glue in the center of the face and Markus put the triangle on. The conversation continued as they finished the project.*

## Mathematical Multiliteracies

Throughout this conversation, Markus demonstrated literacies related to geometry, spatial reasoning, and representation. The Principles and Standards (NCTM, 2000, p. 41) asks that young students "analyze characteristics and properties of two-and three-dimensional shapes," "specify locations and describe spatial relationships," "apply transformations," and "use visualization, spatial reasoning, and geometric modeling to solve problems." In addition students are expected to "use representations to model and interpret physical, social, and mathematical phenomena" (Ibid, p. 67). Repeatedly, Markus studied the written diagram presented in the directions to place objects on the paper plate circle that represents the scarecrow's face. He began by placing the large triangle that represented the hat on the top of the paper plate, not only putting it in the correct place, but also orienting the triangle to match the diagram contained within the directions. He went on to place the brim in the correct place, as well as the hair, the eyes, the nose, the mouth, a flower, and a bow tie (some of this happened in the portion of the transcript not reported.)

Making these placements was not simple work for a four-year-old. In the written representation, the picture of the scarecrow was complete, in black-and-white, and much smaller than the craft Markus was making. Thus, to identify the correct piece among the foam cut-outs, Markus had to scale up the black-and-white image, disregard the color, and, often mentally transform the orientation of the cut-out to match the image in the diagram. This demonstrated not only literacy in reading a written diagram, but also in visualizing to solve geometric problems.

Some of the foam cut-outs were regular 2-d figures that preschool children are commonly asked to identify. (The eyes were circles; the nose and hat a triangle; and the long and short hair was differently-proportioned rectangles.) When working, Markus occasionally used the names of these shapes. When talking about the hat, he asked if "the triangle goes on top" and in the unreported part of the conversation, he described the center of the flower as a circle. However, when his mother asked him to identify the shaped of the nose, he did not use the word "triangle." He talked instead about its orientation. Because this question is prominent in the conversation (and most closely resembles the kinds of questions preschool teachers typically ask), one might assume that Markus has difficulty using shape names. However, his casual use of the terms in other contexts suggests that this is not the case, and rather, that it was the problem of orientation that he found more interesting at this time.

Another emerging literacy demonstrated by Markus in this conversation was his use of the written directions and the visual diagram to direct purposeful activity. In both prompted and unprompted moments, Markus returned to the written directions to make decisions about his craft. This demonstrated his expectation that directions are meaningful and that he is competent to interpret them. As in the reading and language multiliteracies work, this meaning-making around visual images can be seen as a literacy that is increasing important in an age of technical diagrams and machines. Despite its value, the interpretation of visual images and diagrams is a literacy rarely assessed in most standard assessments of preschool and kindergarten readiness.

Throughout the conversation, Patrice scaffolded her son's emerging mathematical literacies in a variety of ways. One frequent strategy she used was the making of "see" statements to direct Markus's attention and to model ways of thinking about and performing a task. She introduced the written directions by saying to Markus: "See this page? See what's supposed to go on top? See that triangle?" In the complete transcript, she told Markus to "see" a dozen times. These statements communicated to Markus what was important. Often, even when the statement was phrased as a question, Patrice did not expect Markus to answer, but instead looked at him to make sure that he understood what she was saying. In that opening question, after asking Markus "see what's supposed to go at the top?" she did not allow him to reply, but continued by directing his attention to triangle. She reinforced this move by pointing to the triangle on the written diagram. She then remained silent while he looked for the corresponding piece among the foam cutouts. When he located the correct piece, she reinforced the connection between the foam cutouts and the diagram by saying: "You see how that goes on top?" which was another question that Markus was not intended to answer (and, in fact, did not answer.) Some might critique Patrice's questioning here as not being sufficiently open-ended or as taking over the thinking for the child. However, her prompts can also be seen as promoting opportunities for Markus to make connections and to think. Later in the conversation, Markus picked up the diagram to decide where to place the hair on his own. It seems likely that he did this because his mother encouraged him to see the diagram as a source of information and provided him with the necessary support he needed to interpret it. This is another site where the concept of multiliteracies can open up ideas about competence. Markus does not necessarily need to be able to verbally articulate his thinking about mathematics in order to be seen as thinking mathematically. Competence can lie outside of spoken words.

Patrice also modeled her work interpreting the written directions as a way of figuring out what to do next. After she picked up the yellow foam that was to be taken apart to make the rectangles for the hair, Patrice looked back at the written directions to make sure her actions were correct. She did not explain this Markus, but simply performed it. This is a different kind of modeling then the sort often done by teachers of young children. Patrice did not over-dramatize her actions, narrate each step, or quiz Markus about what she was doing. Instead, she used the directions for information as an adult. Again, this could be seen as problematic because the modeling is not made explicit or because she is taking over the work of interpretation for Markus. However, Patrice's moves can also be seen as productive. Patrice's actions demonstrated to Markus that the reading of directions and the interpretation of a diagram is genuinely useful in the adult world, rather than *acting* as if this was the case. It is in many ways a much more genuine modeling of how adults solve problems in the world.

In addition to examining the mathematical literacies present, it is also worthwhile to think about the kinds of literacies that are not represented here, particularly those that mathematics educators and preschool teachers might expect to see in such an activity. For example, Patrice never asked Markus to count any of the foam cutouts in the project. The only reference to enumeration is when she asked Markus if he could add "one more" hair. (He did.) During this activity, both the teacher and the paraprofessional, who were helping children whose parents could not attend, repeatedly asked children to count eyes, noses, and hair. This emphasis is understandable given the focus on counting in many preschool standards and in many of the assessments that are used to make judgments about children. In some ways, Patrice missed an opportunity to help her son practice these often-assessed skills; however, by focusing on the kinds of mathematical literacies necessary for the task, she presented an image of mathematical literacy aimed at purposeful activity rather than as one imposed unnecessarily on the world. In similar ways, Patrice did not ever ask Markus to explain his thinking, as many mathematics educators might do. There are certainly drawbacks to this; however, it is important not to confuse the articulation of thinking with thinking itself in considering Patrice's ability to support her son's developing mathematical literacy.

In conclusion, it is unacceptable to dismiss what Markus does in this episode as demonstrating "some informal mathematical abilities," as the authors of *Adding it Up* appear to do. In discussions of the early achievement gap, the emphasis on counting, reading numerals, sequencing, comparing, and shape identification has created a narrow view of early mathematical literacy. To appropriately value and assess the mathematical literacies that all children bring to school, broader lenses must be used. The mathematical literacies demonstrated by Markus in this episode are in many ways more sophisticated than those required by many of the preschool assessments used to label low-income and minority children as behind. Systematically looking for diverse mathematical strengths may both broaden our conceptions of young children's mathematical literacies as well as challenge our notions about who is capable of supporting their children's learning.

# A STUDENT'S CAUSAL EXPLANATIONS OF THE RACIAL ACHIEVEMENT GAP IN MATHEMATICS EDUCATION

Niral Shah
University of California, Berkeley
niral@berkeley.edu

*This paper analyzes a clinical interview of one student's understandings of the causes of racial performance gaps in mathematics education. The topic was chosen because there is a literature on teachers' perceptions of racial gaps but little in terms of student perceptions. The particular student was chosen because her thought processes indicated an interesting tension between behavioral and structural explanations for the gap. Data suggest that this student privileged behavioral factors and justified her reasoning by drawing on prior in-school and out-of-school experiences in problematic ways. Implications of student perceptions of racial performance gaps for teaching and learning are discussed.*

## Background

The latest report from the Trends in International Mathematics and Science Study (TIMSS) shows that White and Asian students continue to excel relative to Black and Latino students in both elementary and secondary mathematics, thus confirming the persistence of disparate achievement patterns amongst racial/ethnic groups in the United States (Gonzales et al., 2008). Explanations for the achievement gap have spanned between what race scholar Cornell West (2001) calls "conservative behaviorism" and "liberal structuralism." Those falling in the first category explain the achievement gap in terms of personal responsibility, citing cultural deficits such as an impoverished work ethic passed on to children by their parents. Those in the latter camp find behavioral factors insufficient (Lee, 2002), instead explaining this phenomenon as an effect of racism at both an individual and institutional level (Oakes, 2005). Yet despite tendencies by some to advocate exclusively for either extreme (e.g., McWhorter, 2000), others contend that neither perspective in isolation fully explains the achievement gap (Noguera, 2008); that in fact, understanding the gap as a complex sociopolitical phenomenon implicates the relevance of both behavioral and structural factors.

One factor that has been shown to contribute to academic performance is teachers' perceptions of their students' academic capabilities. Secada (1992) has argued that teachers' perceptions tend to vary based on demographic variables, such as race, socioeconomic status, and gender. These disparate perceptions can result in unequal academic expectations for students, which in turn contribute to a widening of the achievement gap (Ferguson, 1998; Jussium, Eccles, & Madon, 1996).

However, while characterizing teachers' perceptions of the achievement gap continues to be a worthwhile enterprise, it is equally important that students' perspectives on this matter be explored as well. Making sense of the manner in which students' perceive and explain differences in mathematics achievement is significant not only because of students' status as critical actors in the classroom, but also because their beliefs have implications for teaching and learning. For instance, the reform movement in mathematics education encourages teachers to make collaborative learning a part of their pedagogy, an exhortation that is predicated on the idea that appropriately structured discourse facilitates student understanding (National Council of Teachers of Mathematics, 2000). But when students hold particular views on race and on the

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

achievement gap, their perceptions of their classmates may affect collaborative learning. The present study takes a first step in the direction of documenting student perceptions of disparate performance patterns by way of a fine-grained analysis of one student's causal explanations of such variations in mathematics performance.

## Theoretical Perspectives

Given the inherent complexity of the achievement gap, a study of a naïve explanation of this phenomenon must be geared to handle potentially conflicting explanations. In the context of his research on physics education, diSessa (1979) has claimed, "People are more fundamentally model builders than they are formal system builders….Their views are as much conflicting patchworks as they are coherent systems" (p. 251). When asked to explain the physics underlying everyday phenomena such as projectile motion, diSessa (1988) found that in lieu of a coherent, systematic explanation, people tended to provide multiple, occasionally inconsistent, explanations.

Although diSessa's ideas derive from a radically different domain, it has been shown that diSessa's theory can shed light on people's reasoning about social issues such as race and equity (Philip, 2007). Indeed, the notion of people's beliefs as "conflicting patchworks" has precedent in the literature regarding the cognitive underpinnings of stereotyping. For example, Katz (1981) has proposed that Americans embody an "attitude duality," whereby individuals can simultaneously endorse competing values like individualism and egalitarianism—even when doing so results in inconsistent reasoning. From this perspective, the messy way in which people might explain the achievement gap can be thought of as an entirely sensible cognitive process (Monteith, Zuwerink, & Devine, 1994).

Thus, it seems reasonable to expect ambivalence when asking people to explain complex phenomena, but that begs investigation into the factors that influence people's reasoning. Tversky and Kahneman (1974) have argued that biases in judgment are significantly affected by the "availability" of information. That is, people tend to draw conclusions about the frequency of an event based on the ease with which information can be retrieved from memory, and are consequently less likely to account for information that is not directly available to them in a particular context.

In the present study, analysis of data procured from an interview with a student seem to suggest that availability played a critical role in the subject's reasoning as she negotiated a wide range of explanations for the racial achievement gap.

## Research Questions

1. How do high school students explain the racial achievement gap in mathematics education?
2. What is the nature of their causal reasoning about the phenomenon, and what factors influence that reasoning?

## Methodology

Between 2002 and 2007 the author taught mathematics in a racially and ethnically diverse, urban public high school. In 2007 the racial demographics of the school were as follows: 74% Latino, 13% African American, 11% Asian, and 2% White. The racial achievement gap was explicit at the school, as African American students were grossly underrepresented in advanced math courses, while the opposite was true of Asian students. Latino students were proportionately represented, and the White student population was too small to warrant an evaluation. For this study the author recruited former students with whom he had developed strong bonds during his tenure and had since maintained consistent contact. The expectation was that the close relations would encourage the students to candidly express their opinions about a sensitive issue.

Semi-structured, one-on-one interviews were conducted because they facilitated the goal of understanding students' causal reasoning at a fine-grained level. A similar methodology has been used to study people's understanding of issues of race and social dynamics (e.g., Bonilla-Silva, 2003). Interviews lasted approximately forty-five minutes and began with the following prompt: "Research shows that in advanced math classes, Asian students are overrepresented and African American students are severely underrepresented. When I was a teacher I saw the same thing in my classes. How do you explain those trends?" As the interview progressed, subjects were presented a series of probes in order to investigate how being forced to grapple with a problematic context affected their reasoning.

Seven students were interviewed. Each of them had recently graduated high school and was enrolled in a highly selective university at the time of the study. Of the seven interviews, the interview with one student, Nikki (a pseudonym), was chosen for detailed analysis because it most clearly illustrated an individual attempting to juggle multiple causal explanations in complicated and intriguing ways. Nikki self-identified as Asian and was widely considered among her peers and the faculty as one of the top students at her high school. She had been the author's student for three years in the most advanced mathematics courses offered by the school.

## Results

Data suggest that as the interview progressed, Nikki did not settle on any one coherent explanation for the achievement gap. As Figure 1 shows, ten distinct "narratives" (A through J) were identified in the data that Nikki invoked in complicated and occasionally inconsistent ways throughout the interview. The narratives (A through E) that arose in response to the initial interview prompt fell on the "behavioral" side of West's (2001) behavioral-structural dichotomy. In fact, behavioral narratives were repeatedly called on throughout the interview. The most popular of these was Narrative A ("parental influence"), which Nikki called on five separate times during the interview. The lone definitively "structural" explanation, Narrative I ("teacher/counselor bias"), came up near the end of the interview.

A closer examination of the data also suggests a hierarchical organization of the narratives. The following excerpt, which occurred at the very beginning of the interview, illustrates this point:

Interviewer: So you were talking about…let me see if I get you right. You were thinking that because Asian parents – let's say that they emigrated from another country, so they're kind of new here – that you're saying that's why they push education to their kids?

Nikki: Yeah, they strive more for better education, and since…I think, like, for me, personally, parental influence has been a lot on me. If my parents hadn't, like, because even my parents are immigrants, and they tell me that they've come here to give us a better education, to make better…to make ourselves better. And, um, they tell me to, like, do good in class and take advanced classes and everything. And, um, that's what really made me go for it, honestly.

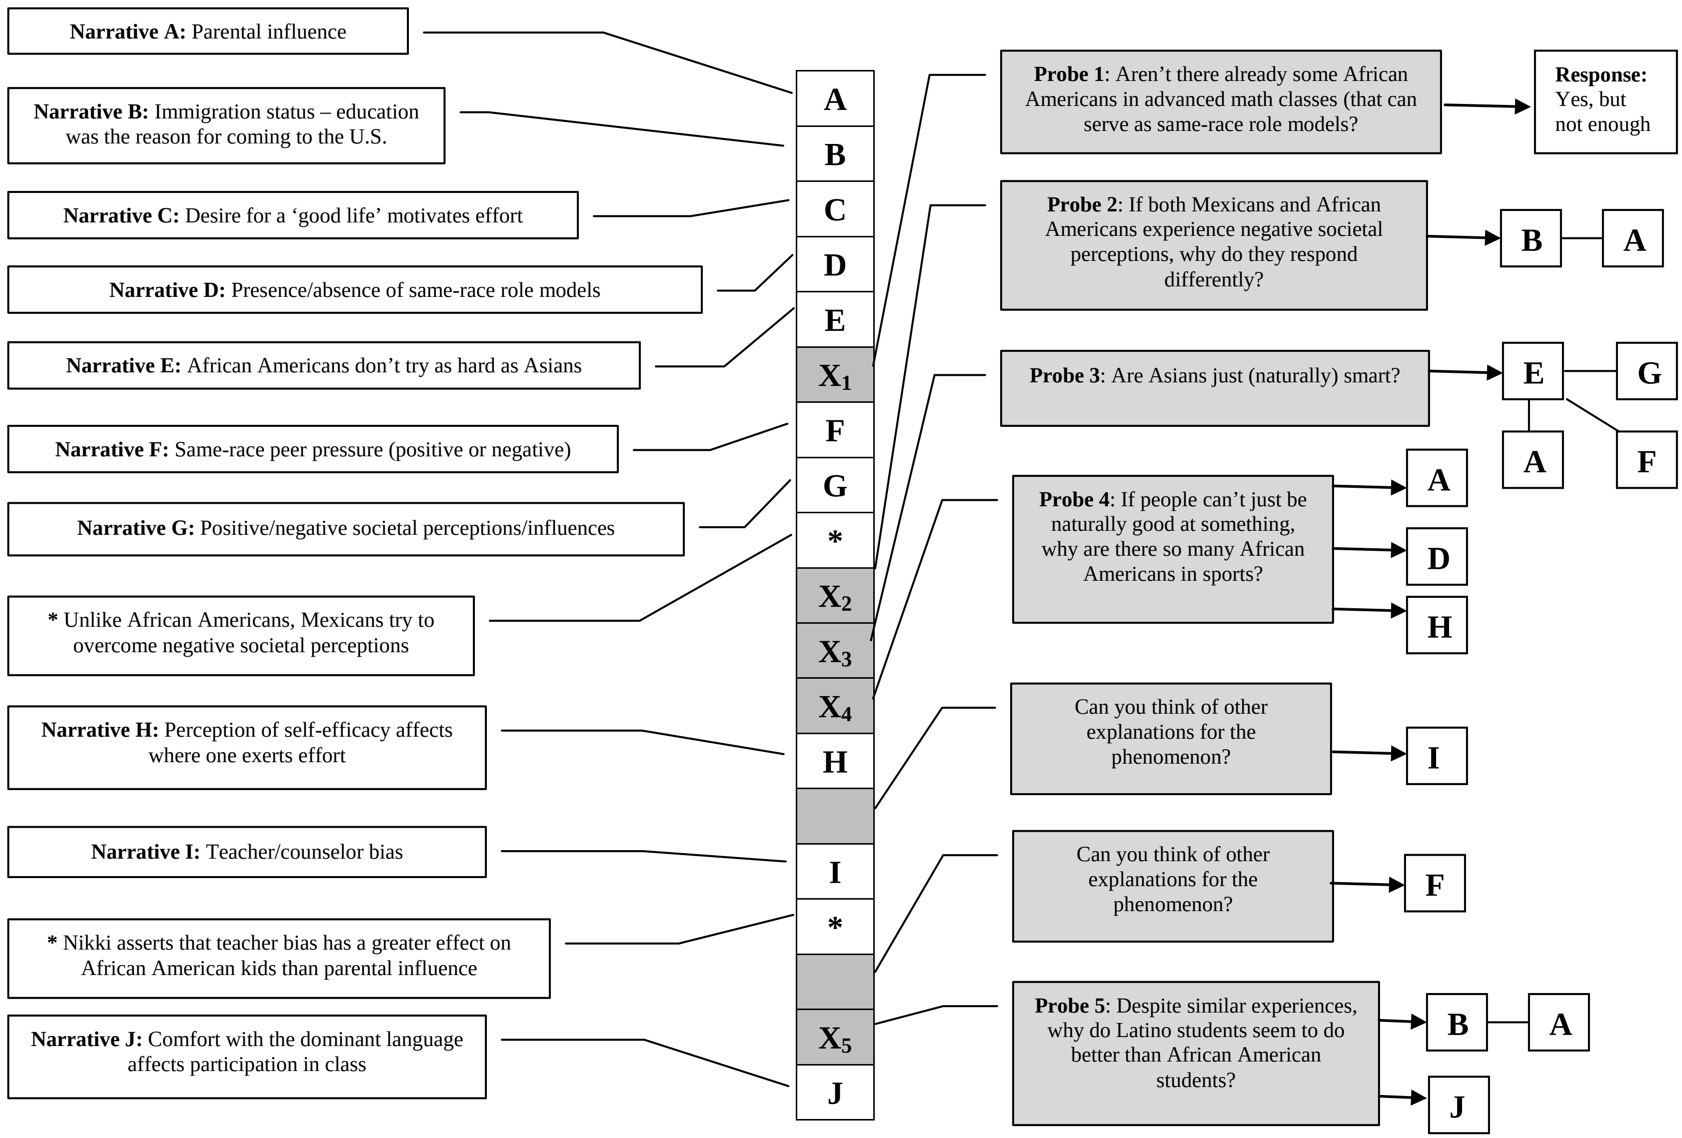

*Figure 1*. Overview of the interview with Nikki. The shaded boxes represent attempts to probe Nikki's reasoning.

A causal hierarchy emerged in Nikki's reasoning. She explained her academic success in terms of her motivation to "do good in class and take advanced classes" (Narrative E), but this explanation depended on other explanations. Nikki's motivation was a product of her parents' influence (Narrative A), and her parents pushed education because of their status as immigrants (Narrative B). Based on Nikki's reasoning, if her parents had not been immigrants, then they would not have been likely to push education, which in turn would have left her less motivated to succeed in school.

In addition to the hierarchical relationship between the narratives, the previous section of transcript highlights the way in which Nikki privileged Narrative E ("personal effort") as a prime determinant of success in mathematics. Her response to Probe 3 provided further evidence to support this claim:

Interviewer: One thing I've been trying to make sense of is, I guess, you know, why can't it just be that Asians are just better at math than African Americans? Why can't that be true?

Nikki: You can't really single out a race. It's just that Asians try a lot harder than African Americans, it's not that they're better at it, they just try harder. That's why they become better at [math].

But while Nikki touted behavioral narratives during the entire first half of the interview, when asked if there were other explanations for the achievement gap, Nikki provided multiple, first-hand accounts of biased teachers and counselors limiting the academic opportunities made available to African American classmates (Narrative I). Unclear as to how she reconciled her behavioral and structural explanations, the author asked Nikki whether parents or teachers/counselors had a bigger impact on African American students' achievement, to which she replied:

Nikki: I think both have similar impact, but probably teachers and counselors have a bigger impact, because they're the ones that set the standards for African Americans, for students in general. I think it's a really big impact from teachers, personally.

Interviewer: Why do you think that?

Nikki: Because, like, even if parents say, "Do good in school," if the teachers aren't paying attention, then *how* are they going to do good in school? If their teachers aren't paying attention to them, or if having talks with them about college or about other things, how are they going to know about those things?

To that point, Nikki had built a fairly consistent story around the behavior of students and parents, so it was interesting that she would demote it in favor of Narrative I. However, it was even more surprising that Nikki changed her mind once again when confronted with Probe 5. Given that Latino students at Nikki's high school were proportionately represented in advanced mathematics courses, the author asked her why Latinos and African Americans were achieving at different levels. This was her response:

> If they have the same group of friends…it's a lot probably coming from parents and a little bit coming from teachers. Because, well, Latinos if they just immigrated here, they're probably having a hard time getting to know English. At [her high school], I've seen that. So, um, they usually ask for help, I think, because their parents probably tell them, "If you don't get something, just ask for help." And African Americans already know English, so they think, "What am I going to ask for help for?" And then if the

> Latinos start talking to the teachers, they'll interact more and start speaking [with their teachers] about college and other stuff.

The primacy Nikki attributed to Narratives A and I changed once again. Just moments after arguing for a "really big impact from teachers," Nikki stated that "it's a lot probably coming from parents and a little bit coming from teachers." It is also noteworthy that Nikki shifts the burden for academic achievement from teachers to students when considering the issue in the context of Latino students. Recall that Nikki had previously criticized teachers for not "having talks with [African American students] about college and other stuff," but here she implied that teachers present academic opportunities to students when students reach out to teachers.

## Discussion

It is not altogether surprising that Nikki did not fixate on a single explanation for the racial achievement gap. The ambivalence Nikki showed in negotiating the ten narratives she generated reflects the complex nature of the phenomenon she was trying to explain (Katz, 1981). Moreover, the fact that nearly all of those narratives were of a behavioral nature is consistent with Bol and Berry's (2005) findings that secondary mathematics teachers tended to explain the achievement gap in terms of behavioral factors.

On the other hand, it was interesting that Nikki could vacillate so quickly between behavioral and structural narratives without appearing to consciously realize it. Why did Nikki make such a thorough case for Narrative I ("teacher/counselor bias") when the data indicate that she more likely favored behavioral explanations? And if in fact she actually attributed greater priority to Narrative I, why was it not among the first of her explanations?

One possibility is that Nikki simply did not immediately feel comfortable talking about prejudiced teachers in front of the author (who happened to be her former teacher), so she delayed mentioning Narrative I until halfway through the interview. Although the author and she had developed a family-like rapport over the years, the topic of race had never before been explicitly broached in one-on-one conversation. A related possibility is that Narrative I was actually a misrepresentation of her true beliefs, designed to provide balance to her point of view so that she did not come off as racist.

While more data would be needed to establish the validity of those conjectures, considering the role of Nikki's prior experiences in her reasoning may illuminate the issue. The data suggest that Nikki had a wealth of prior experiences regarding the academic consequences of both "parental influence" and "teacher/counselor bias," and yet for some reason she delayed mentioning the latter narrative. However, a potentially important difference between Narrative A and Narrative I is context. Because Narrative A depended on past interactions with her parents, it may be that the memories that gave rise to Narrative A were in some sense more "available" to Nikki than those that gave rise to Narrative I (Tversky & Kahneman, 1974). For although she cited specific examples in which she directly observed differential treatment of her peers with respect to race, those in-school experiences were of a markedly different nature than her prior experiences with her parents. Not only were the latter experiences more personal, but it is also likely that they were more frequent than the instances of bias she noticed in school. Calling on the experiences needed to vocalize Narrative I required Nikki to empathize with a largely unfamiliar perspective. And in the pressure of an interview setting, telling a story of her parents' influence may have been an easier story to tell because it did not require her to see the world through the eyes of another person or group. Whether or not experiences of an egocentric nature are more accessible is a question worthy of further investigation.

Another aspect of the data related to the availability of information was Nikki's tendency to over-generalize from her past experiences. In Narrative G Nikki described how people respond to negative societal perceptions of their racial/ethnic group: "Sometimes [African American students] adjust to what society thinks of them, and they don't try to overcome that" (marked with an asterisk in Figure 1). She also cited the existence of a negative perception about Mexicans being "lazy in academics and stuff," but went on to say, "But I know a lot of my Mexican friends: they're not lazy, they strive harder. They've overcome that perception."

Noteworthy here is that Nikki made this claim based not on her knowledge of her school's Mexican population as a whole, but instead on her knowledge of her Mexican *friends*. Because the overwhelming majority of her friends were also enrolled in advanced classes, generalizing from the slice of the population would result in an obviously skewed perspective. Nevertheless, Nikki reasoned based on the information that was available to her. Still, given the low enrollment in those courses overall, and the fact that the majority of Latino students at the school were not achieving at dramatically higher levels than African American students, it was interesting that Nikki did not explicitly acknowledge her sampling bias.

## Future Research

The findings of this study suggest myriad avenues for future research. An important issue that this study raises questions about is the possibility that some students may explain the racial achievement gap in behavioral terms. In spite of evidence that she had observed multiple instances of racial discrimination first-hand, Nikki ultimately placed the onus for getting a good education on students and parents. To what extent were her perceptions of the racial achievement gap a function of her background as someone who "made it" in a beleaguered educational environment? Given her background, one might argue that it was to be expected that Nikki would lean toward behavioral factors rather than structural factors. But might a high school sophomore repeating Algebra 1 explain the achievement gap differently? Interviews with students at varying levels of academic success may reveal different perspectives.

Also worth pursuing is how the notion of the "model minority" may influence student perceptions of the achievement gap. As a member of a "model minority," Nikki expanded the application of the label in a unique way. Historically, the "model minority" label has been reserved for Asian students (Wu, 2003), but Nikki stated that African American students respond to negative societal perceptions of their racial group by "conforming to the stereotypes," while Mexican students respond by "overcoming the stereotypes through hard work." Based on this datum, Nikki seemed to position Mexican students as a de-facto "model minority." Whether or not her framing of this population indicates an emerging trend in education, in addition to what it might mean for African American students, are both matters that deserve attention.

Finally, the tendency for students to explain the achievement gap in behavioral terms has serious implications for classroom dynamics. What impact might those perceptions have in classrooms where collaborative learning takes place? How should teachers account for students' perceptions in their pedagogy? In what ways can reform-oriented curricula and forms of classroom discourse militate against the effects of potentially negative perceptions among students? Exploring such questions would certainly benefit our understanding of teaching and learning, particularly in racially and ethnically diverse schools.

# DOMINICAN PARENTS LEND THEIR PERSPECTIVE TO THE CONVERSATION ON MATHEMATICS TEACHING AND LEARNING

Mary Q. Foote
Queens College-CUNY
mary.foote@qc.cuny.edu

*This study examines the perspectives of two Dominican mothers on the teaching and learning of mathematics. Through interviews and classroom observations by the parents, we learn about their mathematical learning experiences (both in formal school settings and in informal settings) in the Dominican Republic and their children's mathematical learning experiences (again, both in and out of school) in the United States. The mothers compare their own educational experiences to those of their children. The findings indicate that a more inclusive stance toward parents by the school would benefit the children's learning of mathematics.*

## Purpose of the Study

The purpose of this study was to give voice to the perspectives of two Dominican parents with regard to their own and their children's mathematics education with the intention of informing the school-home discourse around the teaching and learning of mathematics.

## Theoretical Perspective

This chapter builds on a small body of work that has been done about parental perspectives on the teaching and learning of mathematics. It is built on strands of research that examine issues of (a) the power relationship that exists between school and parent, and (b) the funds-of-knowledge that exist in homes and communities including the value that is (or is not) placed on knowledge the parent may possess.

The perspective of parents is one that is often missing from conversations of how to address the learning needs of children. Yet, parents are their children's first teachers, and their role as teachers continues to be an important one throughout elementary school and beyond. In spite of this, parents (particularly non-middle-class parents including immigrant parents whose facility with English may be emerging), and the homes and communities of many students are often positioned as a problem rather than a support for academic achievement (Foote, under review).

Research indicates that schooling in the United States maps best onto middle-class child rearing practices (Lareau, 2003). It is understandable that immigrant parents, schooled in an educational system distinct from that of the United States, may have different understandings and perspectives on schooling from parents schooled exclusively in the United States. Exploring and understanding the gap (or lack of it) between the mathematics learning experiences of parents and their children can only serve to support educators in understanding how to acknowledge and possibly build on parental experiences in the service of being more effective teachers for their children. Tapping into parents' actual perspectives may support educators in understanding what parents see as their role in supporting the mathematics learning of their children as well as how their own personal schooling histories inform that perspective.

Moll and Civil (Civil & Bernier, 2006; González, Andrade, Civil, & Moll, 2001; Moll & Gonzalez, 2004) and their colleagues developed the construct of "funds-of-knowledge" that countered the deficit perspectives often held by schools about poor or immigrant parents and families. In this work, power relationships between family/community and school are acknowledged and interrogated. The present study expands these ideas to include parental knowledge of educational systems (in this case that of the Dominican Republic) and how the lens of their personal educational experience influences their perspectives on mathematics teaching and learning as it plays out in their children's school in the United States.

The importance of including the parent voice in the discourse around mathematics learning is a position taken by Remillard and Jackson (2006). They state that it is important for preK-12 educators to understand the parent perspective so that they can work with parents toward common understandings. They further indicate that partnerships between parents and schools (including very importantly, teachers) must acknowledge (and I believe, fight against) the inherent power differentials that exist between the dominant culture (of which school is a force) and (in this case) the immigrant parent. Allexsaht-Snider (2006), suggests a question that is particularly appropriate to this study:

> If we do create more mathematics education contexts that bring together educators and diverse parents and link home, school, and community contexts, how can we help students, parents, and teachers find common ground and negotiate potential conflicts and areas of dissonance to create meaningful and successful mathematics learning for urban children? (p. 193)

This study explores one such avenue for finding common ground. Through this study I hoped to address the question of how understanding parental perspectives on the teaching and learning of mathematics might inform the discourse on classroom practice, so that eventually classroom practice can more effectively address the needs of some of the traditionally more vulnerable learners.

## Methods

*Researcher Position and Participant Selection*

I was a volunteer and researcher in two classrooms in an elementary school in New York City at the time of the study. I spent one half day a week in a Kindergarten classroom and one half day a week in the English component of a third grade. I was engaged in working on a separate research project with the classroom teachers and also assisted them in individual and small group instruction at their request. Although I did not know the parents at the onset of the study, I knew their children and I knew their children's teachers. Because of these relationships that I had formed with these teachers and students, I solicited parent participants from these two classrooms through letters sent home. A number of parents, all mothers, responded showing interest. For several of these mothers, it proved logistically impossible to set up interviews and classroom visits. Many of these mothers work long hours and do not have the flexibility at their jobs to come to school easily during the day. In the end four mothers participated in initial data gathering and three of those four were able to participate completely in all phases of data gathering; ultimately, one did not prove to meet the participant criteria of significant schooling in the Dominican Republic. Further discussion of participants is limited to the two who met participant criteria and completed all phases of data gathering.

*Setting and Participants*

Two mothers whom I call Silvia (child: Sarita, Kindergarten) and Vera (child: Victor, Grade Three), participated in this study. (All names of parents and children used in this chapter are pseudonyms). Both mothers were born in the Dominican Republic and currently live in the United States. Their children attend the same K-5 public elementary school in New York City.

Vera was raised and schooled in the Dominican Republic including attending university and receiving a degree in Accounting. She moved to the United States as a young adult and currently works as a school crossing guard. Vera is the sole adult living in her household. Vera identifies herself as able to understand, speak, read, and write Spanish, and to understand and speak a little English. In addition to her third grade son, Victor, Vera also has an older son who currently attends Middle School.

Silvia was raised and schooled in the Dominican Republic, moving to the United States when she was a young adult. Silvia currently cares for children in her home where she lives with Sarita, her kindergartener, another daughter, aged two, and her husband. Silvia identifies herself as able to understand, speak, read, and write Spanish, and to understand, speak, read, and write a little English.

Both mothers then have finished secondary school with Vera having finished a university course of study. They both have studied algebra, geometry and trigonometry in high school. Vera counts calculus, statistics, and accounting among her university courses. The participants in this sample of convenience prove to have extensive school-based experiences with mathematics and are therefore well positioned to note differences and similarities between the teaching and learning of mathematics in the Dominican Republic and the United States.

*Data Gathering*

Data gathering included (a) a preliminary interview with each mother, (b) a classroom observation of a mathematics lesson by each mother in the classroom of her child, and (c) a post-observation interview with each mother. The researcher took field notes during or immediately after each of the above sessions. The interviews were conducted in Spanish by parental choice. All interviews were audio-taped. The interviews were transcribed and translated into English for analysis.

In the preliminary interviews, participants were asked to provide personal information about their language proficiency in English and Spanish, their employment, their children living at home, (these data are reported above in the section on setting and participants), their own school history and that of their children. In addition to this basic information, participants were asked about their own personal history with mathematics, as well as their perspective on their children's experiences with mathematics, including interactions between parent and child around mathematics homework and mathematical activities more generally.

Each parent observed a mathematics lesson in the classroom of her child. Although the lesson observed in the third grade classroom was conducted in English, the teacher repeated much of what she said in Spanish for the benefit of Vera (whose language of preference is Spanish, although she understands English). The lesson observed in the Kindergarten classroom was conducted in Spanish.

Each mother participated in a post-observation interview either immediately after or within a few hours of the observation. In the interview parents were asked to give their perspectives on what they noticed in the classroom in general and in the mathematics lesson in particular with special attention to the teaching approach and goals, and the participation patterns. The participants were also asked to reflect on whether what they observed was consistent with what they had expected to see. They were asked as well what they had liked about the lesson and whether there were concerns that were raised for them. Finally, the parents were asked to reflect on how the teaching and learning that they had observed in their child's classroom compared with their own classroom experiences in the Dominican Republic.

*Data Analysis*

Upon completion of the data gathering, the entire data record (all interviews and field notes) was reviewed. Emergent themes were noted. The data record for each individual participant was then reviewed chronologically. Interim research texts (narratives) were constructed for (a) the initial interview, (b) the classroom setting on the day of the observation from the researcher's perspective, and (c) the post-observation interview (Clandinin & Connelly, 2000; Clandinin, et al., 2006). Using these interim research texts, chronological narratives were constructed with particular attention to the individual cases within this chronology. Finally themes were noted that cut across participants. This was done by re-examining the data from all participant responses to each question in each of the two interviews. In this way, the focus of analysis shifted from the individual case as the focus to the particular interview question as the focus. By providing another perspective on the data, a triangulated perspective was obtained. These themes and the interim research texts (initial narratives) were then used as the basis for constructing the final narratives found in the results section.

In an attempt to respect the perspectives of the parent participants, the results of the study were shared with them through informal conversation. The support of the teachers was likewise acknowledged by sharing with them, through informal conversation, the results of the study. This was done so that these important contributors to the research story had the opportunity to review the manner in which they were represented, modifying the picture if they thought it necessary. In the end, parents and teachers both were comfortable with their portrayal.

What follows is the story of two Dominican mothers and their perspectives on the teaching and learning of mathematics. These perspectives take into account their own mathematical learning experiences (both in formal school settings and in the informal setting of the home) in the Dominican Republic (and in the case of one mother in the United States as well) and their children's mathematical learning experiences (again, both in and out of school) in the United States.

## Results

In presenting the results, I will first present individual narratives of the perspectives of each of the two mothers regarding her own, and her child's experiences learning and using mathematics. I will then present individual narratives of the parent perspectives on the classroom and mathematics lesson.

*Parent Perspectives on Learning Mathematics*

*The case of Vera.* Vera describes herself as someone who loves mathematics and was an excellent student of mathematics. Algebra was an area that she particularly liked. Vera describes the school system in the Dominican Republic, where she graduated from university, as much more formal in many respects than that in the United States, from the more formal clothing worn by both teacher and student to the teacher directed manner in which the classes are conducted.

Vera reports that both her children (Victor, the third grader and an older child who is in eighth grade) like mathematics. Vera indicates that she works with Victor on word problems teaching him to look at the language in the problem. For example to know to add if you see "in all" in the problem, to know that if it says someone has more than another, you have to subtract. She also helps him to draw out or diagram the problem situation. In the case of a problem such as five children needed to share 100 balls, she would encourage him to draw five circles to represent the children. She would tell him that everyone needs to have the same amount so that they don't fight. When he was younger, she would encourage Victor to use beans or other small objects to model the problems and to work on calculations. Vera indicates that it is quite common in the Dominican Republic to work with beans or other small materials when doing math with young children.

Vera says that the notational system for standard algorithms in the Dominican Republic differs from that in the United States and has caused her some problems in working with her children. Once, for example, the older child came home with a system for multiplying that involved dividing the paper into small squares (something I recognize as lattice multiplication). Vera says she never understood that method. In addition to the notational issue, language use can also present difficulties for Vera. When she directly translated *"dos por dos"* into English as "two by two" instead of "two times two," Vera's older child said that wasn't the way he was learning in school and that his mother was confusing him.

Vera does not feel well informed about what Victor, her third grader, is doing in school. Vera reports she knows what's going on in the mathematics classroom mainly through homework. She feels that she should get some indication at least once a month as to the child's progress. No school work or tests come home. She sees only homework. This she says is in sharp contrast to the Dominican Republic where completed quizzes are regularly sent home. Since Vera works as a school crossing guard, she is not in a position to pick her son up at school and so does not (like so many other parents) have access to those quick, informal, after-school conversations with the teacher. Vera is concerned that Victor is beginning to show less interest in school this year and has tried to hook him up with an after school program to support his learning, but hasn't heard anything back from the school.

Vera is a single parent and as such is the sole earner as well as the person who manages all household finances. She has begun to talk to the older child about spending money and at times asks him to do shopping for her. Aside from this, she does not explicitly make a point of addressing mathematics in home and community situations. She takes a more organic approach. If something comes up that involves mathematics, they talk about it. They play cards and dominoes at home and Victor, the third grader, much like Marta's son, loves to play with and count pennies.

*The case of Silvia.* Silvia feels that she was a good student of mathematics, maybe not earning top grades, but making a solid showing. Silvia feels her kindergartener, Sarita, learns math easily and with enjoyment. Silvia describes herself as very involved in the mathematics homework that her daughter brings home from school. Sarita's father also helps her with her homework. Silvia supports Sarita's leaning by working with her using a variety of manipulative materials such as dried corn or beans. She recalls that this is how her own father helped her with her mathematics when she was a young child. In addition to using manipulatives available in the home, Sarita's parents also try to support her developing mathematics understandings by putting mathematics problems into contexts that she might find motivating, such as money. They try to find ways that are both interesting and understandable when explaining mathematics situations or contexts.

Silvia feels well informed about what is happening in school with Sarita. She picks up her child from school each day and has the opportunity to have a quick informal discussion with the teacher. In addition, Silvia cites parent-teacher conferences as time when she has an opportunity for more extended conversation with the teacher about her daughter's progress in school.

In addition to using mathematics while she helps her child with homework, Silvia identifies grocery shopping as an area in which she regularly uses mathematics, doing comparison shopping, for example. Sarita often accompanies her to the grocery store and she involves her in the shopping process, tying in mathematics by asking the child to select, for example four oranges or three pears. Silvia tries to buy games that are educational in order to support learning at home.

*Parent Perspectives upon Observing a Mathematics Lesson*

After both of the observations, I met with the mother to discuss her perspective on what she had observed in the classroom.

*The case of Vera.* Vera observed a lesson on volume of a rectangular prism. She liked the look of the classroom and how the children worked in groups. She was definitely surprised by the lesson. She had expected to see a lesson on computation and to see the students working individually out of a text book. She noted the difference between the structure for learning she observed in this classroom and what she had experienced as a student, which was primarily individual work done exclusively on paper, copying an example from the board and completing similar problems after hearing the teacher's explanation. Vera commented on the manner that the teacher had with the children, calling her accessible, caring, and calm. She noted that gathering the children in the meeting area supported them in being more focused and attentive.

Vera mentioned that there were wide attempts at participation, with many students volunteering during the mini-lesson, even if they were not all called upon. She felt that the children were very involved in the lesson both during the mini-lesson and afterward during the work period. This was an aspect of the lesson that Vera liked well. She did notice that after the mini-lesson, while the majority of children were working in table groups, that the teacher kept a small group with her in the meeting area and was able to focus more attention on their particular needs, supporting them in focusing on the activity.

Vera commented on how the learning environment was structured through what she described as play. She was impressed by the use of centimeter cubes to explore the concept of volume. She thought, however, that the teacher's explanation of the relationship of the base to the volume was confusing. Vera noticed that during the work period when the children were constructing a rectangular prism, for example, with a base of six, that they would draw the base as a 6 x 6 rectangle. She felt this confusion on the part of the students was due to what she saw as the teacher's confusing explanation. Vera thought that an exploration of more examples might have dispelled some of the confusion. Vera also thought that a review of the work at the end of the work period would have supported student learning. She noted that the need to go to lunch precluded this, but she felt that a discussion of the results the students had obtained as well as why they had obtained them would have contributed to the learning.

*The case of Silvia.* Silvia observed a lesson on comparison of numbers. Silvia was positive about her lesson observation. She too commented on the manner that the teacher had with the children which she found to be an encouraging one where the children were also supported in helping one another. She was impressed with how readily the children helped each other, how well they worked together, and how the teacher supported this atmosphere of cooperation that pervaded the classroom. She thought the classroom was inviting with much useful and interesting information about mathematics posted for the children to see. She was pleased with the level of participation as it seemed to her that every child in the class participated fully in the lesson. She liked the use of materials (pattern blocks in the routine portion, and number cards in the main activity) to support the learning.

Silvia found the class to be very different from her early childhood experiences in the Dominican Republic where the emphasis had been much more on simply play as opposed to play as a vehicle for learning particular content. She was impressed with the children's knowledge.

Silvia had expected that the work the children would be engaged in would be at a simpler level. She found the level of mathematical understanding demonstrated by the children including the range of numbers they were comfortable with to be well advanced over what she experienced in kindergarten. She thought that the dual focus in the use of games, both to entertain and to teach was a laudable one.

## Discussion

I will begin this section by discussing the initial perspectives that parents expressed in their first interviews. I will then discuss their reaction to and reflection on the lesson they observed in their child's classroom.

*Initial Perspectives*

I will begin this section by discussing two themes that emerged from the data: parental help at home at support from school.

*Helping at home.* Silvia and Vera both talked about how they used the same kind of manipulatives (dried corn and beans) in working with their children as were customarily used in the Dominican Republic. They also mentioned that she tried to reframe mathematics problems using interesting contexts or contexts that were motivating to her child. We see parents who see one aspect of their role as a parent to include fundamentally that of teacher.

*Support from school.* The perception of the support provided to the parents by the school (including the classroom teacher) varies from parent to parent. Silvia seems satisfied, even pleased, with the communication she has with the school. We can speculate that some of this may be due to the fact that her daughter is in Kindergarten and just easing into the school system. Vera is frustrated by the paucity of information she receives about her child's progress. Who knows if this lack of communication between home and school is contributing to what Vera identifies as a gradual lessening of interest in school on the part of her son, Victor. As Remillard and Jackson (2006) note, when parents are left out of discussions of mathematics learning, it can have a negative impact on their ability to be actively involved in their children's schooling.

*Reaction to the Lesson*

Both of the participants' experiences with mathematics in school were with traditionally taught mathematics. Based on their own schooling histories, both mothers expected to see more traditional mathematics lessons when they observed their children's classrooms. One might think that this would orient them toward resisting the teaching style they observed. This did not turn out to be the case. Both mothers were pleased by many aspects of what they saw in the classroom.

They both commented on being pleased that the teacher was using manipulative materials that supported the children in understanding the mathematics. Since they had both previously mentioned how it was typical in their experience in the Dominican Republic that small objects were used at home to support their developing mathematical understanding, the use of these materials may have been recognized as a support familiar to them.

In addition, they both commented on the teacher's manner with the children (saying similar things about the two different teachers); they liked how calm and supportive they were. This speaks to the importance of the connection between teacher and student for supporting learning. And more particularly, in the data being examined here, that parents recognize and appreciate this fact.

Vera alone pointed to a feature of the lesson that she thought was lacking. She recognized that simply engaging in the mathematical activity (building rectangular prisms with centimeter cubes) was not sufficient to develop a sufficiently deep understanding of the problem at hand. She recognized that a discussion following the activity would have supported the children in processing their work and arriving at a clearer understanding. Perhaps because she is the mother with the more advanced education (including a degree in accounting), Vera is positioned to understand the important role that discussion can play in learning. Whether this is the case or not, Vera's understanding of what is necessary for learning is impressive. This mother brings understandings to the learning of mathematics which could be exploited for the benefit of her child's learning.

These two mothers brought a keen eye to their observations of the mathematics lessons in their children's classrooms. Their comments are show a sophisticated understanding of children's learning needs. In addition to Vera's noting that a follow-up discussion to the mathematics activity would have supported student learning, Silvia understood and appreciated the level at which the Kindergarten children were functioning.

Here we see parents eager to help their children. The suggestions they have of more communication from the school and access to materials that can be used in the home to support learning are indicative of a desire to be involved in and support their children's learning. It seems that they recognize that having home and school learning environments better aligned would be supportive of their children's learning.

# EXAMINING THE IMPACT OF DIVERGENT PEDAGOGICAL STYLES ON THE MATHEMATICS LEARNING OF AFRICAN AMERICAN MIDDLE SCHOOL STUDENTS

Oren L. McClain
University of Virginia
oren@virginia.edu

Robert Q. Berry, III, Ph.D.
University of Virginia
robertberry@virginia.edu

*This study investigated the impact of two divergent pedagogical styles on the mathematics learning of African American middle school students. One of the teachers used her knowledge of students' background and culture, and aligned her instruction with their learning preferences to design meaningful and contextual learning experiences. In doing so, mathematics learning was positively impacted. Results suggest while knowledge of mathematics and pedagogy is crucial to teaching mathematics, an understanding of African American cultural style and learning preferences are also essential to effectively teaching African American learners.*

## Purpose of Study

The National Assessment of Educational Progress (NAEP) results show significant gains in mathematics achievement among African American middle school students (Tate, 2005). Even so, African American students are more likely to be enrolled in lower-level mathematics courses and experience a mathematics curriculum that stresses basic skills (Tate, 2005). As a consequence, African American students can expect to use computers for drill and practice, as opposed more meaningful activities such as simulations, demonstrations, or applications of mathematical concepts (Lubienski, McGraw, & Strutchens, 2004). Worksheets are also more commonly used on a daily basis in classrooms that serve African American students (Strutchens, Lubienski, McGraw, & Westbrook, 2004). The National Council of Teachers of Mathematics (NCTM) recommends students receive standards-based instructional practices (Lubienski, McGraw, & Strutchens, 2004). Standards-based instruction is characterized by an emphasize on conceptual understanding, mathematical reasoning, student engagement with mathematical ideas, multiple representations, collaborative investigations, and open discussion and writing (Goldsmith & Mark, 1999). Unfortunately, many African American students are less likely to experience these standards based approaches in mathematics classes (Lubienski, McGraw, & Strutchens, 2004).

This study investigates the impact two different pedagogical styles had on middle school students' mathematics learning. The study was conducted at Spartan Middle School, located in a rural county in a southeastern state. The two teachers involved in the study, Ms. Canady and Ms. Able, are both experienced mathematics teachers; Ms. Canady has taught for 14 years, and Ms. Able has taught for 12 years. Both are White women who graduated from the same teacher education program and they both grew up the community where Spartan Middle School is located. During the period in which the study took place, there were 514 total students at the school: (a) 258 Black, (b) 248 White, (c) 3 Hispanic, (d) 4 Asian, and (e) 1 unspecified. Two hundred eighty-nine students (56%) at SMS receive free or reduced lunch.

The pedagogical teaching styles of the two teachers are very different. Ms. Canady's teaching style can be described as an aggregate of high-demanding structure and a disciplined environment coupled with instruction that utilizes students' lived and cultural experiences. She feels it is her responsibility to know and understand her students' backgrounds and struggles, and

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

she says she uses this knowledge to help her students succeed. Irvine and Fraser (1998) used the term “warm demander” to describe teachers like Ms. Canady. Ms. Able describes her teaching style as “professional,” and she appeared to maintain both emotional and physical distance from her students. She required all students to use her prescribed procedures and techniques to solve problem, with the main to goal being to get the right answer.

## Theoretical Perspective

The most prevalent mathematics classroom teaching pattern in American schools is the initiation-response-evaluation (IRE) pattern (Hiebert & Stigler, 2000). IRE is a teacher-centered pattern of teacher-initiated questions, student response, and teacher evaluation (Cazden, 2001). In classrooms where the IRE pattern is emphasized, teachers place little focus on having students explain their thinking, work through mathematical ideas openly, make conjectures, or develop consensus about mathematical ideas (Franke, Kazemi, & Battey, 2007). Mathematics educators have argued that an IRE teaching pattern limits students’ ability to fully understand and appreciate the complexities of mathematics because it emphasizes school-learned methods and rules (Boaler, 2000; Malloy & Malloy, 1998; Tate, 1995), without proper attention to meaningful understanding.

This instructional pattern is well documented in mathematics classrooms that serve African American students (Lubienski, 2002; Lubienski, McGraw, & Strutchens, 2004; Strutchens, Lubienski, McGraw, & Westbrook, 2004; Strutchens & Silver, 2000). Describing teaching parallel to the IRE pattern, Tate (1995) says this “foreign pedagogy” (p.166) has negatively impacted African American students. Tate suggests this “foreign pedagogy” has attributed to: (a) African American students being tracked into remedial mathematics; (b) low numbers of African American students in college preparation or advanced mathematics courses; and (c) fewer opportunities for African American students to use technology in school mathematics.

In contrast to the IRE teaching pattern, Franke, Kazemi, and Battey (2007) suggest mathematics teaching should be relational and multidimensional. In this sense, mathematics teaching takes the form of developing relationships between (a) students and teachers; (b) among students themselves and mathematics; and (c) engagement among students and teachers to develop mathematical understanding (Lampert, 2004). Mathematics teaching is multidimensional with respect to the interactions that occur between (a) teachers’ pedagogical content knowledge, (b) teachers’ beliefs about mathematics teaching and learning, (c) teacher understandings about students’ social and cultural contexts, and (d) creating an environment for mathematics learning (Lampert, 2004; Moschkovich, 2002). These interactions influence the ways teachers structure mathematics experiences for students.

We contend that for African American students, experiencing mathematics teaching and learning as relational and multidimensional requires teachers to know and understand these students’ cultural background, prior experiences, and contexts. In doing this, we give credence to culturally relevant pedagogy. Ladson-Billings (1995) defined culturally relevant pedagogy as a pedagogy that fosters meaningful classroom experiences that affirms students’ backgrounds and prior knowledge. Culturally relevant pedagogy provides a framework for making connections between using contextual situations for mathematics teaching and learning, connecting to students’ experiences, and linking mathematics to students’ social and cultural ways of knowing.

Culturally relevant pedagogy rests on three criteria: (a) students must experience academic success; (b) students must develop and/or maintain cultural competence; and (c) students must develop a critical consciousness. Culturally relevant teaching requires teachers to attend to students' academic, social and cultural understandings (Ladson-Billings, 1994, 1995, 2000). Consequently, mathematics teachers must demand, reinforce, and produce excellence in their students. Achieving excellence requires mathematics teachers to use students' social and cultural backgrounds as a bridge for developing mathematical understanding. Culturally relevant teaching allows students to use mathematics to critique the cultural norms, values, mores, and institutions that produce and maintain social inequities (Ladson-Billings, 1994, 1995, & 2000).

Culturally relevant teachers identify the resources that students bring to the mathematics classroom and these teachers construct experiences that utilize these resources to produce meaningful mathematical understanding (Gutiérrez, 2002). Therefore, effective culturally relevant mathematics teachers of African American students have strong mathematics content knowledge, pedagogical skills, and knowledge of African American cultural style and learning preferences. For this research, we used culturally relevant pedagogy as the foundation for examining the impact an IRE teaching pattern and a relational and multidimensional teaching pattern have on African American students.

*African American Students' Learning Preferences*

In order to engage in culturally relevant pedagogy for African American students, mathematics teachers must have an understanding of African American culture and accept that African American culture is a significant socializing force for African American students. African American students' mathematics identities are shaped by culture, learning preferences, and experiences with mathematics (Berry, 2003). Martin (2007) refers to mathematics identity as one's belief about "(a) their ability to do mathematics, (b) the significance of mathematical knowledge, (c) the opportunities and barriers to enter mathematics fields, and (d) the motivation and persistence needed to obtain mathematics knowledge" (p. 19). The development of a positive mathematics identity is essential if students are to sustain an interest in mathematics and develop persistence with mathematics.

Shade (1997) described the African American learning preference as a combination of holistic, relational, and field dependent learning styles. Holistic learners seek to synthesize divergent experiences in order to grasp the fundamentals of experiences. They are successful with content tied to a larger whole, and view cause and effect as separate entities. The kinesthetic mode is the principal mode of information induction; thus, concreteness is used to facilitate new learning (Shade 1997). Relational learning preference is characterized as freedom of movement, variation, creativity, divergent thinking, inductive reasoning, and focus on people. Field dependent learners require cues from the environment, prefer external structure, are people-oriented, are intuitive thinkers, and remember material in a social context (Shade 1997). Taken together, learning preferences of holistic, relational, and field dependent learners are directly related to African American culture.

Culture and ethnicity are frameworks for the development of learning preferences; however, other factors play a significant role in cultural and learning preferences (Irvine & York, 1995). The learning preferences of African American students suggest that these students should not only receive mathematics instruction that includes opportunities to learn mathematics in an abstract manner, but also instruction that embed relevant contexts, use concrete imagery, and provide experiences based on how mathematics concepts are related to each other. Teachers also need to understand the complexity of students' experiences, which may lead to doing things with students that are not mathematics, such as interviewing them, having them write autobiographies, and discussing their interests (Ladson-Billings 1997).

*NCTM Process Standards*

The NCTM Process Standards complement the learning preferences of African American students. Berry (2003) theorized the overlap between the NCTM Process Standards and African American learning preferences. The NCTM Process Standards are: Problem Solving, Reasoning and Proof, Communication, Connections, and Representation (NCTM 2000). Each of these standards focuses on how students should learn and use mathematics. The Problem Solving Standard is consistent with the learning preferences of African American students because it supports the notion that learners should have opportunities to experience mathematical problem solving in a social context and utilize various strategies to solve problems. The Reasoning and Proof Standard suggests that students make and investigate conjectures, develop and evaluate mathematical arguments, and select and use various types of reasoning and methods of proof (NCTM 2000). This standard aligns well with African American students' preference for expressive individualism, experimentation, and divergent thinking. The Communication Standard proposes that students organize and consolidate their mathematics thinking, coherently communicate their mathematics ideas to others, analyze and evaluate the mathematical thinking and strategies of others, and use the language of mathematics to express mathematics ideas (NCTM 2000). Complementary to the Communication Standard is African American learners' cultural and learning preferences towards oral expressions, social and affective emphasis (Boykin, 1986; Shade, 1997).

The Connections Standard recommends that students interconnect mathematics ideas within mathematics and outside of mathematics, and understand how mathematics ideas relate to and build on one another to produce a coherent whole (NCTM 2000). The Connections Standard supports the holistic view of learning suggested by Shade (1997), because African American learners need contextual experiences that connect mathematical ideas within and outside of mathematics. The Representation Standard suggests that students create and use multiple representations to organize, record, and communicate mathematical ideas; select, apply, and translate among mathematical representations to solve problems; and use presentation to model and interpret physical, social and mathematical phenomena (NCTM 2000). Since African American learners have a propensity for verve, mathematics learning and teaching should be stimulating and interesting as well as offer opportunities for hands-on experiences that promote interactivity.

## Methodology

There were a total of 100 students that participated in this study. Fifty one students (33 African American and 18 White) were taught by Ms. Canady, and 49 students (30 African American and 19 White) were taught by Ms. Able. To access the impact of the two pedagogical styles on students' mathematics learning, pre- and post-test were given to both groups of students. The tests were constructed from released items on the state mandated assessment. The pre- and post-tests were designed to be parallel to each other, with both having the same number and types of items. The tests were each composed of 10 items which consisted of a combination of multiple-choice open-ended problems. Both tests were reviewed by a mathematics educator, a mathematics education doctoral student, and a high school mathematics teacher for face validity.

The six multiple choice items were adapted from the state assessment released items. The state assessment gave students choices of solution to a given addition of integers "naked numbers problem." The pre- and post-test were adapted by giving students choice of whether the solution would be positive, negative, neither, or unsure. In addition, the students were asked to explain their thinking. Figure 1 is representative of the multiple-choice items with directions.

Using mental mathematics

- circle **positive** for the problem(s) that will result in a positive answer,
- circle **negative** for the problem(s) that will result in a negative answer,
- circle **neither** for the problem(s) that will result in neither negative nor positive answer,
- circle **unsure** for the problem(s) that you do not know what the result will be.
- Explain your answers.

1. $-24+78$ a. Positive b. Negative c. Neither d. Unsure

Explain your answer.

*Figure 1*. An example of a multiple choice item with directions.

On both the pre- and post-tests students analyzed the thinking of three persons who solved "naked numbers" problems. These problems were adapted from multiple choice items among the released items of the state assessment; the choices were reduced from five to three choices and were put into a context of solutions found by three students. Figure 2 represents an adapted problem that appeared on the pre-and post tests.

This class was given the problem: $7+(-12)$.

- Oren stated the answer is 5 because he subtracted.
- Robert stated the answer is -19 because it is an addition problem but he put the negative in front because of -12.
- Joe stated the answer is -5 because he said there are five more negatives than positives. Who is right? Why?

*Figure 2*. Post-test analytical problem.

Two open-ended items were on both tests. On the post-test, students were asked to solve, "Sam the snake slithers forward 4 feet and backwards 2 feet everyday. How many days will it take Sam to reach a rock 25 feet away from his starting point?"

The pre- and post-test measures were scored by two raters – one mathematics educator (one of the authors) and a high school mathematics teacher. The pre-and post-test measures were scored after the instructional units were completed. The raters used a sixteen-point rubric to rate the overall quality of the open-ended responses. For the items that required subjective ratings on the pre-test, the mean inter-rater correlation was .92. On the post-test, the mean inter-rater correlation was .96. These correlations were considered sufficiently high to provide reliable assessments of students' performance on these measures.

## Results

A two-way analysis of covariance (ANCOVA) was used to investigate the effectiveness of the two methods of instruction, controlling for group differences. Students were administered a pretest before the units were taught and a posttest after units were completed. The effect size was obtained to measure the amount of variance accounted for in achievement by the two types of teaching methods.

Prior to evaluating the different methods of instruction on student achievement, several assumptions underlying the two-way factorial ANCOVA were examined. Observations of skewness values and normal probability plots indicated that normality was satisfied. Levene's test of homogeneity of variance indicated that the variances of the two groups were not significantly different; $F(3, 96) = 0.16$, $p > 0.05$. Linearity between the covariate and dependent variable was shown to be satisfied by a linear regression of posttest scores on pretest scores. Also, interaction between the group and pretest variables indicated the interaction term was insignificant ($p > 0.05$), supporting the assumption of homogeneous regression slopes.

A two-way factorial ANCOVA indicated that the method of instruction students were exposed to had a statistically significant influence on their achievement, $F(1, 96) = 13.06$, $p < 0.05$. Within each respective group, African American and White students' scores were not statistically different. Parameter estimates indicate that, given two students with similar pretest scores, you can expect the student in the intervention group to have a score of 6.5 points higher than the student in the control group. Furthermore, the adjusted r-squared indicates 55 percent of the variance can be accounted for by group assignment.

## Discussion and Conclusion

While the results of this study may not be generalizable, we can not discount the fact that Ms. Canady's instruction appeared to have a strong impact on African American students learning of addition of integers. The reasons for this impact are hard to isolate but we speculate that the use of contexts for teaching addition of integers, students sharing and justifying their thinking, and Ms. Canady's disposition of a "warm demander" positively impacted students' motivation to do mathematics. Observations of both classrooms revealed that Ms. Canady's classroom was more engaging and respecting of students' perspectives. Hence, the difference might be found in the level of engagement of the students. The activities and engagement of Ms. Canady's pedagogical practices are strongly correlated to relational and multidimensional teaching, which appears to complement the learning preferences of African American learners.

The knowledge required for effective teaching is substantial. While having a solid foundation in mathematics content is essential, teachers must also be able to ascertain students' understanding of the mathematics content, and have a firm grasp of curricular goals (Schoenfeld, 2002). This means they must know and be able to teach problem-solving skills, represent mathematics concepts in multiple ways, connect mathematics concepts within mathematics and to other subjects, and be able to analyze students' thinking about mathematics. Schoenfeld (2002) contended that this is a gross underestimation of the knowledge and skills required to be effective mathematics teachers. This knowledge alone will not have the sustaining impact necessary for long-term effects on the mathematics teaching and learning of African American students (Martin, 2007). Effective mathematics teachers of African American students must also possess the tenets of culturally relevant pedagogy. These teachers must be "warm demanders," that is, they must demand academic excellence from their students while possessing culturally competence. Mathematics teachers of African American students must have knowledge of African American cultural style and learning preferences and how to use this knowledge to develop effective learning experiences in mathematic for African American students.

salsbury@wsu.edu

*Many teachers find themselves challenged to teach mathematics to students who are also learning English. Research in English as a second language recommends the use of objects, pictures, gestures, and language supports to help English language learners (ELLs) develop language and content. For example pictures and gestures can be used to augment a story similar to enacting a play. However, how can a mathematics teacher utilize these practices? The purpose of this study was to describe how a teacher used language structure to support two ELLs and how these students used the language structure to develop their mathematical thinking. Findings of the study suggest that modeling language structures for students enables ELLs to participate in mathematical discourse and deepen their understanding of mathematics through oral communication.*

## Introduction

Mathematics educators facing the challenge of raising the performance levels of students and are forced to examine how to accomplish this within growing culturally and linguistically diverse populations (Gebhard, 2002). Adler (2001) and Barwell (2005) described the challenges that teachers and students face when students are learning mathematics in a language different from their home language. Limited proficiency in the academic language of mathematics appears to be one reason why students that appear fluent in social English still have difficulty in mathematics (Irujo, 2007).

Words used in mathematics draw from two sources: everyday words with specific mathematical meanings and words specific to the domain (Irujo, 2007). A common strategy to decode the meaning of a word is to identify the root and build meaning from it. For example, *triangle* can be broken into the root *angle* and the prefix *tri*, which indicates three. Thus, triangle means three angles and describes a specific shape. However, individuals can not always discern the embodied concept when this strategy is applied to groups of words. A person who knows the meaning of least, common, and multiple may unpack the term *least common multiple* as the smallest familiar multiplication. This does not lead to a correct mathematical meaning and the individual may have difficulty understanding the concept embodied by the phrase. Interpreting academic mathematics language can be difficult for students with proficiency in English. However, these challenges compound when a student has limited English proficiency. The purpose of this research report is to describe how a teacher supported students who were gaining both proficiency in English and mathematics.

## Theoretical Framework

Gee (1991) theorized that discourse is socially constructed by groups of people to communicate ideas and this discourse is defined by the distinct language, thought, and actions shared by individuals in the community. Thus, social interactions, class structure, and curriculum combine to create the unique discourse of a mathematics classroom (Yackel, 2001). This discourse is created by the teacher and the ability of students to express their thoughts.

Classrooms with native English speakers are diverse and not all students have the same ability to articulate their ideas. However, the classroom discourse changes significantly when it includes students who are learning English. The teacher may ignore these students and rely on outside support to translate the classroom discussion or change his or her discourse to make the discussion more accessible to English language learners (ELL).

Monitoring vocabulary is an obvious way to modify discourse (Irujo, 2007). To further help ELLs develop a deeper understanding of words, a teacher can link those words to pictures, symbols, and actions. The choice of words and how those words are linked to sensory experiences determines the degree to which an English language learner (ELL) can construct meaning. Two considerations in word choice are helpful. First, concrete words that link to sensory experience are easier for children to learn. Second, certain words are key to understanding content in a lesson. Emphasizing concrete word choice and highlighting key content words are helpful ways that teachers can modify their discourse.

Echevarria, Vogt, and Short (2008) describe specific research-based techniques to help ELLs construct meaning in classrooms, including the use of objects, pictures, gestures, and language supports. The use of these techniques encourages ELLs to develop a vocabulary that goes beyond translating nouns from one language into another. For example, a rectangular prism is introduced by showing students several solids as examples with a discussion of their attributes. ELLs may learn to identify the shape with the term but the discussion of its attributes is often incomprehensible. However, if ELLs are given several solids to feel and provided language supports to describe its attributes (straight, flat, surface, edge, point, sharp, etc), they are more likely to appropriate descriptive language to characterize the rectangular prism's attributes. The word bank provided in this example enables an ELL with appropriate words that do not solely rely on memorized vocabulary.

Research and literature on instructing ELLs provide many examples of how the strategies described by Echevarria, Vogt, and Short (2008) can be infused in courses that focus on speaking, reading and writing. However, in mathematics there are fewer examples. The purpose of this study was to describe language supports that were used by a teacher to help ELLs gain proficiency in English and mathematics.

## Methods

This study took place in a classroom in the western United States. 62% of the students in the school spoke English as a second language. During the previous year, Olson and Salsbury worked with teachers in the school to incorporate language structures into their mathematics instruction through professional development. Braun was both a teacher leader who planned professional development with a team (Olson, Salsbury, Braun, Colasanti, 2008) and a researcher who conducted semi-structured interviews with ELLs over 18 months. Braun was curious about how she used language structures to support the learning of ELLs in her classroom and collaborated with Olson and Salsbury to characterize her practices.

Braun's fifth grade classroom had 27 students. She had 14 ELLs one of whom we will call Shi. Shi moved to the United States from Nepal during the summer of 2008. His native language was Chinese. Even though Shi's English was very limited, he found ways to communicate with other children, suggesting an outgoing personality. A second learner we will call Ricca. She moved to the United States from Mexico in 2006. Ricca participated in a larger study that examined how ELLs developed mathematical thinking while gaining English proficiency during the fourth grade. She spoke both conversational and academic English with hesitancy and difficulty. During the study, we developed a good relationship with Ricca through the monthly small group meetings and she gradually increased her spoken language during the small group meetings. At the beginning of the 2008 school year, Ricca was an intermediate speaker. Even though Ricca had a good relationship with Braun, she seldom spoke to Braun or her peers. Ricca was quite shy and would only communicate when she felt secure in her environment and confident in her content knowledge.

Qualitative methods with two case-studies (Merriam, 1998) were used to identify and describe the discursive practices that Braun used during her instruction. Data were collected from five sources during the fall semester. These sources included (a) reflections, (b) video recordings of classroom and small group instruction, (c) detailed lesson plans, (d) students' written interactions recorded on a smart board, and (e) informal interviews. Constant comparative methods (Merriam) were used to code, analyze, and collapse the data to display in a conceptual matrix with illustrative examples in each cell. These examples were used to characterize Braun's use of language structures.

## Results and Discussion

Braun made three instructional decisions to encourage students' vocalization of their mathematical thinking. First, she instituted a number talk at the beginning of the mathematics lessons a couple of times each week. During the number talk the students sat on a rug in front of a large sheet of paper. Braun wrote a problem on the paper that could be solved using mental arithmetic and after a short discussion, students thought about the problem silently, without paper and pencil. Then, Braun called on several students to share their solution strategy and recorded it on the paper using notation. Second, Braun wrote problems that would not be cognitively difficult for her fifth grade students. She wanted the students to be able to understand the process of a number talk which includes: mental math, sharing their thinking to the whole class and questioning each other. The third instructional decision was to provide students with a structure to share their strategy. This language structure was designed to provide students with limited English with the words necessary to enter a mathematical conversation. The language structure posted on the wall was, "I know __ x __ = __. This helped me solve __ x __ = __. The answer is ___." The language structure allowed students to focus on sharing their reasoning and establishing group norms. This technique provided a scaffold from which students could discuss complex mathematical ideas. Braun wanted students to be successful within the number talk and create a learning community in which students felt safe in sharing their ideas.

The following is an illustrative example of a typical number talk during the first month of school. Braun wrote 28 x 6 = on chart paper.

| | | |
|---|---|---|
| 1 | Braun | I have the problem 28 groups of 6 on the board. Who would like to |
| 2 | | make an estimate of the answer? Student A. |
| 3 | Student A | I know that the answer is going to be less than 180 because 28 is close |
| 4 | | to 30 and 30 times 6 equals 180. |
| 5 | Braun | Anyone else? |
| 6 | Student B | I know that the answer will be more than 120 because 20 times 6 equals 120? |
| 7 | Braun | Our answer should be between 120 minus 180 according the estimates |
| 8 | | from Student A and Student B try solving the problem. (Students sat |
| 9 | | quietly and solved the problem mentally. They took turns sharing their |

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

| | | |
|---|---|---|
| 10 | | answers until several were posted on the chart paper.) Who would like |
| 11 | | to share how they solved this problem? |
| 12 | Student C | I split the 28 into a 20 and an 8. Then I multiplied 20 times 6. I know 20 |
| 13 | | times 6 is 120 from Student B. Then I multiplied 8 times 6. I know 8 |
| 14 | | times 6 is 48. 120 and 48 equals 168. My answer is 168. |
| 15 | Braun | Does anyone have questions for Student C? |
| 16 | Student D | How did you know that 8 times 6 is 48? |
| 17 | Student C | I know that 4 doubled is 8. I can multiply 4 times 6 which is 24 and |
| 18 | | then I need to double the answer. 24 and 24 is 48. |
| 19 | Student D | Ohhhh, I get it. |
| 20 | Braun | What strategy did Student C use and how do you know? |
| 21 | Student A | Splitting number because he split the 28 into a 20 and an 8. |

Braun initiated the number talk with a problem that students could easily solve (line 1) and engaged them in it mathematically by asking them to estimate the answer (line 2). Notice that students A and B use the language structure, *I know that,* followed by a reason (lines 3 and 4). Braun used the students' estimation to define the boundaries of acceptable answers, setting the norm that students need to estimate an answer and that the answer should be within the boundaries. Student C shares her solution, stepping out of the language structure (line 12) to describe the strategy that she used. The student then moves back into the language structure, *I know that,* to finish her description of her strategy (lines 12 and 13). Braun encourages students to question each other (line 15) and a student asks a question (line 16). Student C further explains (lines 17 and 18) which leads to an insight (line 19). Braun then reinforces the naming of a strategy (line 20), bringing closure to the number talk. Braun reflected that "the student named the strategy, splitting numbers. This type of naming became important because naming strategies helped students during the share time to express the concept that they were applying to the problem. It also allowed them to decide whether their strategy was different from ones that other students had shared." The teachers in her school decided to use consistent words for particular strategies. Here splitting is used to refer to the strategy of 'breaking apart'. This was a conscious decision to help ELLs and learning disabled students who became confused with multiple labels for a strategy.

During these early number talks, Shi watched and listened to other students during the beginning of the school year. He felt comfortable with one little girl and followed her lead through the daily routines. During number talks, Shi was able to figure out the answer to the problem, but he was unable to share his solutions or thinking with the rest of the class. After the first couple of weeks, he ventured to give the answer to the problem because he felt comfortable with numbers. However, with limited English he did not explain or share his solution strategy. Shi seemed to really enjoy math and felt comfortable with solving written problems. While there were times during the school day when Shi became uninterested in a lesson, this never occurred during math. Braun noted that Shi was engaged and appeared to use his background in math to build upon what the class was doing. He seemed to make connections to the ideas being taught. Like Shi, Ricca was also quiet. She kept her eyes on the speaker and watched Braun write on the chart paper. As both the structure of the number talk and the structure of the language became familiar, Ricca began sharing her thoughts using the language structure. Initially, when she tried to share her thinking during number talks, she became stuck and forgot her next step. After 30 seconds of wait time, Braun would ask her if she wanted to think about the problem for a little bit. Ricca always nodded shyly with relief. Occasionally Braun led the class back to the problem and asked Ricca if she was ready to share her thinking. She either finished expressing her steps or she asked for help from the class. When a peer helped her complete the problem by providing the needed language, Ricca listened intently trying to absorb everything that the student said. During the first quarter of the school year, Ricca shared her thinking only two or three times. During the second quarter, Braun introduced *cluster problems* as a strategy to help students solve more difficult problems mentally. Cluster problems were related to the original problem using the operations of multiplication or division. A combination of them could be used to solve the original problem often using the distributive property. For example, cluster problems related to 28 x 6 could include the following: 20 x 6; 8 x 6; 120 ÷ 6; 48 ÷ 6. Braun encouraged students to use one of the cluster problems to find the solution and if they finished quickly to use a different one. Students shared a solution strategy using each of the cluster problems. Initially, Braun provided the cluster problems for students to use and later students generated their own set, first as a class and then independently.

The following except illustrates how Ricca and Shi used language structures during number talk to share their mathematical thinking. Braun posted two problems, 184 ÷ 8 and ¾ of 24**,** on chart paper with four cluster problems (Figure 1).

**184 ÷ 8**
Cluster problems to help: 160 ÷ 8 24 ÷ 8 11x 8 1x 8

**¾ of 24**

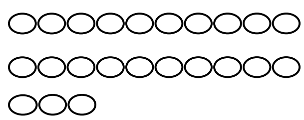

*Figure 1*. Two number talk problems posted on chart paper with four cluster problems.

Braun began the number talk by asking students for answers to the four cluster problems and students quickly provided them. Following the routine, students thought quietly for about two minutes and Braun asked for solutions which were recorded on the chart paper. Braun then asked for a volunteer to share a solution strategy.

| | | |
|---|---|---|
| 1 | Shi | 160 divided by 8 is 20. 24 divided by 8 is 3. 160 and 24 is 184. 20 and 3 |
| 2 | | is 23. Answer is 23. |
| 3 | Braun | Thank you, Shi, for sharing! |
| 4 | Student E | Shi, is learning English quickly. |

Shi quickly raised his hand and began using a slight modification of the language structure (line 1). Rather than beginning with, *I know that,* he simply stated the facts that he used, resembling the model provided by Student C (lines 12 to 14) in the previous example. As modeled by Student C, the classroom norm was to split the problem into two related cluster problems that were easy to solve mentally. Shi, following the classroom norm, articulated his answer to the cluster problem with the larger numbers (160 ÷ 8) before stating the answer to the cluster problem with smaller numbers (24 ÷ 8). Then he combined the pieces and stated his answer. Clearly, Shi followed the classroom norm that established an order for splitting numbers apart and used the language structure to articulate his mathematical thinking. His ability to communicate his thinking was recognized by a peer (line 4). From this peer student's perspective, it was unusual for an ELL to gain fluency so quickly.

After Shi's explanation, Braun moved the discussion to the second problem. She had recently introduced fractions to the class and wondered how they would apply their understanding of fractions in a new number talk. Previously, students found fractional parts of sets using unit fractions (e.g., find $^1/_8$ of 24).

| | | |
|---|---|---|
| 5 | Braun | Who would like to solve ¾ of 24? (Ricca raised her hand). Ricca. |
| 6 | Ricca | I know that 6 fours equals 24. And that 6 and 6 and 6 is 18. The answer |
| 7 | | is 18. |
| 8 | Braun | Three of the 4 groups of six is 18? |
| 9 | Ricca | Yes. |
| 10 | Braun | Questions? |
| 11 | Student G | Where did you get the six? (Ricca was silent.) |
| 12 | Student H | What was the question? |
| 13 | Braun | Where did Ricca get the 6? |
| 14 | Ricca | I divided (pause). I divided 24 by 4 is 6. |
| 15 | Braun | Student J, do you have a question? |
| 16 | Student J | No, I was going to help Ricca if she was stuck. |
| 17 | Braun | Oh, that was very nice of you. So, which number did Ricca use to |
| 18 | | divide the 24? |
| 19 | Student K | The 4 in the ¾'s. |

Ricca responded to Braun's invitation to discuss a mathematical idea that students in the class were beginning to understand. Ricca used the provided language structure, beginning with *I know that* (line 6). Then, stated the facts and her answer. It is interesting to note that Ricca was developing multiple ways to express an idea through her use of equals as seen in her statements (lines 6 and 7). Her thinking is less transparent for the students in the classroom, prompting Student G to ask a question (line 11). Ricca needs more time to think about her response. Another student, taking advantage of the silence, asks his teacher to repeat the question (line 12). This seemed to give Ricca the time that she needed to explain her use of division (line 14) to find the size of four equal pieces of 24. Anticipating that Ricca may need help articulating her thinking, Student J is ready to help (line 16). This exchange illustrates the collaborative nature of the classroom in which students worked together to solve problems and explain their thinking. Braun decided at this point to intervene and bring closure to the problem (line 17 and 18). While many of the students may not fully understand how Ricca found three-fourths of 24, Ricca was able to articulate her strategy in a way that some students understood.

## Summary

Shi and Ricca seldom spoke in the initial weeks of fifth grade. Shi was a beginning ELL student and did not know very many words. Ricca was classified as an intermediate ELL but was shy and lacked confidence in her mathematical thinking and ability to communicate in English. Like many ELLs they both listened intently to the other students during this silent receptive stage (Echevarria, Vogt, & Short, 2008). The number talks were ideal to support the language development and mathematical thinking of these ELLs. First, students were able to share their answer which was a single number. There was no expectation for an explanation and no judgment as to whether it was correct or incorrect. Thus, Shi and Ricca could provide a solution. If they made a mistake translating numbers into English, it was not an embarrassment for them. Second, the number talks were short (about ten minutes). The shortness of the number talks encouraged more intense concentration and focused listening to peers. Third, the language structure that Braun provided created a predictable pattern that they could follow and later use themselves. The early number talk problems were purposefully selected to pose little cognitive demand so that students could focus on articulating their reasoning using the language structure. Like many elementary school students, the students in Braun's class naturally split numbers into pieces and manipulated the larger place values before the ones and tens. This became a classroom norm that the ELLs adopted.

The use of a language structures helped the ELLs gain proficiency and confidence using English to express their thinking (Echevarria, Vogt, and Short, 2008). These structures also helped the two ELLs develop their mathematical thinking. Shi quickly used the distributive property to mentally solve a division problem and Ricca applied her understanding of fractions to find three-fourths of a set. Sfard (2008) illustrated the important role of discourse to the development of more sophisticated mathematical thinking. Providing language structures that are predictable and easily modified supported the ELLs' emergent mathematical discourse, which in turn allowed them to explore mathematical ideas in collaboration with their peers and teacher. This study suggests that language structures may not only help ELLs but also all students learning mathematics. The language structures help students explain their ideas in concise ways that their peers can easily understand. In doing so, these structures may also help solve a quandary that many teachers face: What do I do when students ramble in incoherent ways while trying to explain their thinking to their classmates? More research is needed to describe how language structures and other supports described by Echevarria, Vogt, and Short (2008) support the learning of mathematics.

*Despite recent process toward gender equity in mathematics and science education, the persistent underachievement among low-income African American girls remains a challenge. This presentation offers the preliminary outcomes of a longitudinal study examining the positionality of fifth grade students toward mathematics and science. From the data speak diverse voices, voices of African American girls, their parents, their teachers, and their school counselors, and they tell how the girls regard themselves as learners of mathematics.*

## Background

The centrality of mathematics for advanced degrees and economic advancement has been widely acknowledged. A comparison of the National Assessment of Educational Progress (NAEP) mathematics scores for students in fourth and eighth grade clearly demonstrates the difference in the mean achievement between Blacks, Hispanics, and Whites.

| NAEP Mathematics | 5th (1996) | 5th (2000) | 8th (1996) | 8th (2000) |
|---|---|---|---|---|
| Blacks | 243 | 247 | 280 | 274 |
| Hispanics | 251 | 253 | 287 | 283 |
| Whites | 282 | 286 | 310 | 308 |

Results of the Scholastic Achievement Test (SAT) mathematics exam reveal a gap of about 100 points between the lower-scoring Blacks and the higher scoring Whites. The gap that begins in fourth grade only gets larger as the years of schooling pass (Bennett, Bridglall, Cauce, Everson, Gordon, Lee, et al, 2004). Although research has been conducted on the African American student achievement (Foster & Peele, 1999; Murrell, 2002), girls and mathematics education (Kerr & Kurpius, 2004), and the impact of socioeconomic status on student learning, little is known about the relationship between teacher expectations and African American girls' self-perception as science and mathematics learners.

## Theoretical Perspective

Positionality, rooted in feminist scholarship, has been used to describe an individual's self-perceived social location that informs that individual's world-view. According to positionality theory, an individual's position in relationship networks defines that individual and also determines the amount of individual power (Cooks, 2003; Harley et al., 2002). According to feminist scholars, positionality is present in the classroom where power dynamics among teachers and students are affected by gender and racial differences (Johnson-Bailey, 2002). This

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

position determines the level of power individuals possess and, if internalized, impacts their access to opportunities. Positional factors have been shown to affect knowledge construction, power, and relationships in and out of the classroom (Maher & Thompson Tetreault, 2001). Therefore, the researchers posited that African American girls' constructed cultural, gender, and class identities dictate their positionalities in relation to mathematics learning.

African American girls must negotiate both race and gender to succeed in school (Picken, 2002). "Living in the context of a larger African American community presents more choices, yet African American women still have to contend with devaluing messages about who they are, and who they will become, especially if they are poor or working class" (Tatum, 2003, p. 57).

Scholarship on positionality indicates that a teacher's positionality may affect teaching practices as well as students' experiences (Cooks, 2003; Rehm & Allison, 2006). The teacher's tendency toward certain behaviors with culturally diverse students, such as being open to cultural differences or tying to correct such differences, is a product of a teacher's views on diversity. Positionality is a salient element of all classroom dynamics. School personnel spend more time addressing the social skills of African American girls (speech and dress patterns), and less time promoting their academic skills. This is exacerbated for low-income African American girls (Morris, 2007).

Research is therefore needed to explore how the positionalities of teachers, counselors, and parents impact African American girls' positionality in relation to mathematics and science learning. The presenters are engaged in a three-year study funded by the National Science Foundation to investigate African American girls positionality toward science and mathematics.

## Research Questions

The primary research questions under study are as follows:

1. How do African American middle school girls position themselves as mathematics and science learners in relation to their gender and ethnic identities?
2. How do parents, teachers, counselors, and administrators position African American girls in relation to the girls' interest and achievement in mathematics and science education?

For this conference, the presenters will focus the component of the research questions that address mathematics.

## Method

The research participants were recruited from local elementary schools where the researchers had previously established working relationships. Thirty African American girls in the fifth grade were asked to join a cohort of female students who would be observed during their fifth grade and the two years following. Participants were drawn from the probable population at a neighborhood middle school where there was in place a magnet program for mathematics and science. The girls were asked to share their reflections on school experiences in mathematics and science. Of the three schools, one school was considered as "parallel", rather than "control," given that the study was not designed to test interventions. This school was already rich in community involvement, a situation atypical for the community, which is generally of low economic status.

Preliminary data sources included semi-structured interviews with teachers of mathematics and science content areas, parents, and counselors, and focus groups with the girls. All interviews were conducted at the schools. Interviewers were members of the research team, doctoral students and post-doctoral researchers in education areas.

Records of student grades and state tests scores were collected. During the summer, an institute was held for parents, teachers, and counselors from two of the schools. Data from the first cohort included observation, interview, and field notes, videotapes of classroom lessons, focus groups, and the summer institute. There is an advisory Board comprised of community members. During the second year, a new cohort of thirty fifth-grade girls was added to the study, comprising the second cohort.

Initial analysis was conducted using grounded theory, beginning with inductive analysis. The data was analyzed according to the data source, be it girls or teachers, parents or counselors. Hatch's (2000) inductive analysis method was used to analyze the data. Inductive analysis is a search for patterns of meaning in the data that guides the researcher to make general statements regarding the phenomenon being studied. Triangulation of the data was achieved by member checking, peer review, and confirmatory analysis using a review of the literature.

## Results

Triangulation of the data was achieved in part through the literature reviewed on African American girls and mathematics and science learning (Butler & Lakes, 2003; Foster & Peele, 1999; Kerr & Kurpius, 2004; Murrell, 2002; Tutweiler, 2005). Consistencies between this literature and the researchers' finding regarding African American girls' positionality in education provide some authenticity of representation, or a confirmation between what the researchers believed to have observed and what was actually observed.

### *Responses of the teachers*

During interviews teachers reported their observations of African American girls in classes in mathematics and science. They report that reading and mathematics are areas in which girls excel, but they are better in areas that involve language. They credit the boys in their classes as being more interested in science and mathematics than are the girls. Teachers hypothesized that the girls typically viewed math and science as a male domain. As one teacher explained,

> I think some girls kind of think that science is more, or a guy thing, cause like, you know. . . Of a lot of their experiences, like you know, who invented this or who invented that, it's a lot of guys, to the point where they don't feel like they fit in.

Teachers acknowledged that the mathematics instruction is based on rote memory, skills and computation, with less focus on higher order thinking, problem solving or hands-on activities, at the same time they are aware that their students would be more successful with hands-on experiences in the classroom. One teacher believed that among the resources that would influence mathematics skill development would be, "Definitely hands-on, definitely giving them something where they can feel it, touch it."

Observing that parental involvement was important to the girls' success, teachers note the significance of the home environment. Girls did better when the parents were supportive and the student was motivated. Early focus on school subject areas made a difference, especially when the work was taught in an earlier grade. Otherwise, teachers felt as if they had to start over at the beginning. Strategies that worked included group work and peer coaching, as did scaffolding of information. However, teachers believed that few of their female students would pursue mathematics in higher education or their careers.

### *Responses of the Parents*

Analysis of the data revealed that parents were indeed directly or indirectly involved in their daughter's mathematics and learning. To the extent that they viewed themselves as mathematics learners, parents were directly involved with their child's homework. Regardless, they were involved in setting up and monitoring homework time. Indirect parent involvement manifested itself in several ways. Parents were in communication with their daughter's teacher, were willing to seek resources to help their daughter in problem areas, and were sources of encouragement.

Another major finding focuses on parents' knowledge of their children and their learning process. They understand their children's learning process and the importance of teacher influence and teaching methods on learning. In terms of their daughters' engagement in mathematics instruction, they stated that they wanted teachers to make learning interesting, fun, understandable, applicable to real life, and hands-on.

*Responses of the Girls*

In their focus groups, the girls described their mathematics classes. In these rooms, the students worked on problems presented by their teacher or from their textbook. Their tools were paper, book, and pencils. The students listened, wrote, and answered questions posed by the teacher. Sometimes they worked on the problem solution with their team, and sometimes they worked alone or with the teacher's help.

To the girls, mathematics is a subject that is sometimes difficult and challenging, and sometimes it is easy. What's easy is, "the multiplication, the division, and . . .that's about it," to one girl. What's hard is " . . .to understand what you are doing." The girls note that a student who is good in math is one who studies and works hard. When asked to visualize somebody doing mathematics, the girls said " . . .knowing the steps and doing it right." "It looks like they are counting in their heads." The students believed that to be proficient in mathematics would require a great deal more schooling, perhaps even a college degree.

However, the girls did have moments of confidence when they knew the answer to the question or they got back a paper with a high score on it. When they knew the answer, they raised their hand quickly. Sometimes they would be so excited that they would shout out the information, but they knew that they might get in trouble for doing so. All of the girls preferred to be called on when they knew the answer. When they didn't know the answer, they were "embarrassed" or "nervous" or "scared." One fear was that their fellow students would think that they had not been "working hard or studying." As the girls struggled with their ignorance for a particular question, the teachers let another one help her or moved on to another student for the answer.

*Responses of the Counselors*

The outcomes of the study revealed that the counselors demonstrated low levels of awareness of their biases towards the students. Additionally it was found that the participants did not see themselves as advocates or agents for social change. Moreover, they did not understand their role in the advancement of mathematics and science learning for these students. For example, one counselor talked about the potential for her students to go to college, but she did not see herself as an agent of change for these students. Although another counselor stated, "There's a big world out there; they can do anything they want to," she also viewed the position of poverty as an obstacle to the girls' attendance at a four-year college, explaining that there are not many scholarships available to families of limited means.

All of the counselors evidenced an understanding of effective ways to engage students in mathematics and science, especially the importance of instruction with hands-on activities. Two of the counselors discussed utilizing prior knowledge and the girls' interests to increase student engagement and success in mathematics. They pointed out the motivation created by success. "When you're successful at something it makes you want to do it more . . .success breeds motivation." Counselors recognized the positive effect of parental involvement, and they noted a need for role models. "I think we see ourselves looking for someone like us."

Counselors are uncertain about their role in facilitating mathematics and science achievement in the girls. One counselor tried to make connections between the girls who were interested in the same things, who had similar career aspirations, but she saw her position as being little involved in the mathematics setting. Overall, it appeared that these counselors might unintentionally play a gate-keeping role in the way in which they position African American girls and place limitation on their potential. Their view of the obstacles faced by the students blocks a vision of a counselor taking a larger role in the students' mathematics experiences.

## Discussion

This study began by studying the girls, but the grounded theory revealed that the teachers' positionality toward mathematics is a critical component of any work regarding the achievement of girls in that subject. Among the strategies recommended for closing the Achievement Gap in mathematics is setting high standards (Bennett, 2004). What the teacher envisions for the girls' futures influences instruction. Teachers who see themselves as strong mathematicians are more confident about developing that capacity in their students. If they doubt that they can be a positive role model in mathematics, they can provide examples of others who are models of achievement, of female African American mathematicians and scientists.

One implication for the professional development of counselors and teachers working with African American girls is that the educators can address the girls' needs better when their own positionality is uncovered. This understanding could be advanced in the professional development context. Additionally, guidance counselors could be encouraged and taught to play a more active role advising and encouraging the girls' participation in mathematics.

All of the adult respondents noted that more hands-on instruction would benefit the mathematics learning of the students. Teachers need more training in providing this type of instruction. Moreover, they could be taught to look forward, taking a positive stance about teaching the girls what they will need for the future, rather than focusing on the deficits in their students' background knowledge.

We acknowledge that the girls are aware of how they are being positioned. They look to their teachers, parents, and counselors, for guidance and support to help them be successful. They want to be the kind of student that is regarded as capable and industrious. They know that boundaries for their horizons are deeply influenced by these important players in their educational lives.

# THE IMPACT OF "MATH FOR SOCIAL ANALYSIS" ON MATHEMATICS ANXIETY IN ELEMENTARY PRESERVICE TEACHERS

Jean Mistele
Radford University
jmistele@radford.edu

Laura Jacobsen Spielman
Radford University
lspielman@radford.edu

*Mathematics anxiety is prevalent in America and has been an important topic of researchers for educators in the past several decades. This paper describes ways mathematics anxiety levels subsided as a result of preservice teachers' engagement with social issues in a new course, Math for Social Analysis, designed to emphasize equity and social justice. Further, we make the case that contrasting models for studying mathematics anxiety generally fall into one of two predominant groups: deficit models and situated models. Our research raises new challenges to deficit models based on our observations that mathematics anxiety is situated within the classroom dynamics.*

## Introduction

Mathematics anxiety is prevalent in America and has been an important topic of research for educators in the past several decades. Ma (1999) found a significant relationship between anxiety in mathematics and achievement in mathematics was significant, as did other researchers (e.g., Satake and Amato, 1995). Mathematics anxiety is widespread in the U.S., including among preservice teachers (e.g., Buhlman & Young, 1982; Burns, 1998; Levine, 1996). This is problematic because, for example, mathematics anxiety among preservice teachers is associated with apprehension when faced with the prospect of teaching mathematics (Brady & Bowd, 2005; Gresham, 2008). Bursal and Paxnokas (2006) suggested nearly half of preservice teachers having higher mathematics anxiety believe they will not be able to effectively teach mathematics. Brush (1981) found mathematics anxious teachers tend to revert to traditional methods of teaching mathematics with a focus on basic skills, ignoring mathematical concepts.

We did not originally set out in our research to examine mathematics anxiety; however, the topic became salient in our research in a new mathematics course for elementary and middle grades preservice teachers. The course, *Elementary and Middle Grades Mathematics for Social Analysis* [*Math for Social Analysis*], incorporates National Council of Teachers of Mathematics [NCTM] *Standards*-based (2000) mathematics content and instructional approaches and uses relevant social issues to provide contexts for preservice teachers' learning of mathematics. Beginning with an overarching goal to understand preservice teachers' assessments of their learning and experiences in the course, numerous references to mathematics anxiety emerged. This paper describes ways mathematics anxiety levels subsided as a result of preservice teachers' engagement with the social issues. Further, we make the case that contrasting models for studying mathematics anxiety generally fall into one of two predominant groups: deficit models and situated models. Our research raises new challenges to deficit models based on our observations that mathematics anxiety is situated within the dynamics of the classroom.

## Math for Social Analysis

The *Math for Social Analysis* course is one component of the Mathematics Education in the Public Interest [MEPI] project.[i] The MEPI project has as its key objectives to support equity and social justice in mathematics education.

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

*Math for Social Analysis* is unique because we integrate mathematics, critical pedagogy and citizenship. In our course, preservice teachers and faculty identify social issues of personal or professional interest. Examples include rainforest depletion rates, poverty, and child labor. The preservice teachers identify and use multiple mathematical methods to better understand both the relevant mathematical content and the social issue. Each classroom unit of study or semester project includes actions which contribute to positive social change.

## Methodology

Results presented in this paper are based on research conducted in a medium-sized public institution located in southeastern U.S. We conducted open ended interviews with 14 White female preservice teachers enrolled in *Math for Social Analysis* in spring 2008. We asked preservice teachers to share their past experiences with mathematics and their thoughts concerning the course, mathematics as a discipline, and teaching mathematics in the future.

## Results

Our data analysis revealed an emergent theme which showed that *Math for Social Analysis* proved beneficial in reducing mathematics anxiety among our preservice teachers. For preservice teachers, a focus on social issues in the mathematics classroom: (1) Increased the utility of mathematics, (2) Redirected attention away from anxiety, and (3) Built confidence to teach.

*1. Increased Utility of Mathematics*

> You say “math” and people get psyched out...because math is one of those high anxiety subjects….Being able to answer why it is *really* important is really going to help some kids….All the word problems in math books I’ve ever seen are situations that are not gonna happen….By finding something that *matters* to the kids and something that they want to learn, where math is more of a tool to better understand it and not a means to get an answer, is going to help. (Megan)

Megan’s reflections are similar to those of several other students in *Math for Social Analysis*. According to some preservice teachers, the course led to decreased feelings of mathematics anxiety. Several expressed developing improved attitudes as a result of learning new relevance for mathematics. A focus on social issues gave new meaning to the mathematics.

*2. Redirected Attention*

> I hated [math]. I never really liked math….I just don’t think I was very good at it….*Math for Social Analysis*—I like the class a lot just because it gives a different spin. I kind of wish that math had been taught to me differently...like incorporating all the social stuff and hands-on learning ….When we did the whole rain forest ... I was like, oh my gosh, that many trees…but I’m learning math at the same time. (Amanda)

Some preservice teachers found their attention was redirected away from their mathematics anxiety and negative attitudes as they became immersed in social issues. In focusing on the social issues, they were at times surprised when they realized they were learning mathematics since they were feeling no anxiety.

*3. Built Confidence to Teach*

> I realized in my senior year of my Bachelor’s degree I would have to…[teach] math and that scared me. So a few years down the road I came back [to school for a graduate degree] and yes, [I] can teach math—I can do it now….[*Math for Social Analysis* has] shown me not only can I do it, but there are better ways….I want to take some of the social issues and make [math] relevant. (Janet)

Janet is not alone in finding her fears to teach mathematics were eliminated or greatly reduced. Some preservice teachers enjoyed learning mathematics in the context of social issues and no longer dreaded or feared mathematics or teaching mathematics.

## Discussion

In reviewing previous research on mathematics anxiety, we observed that much of it seems to fall within two predominant groupings—one based on a deficit model and the other based on a situated model.

Deficit models treat mathematics anxiety as a fixed, measurable quantity located inside the individual. Surveys are often used to evaluate the level of mathematics anxiety, and solutions to reducing anxiety often aim to improve the psychological or emotional state of the person. For example, Furner (2004) believes bibliotherapy is beneficial in overcoming mathematics anxiety. In bibliotherapy, books help educators guide the emotional development of their students as the students connect with the characters in a story. New books for children focus on mathematics anxiety so children do not feel isolated and alone with their fear of mathematics. Bibliotherapy is a form of psychological counseling that requires meaningful follow up discussion to be beneficial.

Another deficit model solution proposed by researchers is *systematic desensitization* (Furner, 1996; Hembree, 1990; Trent, 1985; Olson & Gillingham, 1980). This requires a gradual exposure of the mathematics anxious student to the mathematical concepts that are causing the student stress. Students are then taught appropriate coping skills. Sgoutas-Emch and Johnson (1998) recommend journal writing as an effective method to reduce anxiety, where the student can freely express feelings about mathematics. Hypnotherapy and cognitive skills training are additional techniques used to reduce test and mathematics anxiety. These methods require extensive training and counseling sessions to be effective, which may prove too costly and inconvenient for most students.

The problem with deficit models is that by identifying the problems within the individual, the models largely fail to consider, for example, the ways mathematics is socially constructed in the classroom or the ways mathematics as a discipline may be flawed. Situated models contextualize mathematics anxiety, contending that individuals' mathematics anxiety cannot be understood as separate from their experiences within the classroom or from the nature of the mathematics. People generally are not mathematics anxious prior to attending school (Williams, 1988). Research has suggested mathematics anxiety can be caused by teaching methodologies that do not encourage reasoning and understanding (Greenwood, 1984) and may also be a product of students' lack of mathematical understanding (Butterworth, 1999). To reduce mathematics anxiety, Cohen and Leung (2004) demonstrated the benefits of the reformed methods of teaching mathematics, as cited by the NCTM *Standards* (1989, 2000). However, Alsup (2004) indicated the particular instructional strategies used may not be as important in reducing preservice teachers' mathematics anxiety as the instructor's ability to communicate and clarify mathematical ideas, and the interconnectedness of mathematical concepts, while maintaining a calm and reassuring disposition.

Our research demonstrates a mathematics course with a focus on social issues can reduce mathematics anxiety among preservice teachers. We surmise from our research that situated models for examining mathematics anxiety may be more appropriate. By incorporating social issues into mathematics, this transformed the nature and relevance of the mathematics itself, thereby improving conditions for preservice teachers to engage with the discipline.

## Conclusion

We find it encouraging that mathematics anxiety can be reduced when preservice teachers learn mathematics in the context of social issues. Further research is needed that uses a situated model to examine mathematics anxiety. As previously indicated, we did not originally set out in our research to examine mathematics anxiety; therefore, interview questions were not explicitly intended to reveal preservice teachers' mathematics anxiety levels. To test the validity of the results presented in this paper, additional research is needed investigating mathematics anxiety in classrooms infusing social issues into the curriculum.

## Endnotes

# ACCESS TO MATHEMATICS: A POSSESSIVE INVESTMENT IN WHITENESS

Dan Battey
Arizona State University
daniel.battey@asu.edu

A number of papers and articles call for more attention to race/racialized experience in the work of mathematics educators (see Martin, 2009; DiME, 2007). One way to interpret this call is to focus more on researching people of color. Another way to view it is to critique whiteness as invisible, neutral, or normal, and to make known privileges that come with this status. This shifts a researcher's lens to the perpetrators or oppressors of racism. However in doing this, it is important to expose systematic, structural, and institutional forms of racism. While individual racism has a face and can be quite explicit, institutional racism can be difficult to represent tangibly. Many governmental programs privilege whites even though they purport to be race-neutral. Lipsitz (1995) calls this the possessive investment in whiteness. One way of exposing this is by examining profits or advantages that racism affords whites over minorities while noting the processes that allow that advantage to take place. Perlo (1996) illustrates this by analyzing the exploitation of people of color through cumulative wage differentials for African American and Hispanic workers as compared to whites.

Employing a similar framework, this paper analyzes the wage-earning differential due to differences in mathematics coursework by ethnic/racial groups. These differentials are reported across 3 time points, 1982, 1992, and 2004. Of course, issues such as SES, gender, and geographic location are important, but they are not included for the purposes of this paper on racial differences.

## Whiteness

Lipsitz (1995) states that "a fictive identity of "whiteness" appeared in law as an abstraction, and it became actualized in everyday life." Much like Black is a cultural construction based on skin color, not biology, whiteness developed out of the reality of slavery and segregation giving groups unequal access to citizenship, immigration, and property. By giving whites a privileged position in relation to the "other", European Americans united into a fictitious community. Whiteness is a constantly shifting boundary separating those who are entitled to certain privileges from those whose exploitation is justified by not being white.

While many think of race in a Black/white binary, groups such as Jews, Native Americans, Asians, and Latinos have proved more difficult to classify in the racial hierarchy. In the 1840s and 1850s, California had debates about the status of Mexicans and Chinese. There were some Mexicans with considerable wealth and partners with whites, while the Chinese were exploited for work on the railroads and the field. It was decided that Mexicans would be considered white and the Chinese the same as Blacks and Indians. That decision determined who could become citizens, own land, marry whites, and other basic rights (Almaguer, 1994). To complicate things further, though Mexican Americans were considered white legally, they were denied rights and privileges that whiteness bestowed (Foley, 2002). Despite being ruled as white in courts, the government added a category of Mexican on the 1930 census, counting only 4% of Mexicans as white. This prompted the League of United Latin American Citizens (LULAC) to attempt to establish Mexicans as whites and considered it an insult to be counted Black or a "colored race". The organization turned its back on civil rights battles of the 1940s and 1950s with statements such as “tell these Negores that we are not going to permit our manhood and womanhood to mingle with them on an equal social basis” (Haney-Lopez, 2006, quoting Marquez, pp. 33).

In contrast to LULAC’s stance, the Chicano/a movement of the 1960s, rejected LULAC’s assimilation strategies. This movement found common cause with Blacks, Native Americans Chinese, and Vietnamese. They rejected whiteness and all it came to mean. The response from whites has been “Why do you insist on being different? Why do you have to be Mexican or Chicano? Why can’t you just be American” (Foley, 2002). The lure of whiteness and all that it entails has been a contested boundary for those in the Latino community, some seek it out others reject it. Now, Mexican Americans are not considered white and Chinese Americans are conditionally white at times, not at others, but clearly different from Blacks and Native Americans.

From 1878 to 1909, the courts in the U.S. heard twelve naturalization cases of persons seeking citizenship. Eleven of those cases were barred from citizenship including persons from China, Japan, Hawaii, as well as two mixed race applicants. The cases were argued based on reasoning of common knowledge, skin color, and the subdivision of the human race into five groups; Mongolian, Negro, Caucasian, Indian, and Malay (Haney-Lopez, 2006). White skin itself was not enough to not guarantee one’s property rights in whiteness (Harris, 1993). The courts later ruled that not even all Caucasians were white, cementing the cultural construction of whiteness (Foley, 2002).

Many ethnic groups have sought out equalization through citizenship, but when African American citizens still had to sit at the back of the bus and couldn’t vote, assimilation became the goal. And when the 1940 census stopped distinguishing foreign-born versus native-born whites, official assimilation as white became a possibility. As “not-yet-white” ethnic immigrants strive to assimilate as a way to attain whiteness, “immigrants of color always attempt to distance themselves from dark identities (blackness) when they enter the United States” (Bonilla-Silva, 2003, p. 271). For many immigrant groups the path to whiteness became not so much about losing one’s culture as becoming agreeing to the idea that Blacks were culturally and biologically inferior to whites, “Only when the lesson of racial estrangement is learned, is assimilation complete” (Morrison, 1997, p. 57). While there are certainly still markers for some (e.g. accents, dress, and cultural practices) that lead to prejudices, the fiction of whiteness brings real opportunities and access to particular people.

## White Privilege

White privilege is a result of the institutional and structural investments given to whites. Lipsitz (1995) coined the term possessive investment in whiteness over a decade ago. In this paper, he discusses federal policies in the United States that authorized attacks on Native Americans, restricting naturalized citizenship to “White” immigrants, slavery, and segregation. Many have discussed the legal challenges that weakened the Supreme Court’s decision in Brown vs. the Board of Education (Bell, 1979), but these past policies are still with us today through more covert yet racist systems. Many policies seem neutral, yet their effect is anything but that.

One example is the Federal Housing Administration’s (FHA) loan practices. From a confidential city survey to destroying housing in city centers affecting twice the percentage of African-Americans compared to whites in the 50s and 60s, these housing practices have shifting loan money and therefore future investment in real estate away from communities of color and towards whites since 1934. These practices served to drive up prices in white suburban communities, keeping people of color from benefiting. The development of highway systems as well as public policy cutting political precincts in half, served to reduce the political power of African Americans allowing garbage dumps and incinerators to be located in communities of color (Logan & Molotch, 1987). More recently, studies have shown that African Americans are 60% more likely than whites to be turned down for loans (controlling for credit scores), will be judged on dividend income more often, disqualified for loans at almost 3 times as much, and will receive conventional financing at ¼ the rate (Massey, 1994; Orfield & Ashkinaze, 1991). In fact, in some cases, high income Blacks were turned down at a higher rate than low income whites (Campen, 1991). Although these practices are not termed “Affirmative Action” they benefit whites at the detriment to Blacks.

In addition, tax policies of the 80s made taxation on goods and services higher than it was for profits from investments. Again, by connecting this to the above investment in whites owning their own homes and profiting from raised home values, whites will necessarily benefit from lowered taxes on investments. Similarly, Proposition 13 in California granted tax relief to property owners and reduced funds by $13 billion a year for public education and other social services (McClatchy, 1991). Businesses avoided between $3.3 billion and $8.6 billion in taxes per year (UC Focus, 1993).

Educationally, these same advantages have been invested in whites. Funding in schools is one way that whites maintain privileges. While the history of Brown versus the Board of Education is well know, the fact that we are now at similar levels of segregation in schools to the 1960s mean the problems of yesterday are still here (Orfield et al., 2004). Policies of school funding tied mostly to local property taxes have maintained differential funding for suburban schools at levels twice that for urban schools (Kozol, 1991). This well documented difference impacts teacher quality, curricula, building conditions as well as numerous other educational issues. Deficit ideologies of teachers are also well documented and affect students of color because they are framed as the other, similar to the prior discussion of those not included in whiteness (Perry, 1993). Additionally, outdated representations in history textbooks of Native Americans as a romanticized and almost dead people and slavery and civil rights issues for African Americans as a thing of the past, reproduce the appearance of neutral policies (Kivel, 2002). During the history of the U.S., the population of Native Americans went from 12 million to 237,000 and whites expropriated 97.5% of their land (Churchill, 1994). Yet, we don’t call this genocide in textbooks nor do we have representations of current day Native Americans in schools. The magnitude of those numbers should give one pause. These educational issues privilege the schooling of whites by providing more funding, not having to face advantages we live with today connected to a history fraught with killing and taking another people’s lands, and avoiding cultural deficit ideologies by maintaining the white norm.

Despite these investments in whites – generated through slavery and segregation and augmented by social reforms – a poll notes that 70% of whites believe that African Americans “have the same opportunities to live a middle-class life” (Orfield & Ashkinaze, 1991). There are numerous other policies such as social security, the GI bill, the college draft deferment, and legacy admissions at universities (Conley, 1999; Kivel, 2002). These forms of Affirmative Action for whites serve to guarantee that whites will continue to benefit from historic advantages. Meanwhile the attack on Affirmation Action counters policy trying to balance the playing field from such “neutral policies.”

## Exploitation of People of Color

Centuries of bestowing land, education, and stored wealth in the form of social security to whites means that whites born today begin their lives with more familial wealth stored in houses, educational attainment, and investments. Policies that place wealth in the hands of certain groups and take it away from other groups are a form of exploitation. The profits are essentially the benefits of racism to whites. Perlo (1996, p. 170) calculates the profits from racism as the "wage differentials against African Americans, Hispanics, etc., multiplied by the number of workers employed in private enterprises." He contends that although the median differential in 1991 against black workers overall was 32%, the difference for skilled craft workers was 25%. However, within each skill level, black workers tend to be consigned to the worst jobs – risking their health. This, along with the practice of categorizing the same occupations whites work at lower level for people of color, convince him to use the median differential for the calculation reasoning that there is a cost for subjecting Blacks to health risks and the devaluation of jobs for people of color.

Given this framing, Perlo (1996) calculates that the total profits of racism in 1947 were 56 billion dollars (in 1995 dollars). That number rose to 88 billion in 1972, 112 billion in 1980, and 197 billion in 1992. African Americans were exploited for 48, 60, 74, and 107 billion dollars in those years, while Latinos were exploited for 8, 28, 34, and 84 billion dollars. These numbers do not include the exploitation of white women or whites in poverty, even though they are certainly exploited by the white elite. Even so, these numbers speak to a widening divide between an investment in whites and people of color. They are a symbol of centuries of supposedly "neutral" policies, investing through education, home ownership, and maintenance of wealth in advantaging whites on the backs of African Americans and Latinos.

## Mathematics Education's Investment in Whiteness

We can calculate a similar statistic for mathematics education's investment in whites. Through the availability of AP classes in suburban schools, tracking students of color into lower mathematics coursework, and counselor's referring students to less advanced coursework different access and opportunities are available to students of color (Oakes, 2003). In addition, deficit ideologies of teachers create negative and sometimes hostile environments for students, when some teachers don't believe that students of color have the intellectual ability to think abstractly (Perry, 1993). This could produce what Smith and others have found to be racial microaggressions that lead to racial battle fatigue leading to psychological, emotional, and physiological consequences in the classroom (Smith et al., 2007). These processes serve to reduce mathematics coursework, college opportunities and earning potential for people of color.

In this paper, I calculate the exploitation of people of color, using a similar formula to Perlo, due to different mathematics coursework. This serves as a representation of the investment in whiteness that mathematics education continues to reproduce.

## Methods

The data used in this study were taken from national databases: High School and Beyond 1980 (and follow-ups), National Education Longitudinal Study (NELS) 1988 (and follow-ups), Education Longitudinal Study 2002 (and follow-ups), Current Population Survey (CPS) 1972–2005. This paper presents a secondary analysis of these data with respect to mathematics course completion. All dollar amounts are adjusted to 2008 dollars.

Though race is a constantly changing phenomenon, the data used in this study positions them as fixed groups (due to its use in the national datasets). Also, these national datasets mix ethnicity with race, but the data are presented using the terms from the survey, however problematic they may be.

The equation for the average yearly income for each ethnic/racial group is as follows:

% completed calculus x average earnings by mathematics coursework
% completed trigonometry/algebra III x average earnings by mathematics coursework
% completed algebra II x average earnings by mathematics coursework
% completed algebra I/geometry x average earnings by mathematics coursework
% completed low academic/no math x average earnings by mathematics coursework
+ % dropouts x average earnings for dropouts

Similarly taking this and multiplying it by the number of students each year gives the total investment by each ethnic/racial group.

## Results

The results begin with data across 1982, 1992, and 2004 on the highest level of mathematics completed by racial/ethnic group. In addition, I included dropouts since the dataset only included the highest level of mathematics completed for high school graduates. The analysis then shifts to the income levels ten years after graduation by mathematics achieved and by race/ethnicity. These data are then used to calculate the investment in whites over students of color, ten years after graduation, over a lifetime, and across generations. I want to caution readers in that these numbers should be seen as approximations since, as with all national datasets, survey questions can change over time, under or over estimate results, and have missing data. Still the results speak to major differences.

Table 1 shows the highest level of mathematics completed for high school graduates in 1982, 1992, and 2004 by ethnic/racial group. The right column also presents the status dropout rate. The dropout rates are a major underestimate, but use the only data available across all three years (for an understanding of the problems with dropout rates in national datasets see Orfield et al., 2004).

Hispanics, American Indians, and Blacks took advanced mathematics at lower rates across years and were more likely to take no mathematics than Asians and whites. While this data could be used to reaffirm students of color lack of interest in mathematics, cultural deficit theories, or a discussion of racial "gaps", I urge readers to remember the literature on whiteness and privilege cited earlier in understanding that these are institutional differences generated over the history of this country to advantage whites and that a number of other factors need to be considered as well. First, in urban schools researchers have documented the lack of AP mathematics and science courses available. Even if students of color wanted to take this coursework, it is not available to many, often because they do not have teachers certified to teach AP mathematics. Also, tracking has routed students of color to lower levels of mathematics for decades (Oakes, 2003). One more factor among many is that counselors steer students of color away from college preparatory courses. These three factors, though there are many more, speak to differences due to institutional racism, access to higher quality mathematics instruction to whites, rather than cultural myths of students of color.

Table 1. *Highest Mathematics Completed by Year, Ethnicity/Race, and Average Yearly Earnings 10 Years after High School Graduation*

| | Graduates | | | | | |
|---|---|---|---|---|---|---|
| | Advanced | Middle | | | Low Academic /No Math | Dropouts |
| Year and Ethnicity/Race | Calculus | Trig/algebra III | Alg 2 | Alg 1/Geo | | |
| 1982 | | | | | | |
| White | 6.8% | 22.9 | 18.9 | 30.9 | 20.5 | 8.8 |
| Asian/Pacific Islander | 15.4 | 37.6 | 19.1 | 17.2 | 10.6 | 2.2 |
| Black | 2 | 11.2 | 18.5 | 27.7 | 40.6 | 11.3 |
| Hispanic | 2.6 | 11.3 | 13.8 | 33.1 | 39.1 | 16.8 |
| American Indian/ Native Alaskan (AI/NA) | 2.3 | 8.6 | 13.4 | 27.8 | 48 | 25.1 |
| 1992 | | | | | | |
| White | 11.5 | 28.9 | 26.9 | 20.8 | 11.9 | 4.3 |
| Asian/Pacific Islander | 22.1 | 32.4 | 23.9 | 12.5 | 9.2 | 4.6 |
| Black | 6.9 | 18.7 | 23.5 | 32 | 18.9 | 7.6 |
| Hispanic | 5.0 | 23.9 | 26.3 | 30.9 | 14.2 | 10.9 |
| AI/NA | 1.0 | 13.7 | 28 | 28.5 | 28.9 | 18.2 |
| 2004 | | | | | | |
| White | 16.2 | 39.1 | 23.8 | 16.4 | 4.6 | 4.7 |
| Asian/Pacific Islander | 33.8 | 35.5 | 17.5 | 11.1 | 2.1 | 4.6 |
| Black | 4.9 | 36.3 | 31.5 | 18.7 | 6.6 | 10.5 |
| Hispanic | 7.0 | 28.1 | 31.9 | 26.5 | 6.4 | 13.4 |
| AI/NA | 5.4 | 16.8 | 40.8 | 23.7 | 13.3 | 15.2 |
| Avg. Earnings by Math Coursework (2008 dollars) | 42,625 | 39,581 | 35,014 | 30,447 | 28,163 | 23928 |

Using the mathematics coursework data and the average earnings 10 years after graduation (2008 dollars), I calculated the average earnings by ethnicity/race. Multiplying the percent of whites who completed calculus in 1982 (6.8%) by the average income of that group of students ten years later ($46,625) along with the percent who completed Trigonometry/Advanced Algebra (22.9%) by their income ($39,581) and so forth results in the average wage earned for whites across mathematics course work completed and dropouts. In doing this across years for each ethnic/racial group the calculations result in the average earnings ten years after graduation (or not). The numbers for these calculations can be seen in the first column of table 2. This gives a sense for the earning potential for different groups according to mathematics coursework.

In Table 2, I present the total investment for each ethnic/racial group based on the number of students in each high school class multiplied by their average earnings. To compare the investment with that of whites, I used the same number of students (as each ethnic/racial group) multiplied by the average earnings for whites. The last column compares total and adjusted investments, represents the financial advantages given to whites through mathematics preparation (rounded to the nearest million). This does not include statistics for people of color earning lower wages with the same education working in the same job, SES, or other factors that would make these differentials greater. Therefore, these calculations should be considered an underestimate.

Table 2. *Annual Earnings due to Mathematics Coursework and Total Investment, by Year and Ethnicity/Race*

| Year and Ethnicity/Race | Average Earnings from Mathematics Coursework (2008 dollars) | Percent of High School Population | Total Investment Based on Mathematics Coursework (millions) | Adjusted Investment for whites with same Percent Population (millions) | Net Investment in whites (millions) |
|---|---|---|---|---|---|
| 1982 | | | | | |
| White | 33,129 | 79.9% | 119,507 | -- | -- |
| Asian/Pacific Islander | 36,187 | 1.3 | 2,124 | 1,944 | -179 |
| Black | 29,830 | 11.6 | 15,623 | 17,350 | 1,728 |
| Hispanic | 28,753 | 6.3 | 8,179 | 9,423 | 1,244 |
| AI/NA | 29,458 | 1.0 | 1,330 | 1,496 | 166 |
| 1992 | | | | | |
| White | 34,887 | 72.7% | 91,804 | -- | -- |
| Asian/Pacific Islander | 36,533 | 4.5 | 5,951 | 5,683 | -268 |
| Black | 32,021 | 11.9 | 13,793 | 15,027 | 1,234 |
| Hispanic | 30,862 | 10.0 | 11,171 | 12,628 | 1,457 |
| AI/NA | 31,107 | 1.2 | 1,351 | 1,515 | 164 |
| 2004 | | | | | |
| White | 36,405 | 62.3% | 91,907 | -- | -- |
| Asian/Pacific Islander | 38,289 | 4.5% | 6,982 | 6,639 | -344 |
| Black | 33,481 | 13.3% | 18,044 | 19,621 | 1,576 |
| Hispanic | 32,215 | 15.0% | 19,581 | 22,128 | 2,547 |
| AI/NA | 32,771 | 0.9% | 1,195 | 1,328 | 133 |

There is a surplus in favor of Asians (see table 2). However, whites having more access and opportunity to take mathematics courses than African Americans results in yearly advantages of 1.23-1.73 billion dollars. For Hispanics the range is from 1.24-2.55 billion dollars, in part due to an increase in population. And finally, for Alaskan Indian/Native American the range is from 133-166 million dollars. This accumulation of wealth in favor of whites over Native Americans is for less than 50,000 high school students. These numbers are for only one year of work, ten years after high school, and do not include the years in between the dates included.

Over the course of the 23-year span included in this study, using the average yearly advantage (see column 1 in table 3), whites are advantaged over Blacks (38.4 billion dollars), Hispanics (41.1 billion dollars), and Native Americans (3.84 billion dollars). For a typical 40-year work-life the totals range from 6.67 to 71.4 billion dollars. This means for the life of one high school class, the effects of differential mathematics access results in over 144 billion dollars invested in white students. Notice as well that Asians still show advantages over whites totaling 5.69 (23-year span) and 9.90 (40-year work-life) billion dollars. Importantly, these numbers do not consider that differentials at one point are more likely to grow due to raises, accumulated income, and interest.

Table 3. *Average Investment in Whites over 23-year Span and 40-year Work-life*

| Investment in whites over | Average (over 1982, 1992, & 2004 in millions) | Cumulative over 23 years (1982-2004) | Work-life (40 years) | Work-life * 23 years |
|---|---|---|---|---|
| Asian/Pacific Islander | -247 | -5,693 | -9,901 | -227,724 |
| Black | 1,670 | 38,414 | 66,808 | 1,536,588 |
| Hispanic | 1,785 | 41,077 | 71,438 | 1,643,093 |
| AI/NA | 166 | 3,837 | 6,674 | 153,507 |
| Total | 844 | 83,329 | 144,921 | 3,333,188 |

The last column in table 3 reports the aggregate investment for the 23 years of high school students across an estimated 40-year work-life. The total advantage for whites is over 3 trillion dollars. This number more or less represents the investment in a generation of mathematics students over their careers. However, it does not include wage differentials afforded whites that would likely advantage whites even over Asians.

## Discussion

These differences should be appalling. This makes the work we do as mathematics educators so crucial in challenging so called neutral policies, in bringing more AP courses to urban and poor communities, and merely helping teachers care for, expect more from, and push students of color to take more mathematics.

Approaching this issue generationally, we can see how income, home investments, educational attainment, and mathematics knowledge serve as huge advantages passed on to whites. This historical perspective allows a framing of achievement of Latinos and African-Americans despite numerous obstacles. This different framing moves us out of thinking about deficits and failures to achievement, successes, and the struggle to be educated.

While many are looking at mathematics education from an economic perspective as far as competitiveness in the global market, we haven’t invested enough in African Americans, Latinos, and Native Americans. There are plenty of children to be educated that we are not reaching. While an economic outlook is one slant on this issue, the differential in investment poses a moral problem more than any other. Why do we as a society allow differential funding to schools? Why do we allow students to be put in lower tracks robbing them of access to higher-level mathematics? How can we begin to address such glaring inequities? The answer may be that these policies privilege whites and many are not ready to give up these advantages.

Another perspective might ask, is all of this mathematics, and everything it gives access to, necessary for college admission and citizenship more generally. Although the incomes are different, this could be due more to college admission than using mathematics in careers, which implicates a false gatekeeper. Bob Moses termed access to mathematics as the next civil rights issue and according to this analysis, he is certainly right. But maybe the mathematics required for higher education is merely keeping some from further educational opportunities. The policies of Harvard and Stanford in not counting high school work in calculus, though for a very different reason than educational access, might signify a first step towards slowly lowering the gate for students of color.

## Conclusion

These results indicate that we invest considerably more in whites than Blacks, Hispanics, and American Indians showing the systematic racism that educational institutions reproduce. The numbers indicate one way that historic and current mathematics education practices serve as an investment advantaging whites. In another sense, it raises the need of informing parents of color of the importance to seek out access to mathematics for children. As currently constructed, it serves as a gatekeeper to universities, mathematical careers as well as economic capital and independence.

# COUNTER NARRATIVES OF AFRICAN AMERICAN EXPERIENCES IN MATHEMATICS: THE CASE OF ANDREA

Shonda Lemons-Smith
Georgia State University
slemonssmith@gsu.edu

> How do I commit myself to do work that is predicated on a belief in the power of the mind, when African-American intellectual inferiority is so much a part of the taken-for-granted notions of the larger society that individuals who purport to be acting on my behalf, routinely register doubts about my intellectual competence (Perry, 2003, p. 5)?

## Introduction/Purpose of the Study

Perry's quote is a stark articulation of the dilemma that continues to surround African American children and adolescents in the United States. Lemons-Smith (2008) similarly poses, what *really* prohibits schools and teachers from providing cognitively demanding, high-quality instruction for all students, regardless of race, class, gender, language, culture, or other characteristics? It is a question that lies at the heart of educational underachievement broadly, and specifically within the discipline of mathematics education. Over the last decade or so much has been written regarding the mathematics education experiences of African American students (Berry, 2005; Hilliard, 1995; Ladson-Billings, 1997; Martin, 2000; Moody, 2004; Stinson, 2006; Tate, 1995; Walker, 2006; Walker & McCoy, 1997). These scholars have attempted to give voice to Black students and those who teach them – two groups who are often silenced or superficially addressed within the context of mathematics education research. These scholars' work does not subscribe to entrenched deficit theories nor provide artificial prescriptions or strategies for "fixing" the mathematics performance of African American learners. Rather, they provide a culturally embedded perspective of African American students and their engagement in the mathematics teaching and learning process.

This paper describes a case study that looked critically at the connection between African American students' K-12 mathematics experiences and how they view the discipline of mathematics and themselves as learners of mathematics. Specifically, this paper focuses on one African American student who participated in the study. I will begin by discussing the theoretical framework and study context. Then, I will present excerpts of the student's narratives to illustrate how she perceived her mathematics experiences, views about mathematics, and views about herself as a learner of mathematics. The student's narrative reflects her voice, and therefore is in first person. Brief school and teacher background information precede the narrative.

## Theoretical Framework

This study sought to provide a voice to African American students and their perspectives and experiences in mathematics. Given the historical silencing and negative representation of African Americans in education and society generally, Critical Race Theory was selected as the lens through which to view and affirm their life stories. Critical Race Theory has at least five defining themes: (a) the centrality and intersection of race and racism, (b) the challenge to dominant ideology, (c) the commitment to social justice, (d) the centrality of experiential knowledge, and (e) the interdisciplinary perspective (Solorzano & Yosso, 2001).

Within education Critical Race Theory challenges the dominant ideology of race and racism and its interplay within school structures, processes, and discourses (Solorzano & Yasso, 2001). Critical Race Theory provided the context for considering how the African American students in this study negotiated their K-12 mathematics experiences.

## Methods

How are K-12 mathematics experiences connected to one's mathematics-related views? Specifically, views about the discipline itself and oneself as a learner of mathematics. The study consisted of ten African American undergraduates, one of which is the focus of this paper (Andrea). Participants represent a convenience sample and were solicited from various minority organizations on a university campus. Participants' attitudes toward mathematics, performance, and grades in mathematics were not a criterion for selection.

Data sources consisted of semi-structured interviews, which were audio taped and lasted about three hours, and handwritten autobiographies. The interviews and autobiographies solicited information about (a) the participants' academic and personal histories, (b) experiences in the mathematics classroom as it relates to curriculum, instruction, and classroom culture, and (c) views about mathematics, school, and oneself as a learner of mathematics. Interpretational analysis (Gall, Borg, & Gall, 1996) was used to analyze the transcribed interviews and autobiographies. The data analysis involved open coding in which common and divergent participant responses were identified. From these responses themes that encompassed and summarized the data were established. These themes were central in describing the connection between African American students' mathematics experiences and mathematics-related views.

## The Case of Andrea

Andrea is nineteen year-old biochemistry major. She received her K-12 schooling in public, majority White schools. The demographic composition of Andrea's math teachers was: High school (all White males); middle school (Two White males, a White female); and elementary school (all White females).

*Andrea: In Her Own Words*

> For the most part I like math. I like it because I'm good at it. It's not just that I get good grades, but also because I understand it. I can explain it to other people and make them understand it too. You don't really realize how much you understand something until you try to teach it to someone. Then you realize you really know this stuff. I didn't really focus on math until the sixth grade when I tested into the Extended Learning Program (gifted). Since the sixth grade I've been the only African American in my math classes. At first being the only African American didn't bother me because I was young, but as I got older I started realizing that the students didn't think I was as smart as them. Nor did the teachers expect as much of me. I could tell that by how they interacted with me. My teachers seemed to make me work harder than my white classmates. Even though I was a good math student, my teachers didn't really call on me much. In many instances if I was called upon and gave the right answer, my teachers' reaction was exaggerated, as if they didn't expect me to respond correctly. I found this particularly odd given the level of math courses I was enrolled in. They acted as if I was in remedial math. My peers would seem surprised if I scored an A on an assignment. I guess because I was black they thought I was dumb or something. I enjoyed participating in the minority math and science summer program. It was cool being around other smart minorities like me. No

> one questioned your ability. Everyone was on equal footing. I felt as though most of my math teachers held lowered expectations for me. If I asked them a question they would go back to the very basics and explain it to me as if I were stupid. It was as if I didn't know that a negative times a negative is a positive. If a white student asked a question they would explain it to them assuming they understood the basics. They didn't insult them by reviewing pre-algebra concepts. My teachers lowered expectations made me want to try harder. Since they don't think I'm as smart as the next white person, I'm just going to show them. I vividly recall my ninth-grade teacher making race-related comments and jokes that were inappropriate and made me feel uncomfortable. I don't feel that I received the same quality and quantity of instruction as my white classmates. When I asked for help they'd half explain it or wouldn't explain it and pointed me to the book. Whereas, when white students asked for help they'd explain it with no questions asked. It's like they expected me to work harder even though they didn't expect much of me. If a white student made a C or D on a math assignment the teacher would tell them they needed to get their grade up. If I made the same grade they wouldn't say anything. It's as if they thought a C or D was the best I was capable of doing. Their expectations of me were set from day one. Sometimes when I got a problem right my math teacher's reaction would be exaggerated. It was so transparent. No one was really hostile toward me or outright rude, but I was just there. They didn't ignore me, but they didn't acknowledge me. They would listen to what I had to say, but it wasn't valued as much. The expression on their faces was different when they were listening to white students. It's like they were listening differently, more attentively.

## Results/Discussion

In considering how Andrea's mathematics experiences are connected to her mathematics-related views, the following three themes emerged: (a) teacher characteristics, (b) self-positioning, and (c) resiliency. In this section I will discuss each of these themes.

### *Teacher Characteristics*

Analysis of Andrea's interview and autobiography revealed generally negative perspectives about her mathematics teachers and instruction. Andrea's depiction of her mathematics teachers is interesting when considered within the context of Gloria Ladson-Billings' work on culturally relevant teaching. Ladson-Billings (1995) asserts that culturally relevant teachers exhibit the following broad qualities with respect to the underlying propositions: (a) Conceptions of self and others suggests that culturally relevant teachers hold high expectations for all students and believe all students are capable of achieving academic excellence; (b) social relations infers that culturally relevant teachers establish and maintain positive teacher-student relationships and classroom learning community as well as are passionate about teaching and view it as a service to the community; and (c) conceptions of knowledge suggests that culturally relevant teachers view knowledge as fluid and facilitate students' ability to construct their own understanding. Ladson-Billings' work illuminates an instructional ideology for facilitating the academic success and cultural competence of African American students. Hence, it is salient for contextualizing Andrea's mathematics teachers. As it relates to culturally relevant instruction her teachers receive a grade of "F." Their conceptions of knowledge, conceptions of self and others, and social relations do not demonstrate a commitment to providing equitable mathematics instruction to *all* students. It is interesting to note that during Andrea's K-12 mathematics career all of her mathematics teachers were White. Certainly race is not a determinant in whether or not one demonstrates the qualities of a culturally relevant teacher; however the observation is striking. Embarking on this line of thought raises questions about the broader impact of teacher and school demographics. To what extent are those demographics linked to the existence or absence of culturally relevant teaching? What other dynamics account for Andrea's experiences in mathematics?

In addressing these and other questions related to Andrea's experiences, one must also consider the very personal nature of perceptions. The personal nature of perceptions is evidenced in the two other themes revealed in the data: self-positioning and resiliency.

*Self-Positioning*

Despite the absence of mathematics teachers that can be defined as culturally relevant, Andrea expressed generally positive views about the discipline of mathematics and herself as a learner of mathematics. While this is true for Andrea, it is often not the case for students of color. Her interviews and narrative suggests that the way in which she positions herself within a macro and micro context is a contributing factor in how she views mathematics and herself. In several instances she noted that school was only a small piece of her life, who she was, and relegated it to micro status. In contrast, she drew heavily upon home, family, and external forces in shaping her belief system. Perhaps if school had been assigned a more prominent position in Andrea's being, the lack of culturally relevant teachers may have yielded a more significant impact. That self-positioning is also implicitly linked to the third theme – resiliency.

*Resiliency*

Despite encountering less than empowering teachers Andrea successfully negotiated schooling structures and excelled in the mathematics classroom. She preserved and developed a strong mathematics background. She explicitly contributed her ability to do so to strong family and extended family support. This support appears to be a key factor in her resiliency and ability to challenge the persistent myths and stereotypes surrounding African Americans in mathematics. Rejecting widely held notions of deficiency enabled Andrea to embrace positive views about mathematics and herself as a learner of mathematics.

Andrea did not reflect the more popular theories related to African American achievement. For example, she did not view her academic personas and success as "acting white" (Fordham & Ogbu, 1986). In addition, her perspectives did not reflect stereotype threat (Steele, 2003). That is, she did not rebuff characteristics not typically associated with African Americans. Andrea held a positive self-concept and did not view her success in mathematics as incongruent with her racial identity. Hence, that positive self-concept facilitated her resiliency and ability to combat messages of inadequacy.

## Concluding Thoughts

In considering how one's K-12 mathematics experiences are connected to their views about mathematics and themselves as learners of mathematics, teacher characteristics, self-positioning, and resiliency emerged as salient themes. I opened this paper with the quote: "How do I commit myself to do work that is predicated on a belief in the power of the mind, when African-American intellectual inferiority is so much a part of the taken-for-granted notions of the larger society that individuals who purport to be acting on my behalf, routinely register doubts about my intellectual competence (Perry, 2003, p. 5)?" I would argue that Andrea was successful in rejecting persistent notions of inferiority and excelling in mathematics. Her positive self-concept, affirmative internal dialogue, and strong support system provided the foundation for resisting institutional barriers and perceptions set forth. I would argue that Andrea is the rule, not the exception and success in mathematics is a norm associated with African Americans. Hence, additional research that provides counter narratives to disaffirming messages about African Americans in mathematics is warranted. Collectively, researchers, schools, teachers, and students can articulate a counter discourse that acknowledges the pursuit of excellence in mathematics is an endeavor that can be accomplished by ALL.

# AN ACTIVITY SYSTEM ANALYSIS OF MATHEMATICS TEACHING PRACTICE IN AN URBAN HIGH SCHOOL

Lawrence M. Clark
University of Maryland – College Park
lmclark@umd.edu

Julius Davis
University of Maryland – College Park
jdavis24@umd.edu

*Through use of an activity theory (AT) analytic and explanatory frame, we examine and articulate the ways in which one teacher, April Lincoln, a mathematics teacher in a large urban school, consistently facilitates reading strategies in her Algebra I classroom. After mapping April's practice onto the AT framework, we will focus our discussion on the relationship between three key components of the activity system – subject, mediating tools, and object – with particular attention to April's personal history as a struggling reader and how this experience appears to influence her pedagogical choices.*

## Introduction

There is a movement underway in the mathematics education research community that seeks to better understand students' mathematics schooling experiences by examining these experiences through sociocultural and historical perspectives (Atweh, Forgasz, & Nebres, 2001; Boaler, 2000; Martin, 2000, 2007; Nasir & Cobb, 2007; Secada, Fennema, & Adajian, 1995; Yackel & Cobb, 1996). A guiding tenet of this movement is the acknowledgement that the learning and teaching of mathematics is not 'culture-free'; a complex mix of historical, political, and cultural forces determine that students at specific intersections of societal communities (racial, ethnic, economic, linguistic, geographical) *experience* mathematics differently than students positioned at other intersections, and these differential experiences contribute to differences in performance on measures of mathematics achievement and competence. A thread of this work focuses on examining teachers' mathematics instructional practices from sociocultural perspectives and seeks to conceptualize and study mathematics learning environments that are equitable and responsive to the needs and experiences of all learners. Of particular interest to many are the ways mathematics teachers in urban schools engineer effective mathematics learning environments in school contexts that are often characterized as challenging and difficult due to history of low academic achievement as measured by students' performance on standardized assessments. Through use of an activity theory (AT) analytic and explanatory frame, we examine and articulate the ways in which one teacher, April Lincoln, a mathematics teacher in a large urban school, consistently facilitates reading strategies in her Algebra I classroom. After mapping April's practice onto the AT framework, we will focus our discussion on the relationship between three key components of the AT map – subject, mediating tools, and object – with particular attention to April's personal history as a struggling reader and how this experience appears to influence her pedagogical choices.

## Theoretical Framework

### *Activity Theory*

Activity theory is an analytic and explanatory framework that is useful for research of human behavior (Engerstrom, 1987). This framework first emerged from the scholarship of Vygotsky, Leont' ev, and Luria in Russia in the cultural-historical school of psychology (Minick, 1997). Nardi (1996) contends that research using AT can shed light on the complex experiential unity of

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

individual cognition and social activity; furthermore, AT is perceived as a useful framework to view and understand the complexities of mathematics classrooms in varying contexts (Radford, Bardino, & Sebena, 2007; Walshaw & Anthony, 2008, Anthony & Clark, 2008). The particular and unique characteristics of U.S. urban schools, namely high enrollments of minoritized students, historical trends of low performance as measured by standardized assessments (and, consequently, a palpable assessment culture), high teacher attrition, and the consistent cycle of instructional and curricular 'reforms', demand that teacher practice be examined in ways that more fully acknowledge the complexities of teaching in these contexts. In that the AT framework is designed to explain activity through a broad range of intertwined influences, we found it particularly useful in our efforts to examine mathematics teachers practice in urban schools.

An activity system is the unit of analysis in activity theory. The minimum elements of an activity system, according to Engestrom (1987), is an object, subject, mediating tools (including psychological tools), rules, community and division of labor (Figure 1). The "subject" is the individual or group of individuals involved in the activity, the "object" is the motivating problem or reasons behind why the subject participates in the activity, and it is what connects individual action to collective activity. The "tool" includes people and artifacts that act as psychological tools, mediating activity between the subject and the object. The rules, community, and division of labor components add the historical aspects of mediation that Vygotsky omitted from his work (Engestrom, 1999). Subjects are members of social groups or "communities" that have explicit and implicit "rules" or norms that provide guidance to acceptable interactions among system participants. Rules and mediating artifacts that are accepted by the community mediate relations between the subject and the communities they are a part of. "Division of labor" refers to the tasks and responsibilities that are constantly negotiated among participants of the activity system (Cole & Engestrom, 1993). By considering the influences of rules, community, and division of labor on an activity, Engestrom's model includes both historical and situated aspects of human activity. The model also represents the motive behind situation-bound actions that individuals within the activity system are a part of (Engestrom, 1987). The "outcome" of the system refers to the outcomes or results of the activity.

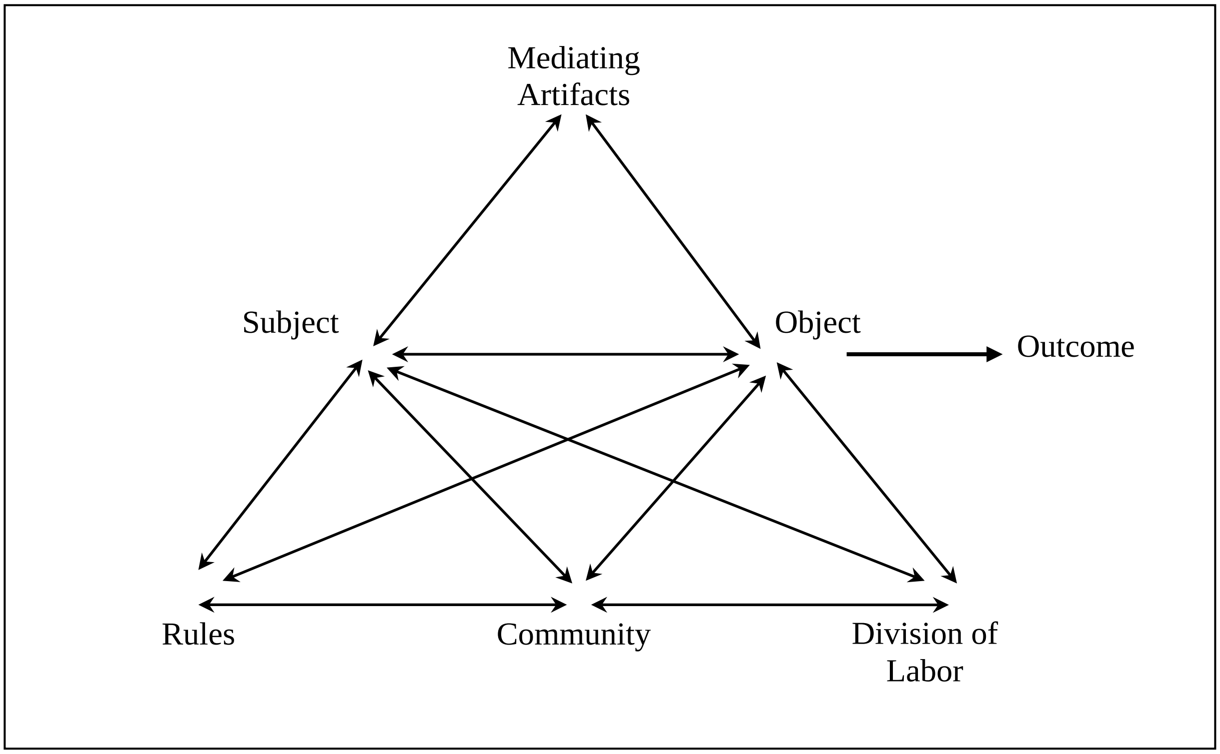

*Figure 1.* Representation of an activity system. Engestrom, Y. (1987).

*Teachers' Personal History as Mediating Tool*

A powerful aspect of examining mathematics teacher's practice through the AT framework is its capacity to broaden traditional notions of the resources and tools mathematics teachers draw on and use to do their work. When mathematics instructional practice is viewed through sociocultural and sociohistorical lenses, 'non-mathematical' resources and tools, namely knowledge of students' lived experiences and community histories, as well as teachers' personal experiences and community memberships, must be examined side-by-side with more traditional physical and intellectual resources (i.e., teachers' mathematical knowledge, teachers' general pedagogical knowledge, teachers' content-specific pedagogical knowledge, curriculum materials). Wenger (1998) states that teachers are far more than "representatives of the institution and upholders of curricular demands" (p. 276); they are doorways into the adult world. Wenger (1998) contends, "Teachers… constitute learning resources, not only through their pedagogical or institutional roles, but also (and perhaps primarily) through their own membership in relevant communities of practice… This type of lived authenticity brings into the subject matter the concerns, sense of purpose, identification, and emotion"(p. 276). In keeping with this perspective, teachers' lived experiences and community memberships (such as gender, as members of various ethnic and racial groups in racialized societies, as once young students of mathematics, as local community members) serve as mediating tools that they employ in their efforts to teach mathematics. Through implicit and explicit means, and through their personal story, teachers communicate to their students what it means to construct a healthy mathematical identity (Martin, 2000, Clark, Johnson, & Chazan, 2009). Minoritized students in the U.S., particularly African American and Latino students, are engaged in a unique, continuous process of negotiating multiple traditions, cultural frames, and identities, some of which arguably have been perceived and/or constructed as incompatible, in an effort to function in U.S. society (Boykin, 1986; Du Bois, 1903). It is reasonable to believe, therefore, that teachers, particularly mathematics teachers of marginalized, minoritized students, play an important role in assisting their students negotiate and reconcile (Wenger, 1998) real or perceived conflicts or dilemmas in their identity formation in general and their mathematics identity formation in particular.

## The Case Studies of Urban Algebra I Teachers Project

In 2004, the University of Maryland's Center for Mathematics Education with funding from the National Science Foundation embarked on the Case Studies of Urban Algebra I Teachers Project through the Mid-Atlantic Center for Mathematics Teaching and Learning. The main purpose of the project was to document the practices, instruction, and perspectives of 'well respected' teachers of algebra in two urban high schools that were mainly comprised of large populations of African American and Latino students. The focus of this paper, April Lincoln, a teacher at Erasmus High School, is one of six mathematics teachers participating in the project. All teachers in the study were African American except for one African American male. The range of teaching experience across teachers was vast – two years to over 20 years.

The research team structured observation and interview protocols around three main themes: 1) teacher's "sense of purpose" of teaching mathematics, 2) the teaching of algebraic concepts, and 3) the teaching of data analysis. Each teacher was observed roughly 30 times across the three themes (most of which were videotaped) and interviewed eight times over the course of a year.

*Erasmus High School*

At the time of data collection (2005), Erasmus High School enrolled approximately 2000 students in grades nine through twelve. Forty-five percent of Erasmus students were African American, 43% were Hispanic, 7% were White, and 5% were Asian. In 2005, 27% of Erasmus students scored at or above the 'percent proficient' cut score on the mathematics portion of the state mandated assessment. Thirty-five percent of students scored at or above the 'percent proficient' cut score in reading during the same year. Student mobility was considered 'high' at Erasmus during 2005, with 20% of students enrolling in school after the start of the school year and 17% leaving Erasmus before the end of the school year. In 2005, 31% of Erasmus classes were taught by teachers that did not have highly qualified teaching status. Attendance rates have been historically high at Erasmus and approximately 76% of 9$^{th}$ graders entering Erasmus in 2001 (4 years prior to projected graduation year) graduated. (It should be noted that by 2008, student performance in mathematics and reading increased dramatically to over 75% of students at or above 'percent proficient' in both areas.)

## Data Analysis Methods

Data analysis techniques utilized in the development of this case study included traditional case study methods that consisted of an iterative process that proceeded from more general to more specific observations (Creswell, 1998). The authors individually studied and coded interviews and observations and identified instances that map onto the AT framework. In some cases, relevant instances did map cleanly onto an element of the AT framework; in other cases the authors did not agree on the how a particular instance should be coded. In the latter case, the authors negotiated until an adequate agreement was reached.

We first present a short biography of April Lincoln, followed by discussion of elements of the activity system that structured April's efforts to facilitate reading strategies in her algebra classroom. We conclude with a discussion of our interpretation of how April's experiences as a struggling reader may influence her commitment and capacity to engage in this practice.

## April Lincoln

April Lincoln is an African American female in her late forties at the time of data collection. She described herself as being a very quiet and shy person, and, throughout her interviews, projected a sense of modesty and humility. Initially, it was one of her professors that suggested she should consider pursuing a career in teaching mathematics and April commented that she was 'shocked' by his recommendation. She did not follow his suggestion upon graduation from college and began working in private industry. During her career in private industry, one of April's children said to her one day "Mom, you act like a teacher". April stated that, "A light went off in my head" at that moment and, as a result, April started teaching kindergarten at the local YMCA. After teaching kindergarten for a few years, April began teaching middle school. After two years at the middle school, she began teaching mathematics at Erasmus High School. At the beginning of this study, April was entering her fifth year at Erasmus.

April described her performance as a school student as mixed – she excelled in mathematics but and struggled in courses that demanded considerable amounts of reading and writing. She repeatedly mentioned that mathematics was the only subject matter that she felt competent and powerful. Despite her challenges with reading and writing, April enrolled in graduate school to pursue a master's degree and, after experiencing continued difficulty in reading and writing, was diagnosed with a reading disability. April's reading difficulty lead to problems with her reading the consent form to participate in the research project which resulted in the interviewer reviewing the document for April. April also experienced difficulty reading and comprehending the prompts associated with this research project.

April projected a very empathetic character and appeared to have a deep sense of concern for her students. April viewed her students as an extension of her children and approached teaching them with her parental instinct and the same level of concern she has for children. She strongly believed that she must better prepare her students to read in order for them to pass the mathematics portion of the high school assessment because "it is all they do is read and write" (Interview, September 28, 2005).

## Activity Theory Activity System: Reading Strategies in the Mathematics Classroom

Research exploring the prevalence of reading strategies in secondary classrooms indicate that few mathematics teachers view incorporate reading strategies into their practice for a host of reasons (Davis & Gerber, 1994), however April was committed to incorporating reading strategies in her algebra class. Of the six teachers in the study, April's classes enrolled the highest percentage of students identified as having learning or behavioral difficulties, resulting in many students with Individualized Learning Plans (IEPs). In April's classes with large numbers of students with IEPs, an additional teacher from the Special Education department was assigned to support April in class. April stated, "I've taken two reading classes. And my whole task this year is to get them to do more reading in mathematics…the [high school graduation test] is nothing but reading and writing, so my whole thing this whole year, we gonna read, we going to write, we going to explain. And uhm… that's what I'm pushing them to do…" (Interview, November 16, 2005). We witnessed three types of reading strategies in April's classroom during the year of data collection: 1) explicitly attending to words that have multiple meanings inside and outside of mathematics classroom, 2) identifying root words of key mathematics vocabulary to find meaning, and 3) utilizing problem solving heuristics that explicitly contain a 'step' related to reading comprehension. Table 1 contains elements of the activity system related to April's facilitation of these strategies in her classroom.

Table 1. *Activity System Elements Related to April's Facilitation of Reading Strategies*

| Element | Elements in April's practice |
|---|---|
| Object | Facilitation of reading strategies in the mathematics classroom |
| Subject | April Lincoln, resource teacher, students |
| Mediating tools | High school graduation assessment, algebra curriculum guidelines, April's experiences as struggling reader, students' achievement history, April's reading courses, students' behavioral problems |
| Rules | Pacing schedule for algebra curriculum guides, students' IEPs |
| Community | Other Algebra teachers, school administrators, other teachers in school |
| Division of labor | April Lincoln, resource teacher, reading support classes |

## Discussion

Our analysis of the activity system around April's facilitation of reading strategies in her class suggest that a primary mediating tool was her concern that her students would perform poorly on the state assessment due to their reading struggles. Additional mediating tools surfaced in our analysis, including April's personal struggles as a reader. April was very candid and open with students about her reading struggles, and described to students supports and techniques she used in her daily life to function. It was evident that April felt it important for students to know of her struggles and her story, and how she has managed to be resilient, successful, and highly functional despite the challenges she faced. Her story complicates notions of the skills, knowledge, and resources effective teachers must possess. As representatives of academic excellence and upholders of curricular demands, it is not common in teacher education circles to consider that some teachers have overcome considerable learning challenges and use these experiences as instructional resources. Had April not been a struggling reader, would she have consistently incorporated reading strategies in her classroom? Our interpretation suggests that her experiences were a significant mediating tool between her and her facilitation of reading strategies in her algebra classroom. There was no evidence that other teachers in her school were engaging in similar strategies.

April's story, however, leaves many critical questions to explore, including:

- Is it important for students who may have a history of low performance on standardized measures of mathematics achievement to be exposed to resilient teachers who have overcome adversities?
- Can this exposure support struggling students' mathematics identity formation?

- Does April's story simply reify characterizations of mathematics teachers in urban schools as low quality and poorly prepared or does her experience actually position her as better qualified in these particular contexts than teachers that may not have had her experience?

# FRAMEWORKS FOR STUDYING MATHEMATICS COMMUNITIES THAT SUPPORT AND RETAIN WOMEN DOCTORAL CANDIDATES

Karen Keene
North Carolina State University
karen_keene@ncsu.edu

Amanda Lambertus
North Carolina State University
ajlamber@ncsu.edu

By examining statistical data only, it seems that women are making great strides in overcoming their under-representation in mathematics (Monroe et al., 2008). However, statistics do not tell the entire story. Qualitative studies (see Monroe et al., 2008; MIT Report, 1999) suggest that women still face barriers in academia. Therefore, the research study described in this poster will focus on qualitatively exploring graduate mathematics departments that have a history of producing women mathematicians. By examining the recruiting and educational practices within these communities and linking those practices to students' and faculty member's perceptions and experiences within their departments, the study hopes to reveal successful practices for producing women mathematicians.

In an attempt to examine the practices and environment of a mathematics department, the researcher has employed both the "Communities of Practice" (Wenger, McDermott, & Snyder, 1998) and "Stewards of the Discipline" (Golde, 2006) frameworks. A community of practice is a "group of people who share a concern, a set of problems, or a passion about a topic, and who deepen their knowledge and expertise in this area by interacting on an ongoing basis" (Wenger et al., 2002, p. 4) while the stewards of the discipline framework focuses on what it means to pursue Ph.D.s. The two frameworks will be combined with gender issues from research.

These frameworks will provide a glimpse into mathematics graduate programs with high percentages of women. It is important to examine the departments because at this level math becomes a choice. Women and men either choose to study it or they choose not to. The frameworks will help us to understand why specific educational environments are appealing to large numbers of women choosing to study mathematics. If either of these frameworks is successful at helping us understand the highest level of education for women, it may be beneficial to examine mathematics classrooms at the K-12 level using this type of framework for improving women's participation in mathematics at all levels.

This poster will demonstrate how the communities of practice framework is related to the stewards of the discipline and how it will be used in the analysis of the data. The poster will also show how research-based gender issues will be superimposed with the frameworks. There will be examples from the data analysis to help exemplify the use of the two frameworks.

# THE REGRESSION OF HIP-HOP

Mara Landers
Los Medanos College
mlanders@losmedanos.edu

Julie Von Bergen
Los Medanos College
jvonbergen@losmedanos.edu

*This poster presents the development and implementation of an activity in which community college students engaged with a standard algebra topic in the context of hip-hop music. Inspired by an article in The New Yorker, the authors developed an activity in which students used data to explore the question "Has Timbaland surpassed the music production record of Dr. Dre?". The poster presents the motivation for creating a context of interest to students, the collaborative effort to develop and implement the activity, student work, student interviews, and a student written article in the college newspaper. We also provide the curriculum and graphs created by students and instructors, and summaries of our reflections for other instructors who might to pursue similar work.*

## Background and Motivation

Teaching Algebra at a community college is about providing students with opportunities to develop conceptual understanding and procedural fluency, but it is also about helping them develop motivation for learning and identities as students who are capable in math. We teach in a context in which a student-centered, reform-oriented, Algebra curriculum has been developed, Lesson Study is an important part of professional development, and concerns about educational equity shape our work. In this context, we created the Hip Hop activity as a replacement activity in the Algebra curriculum, with the goal of providing students a relevant context in which to learn about lines of best fit (LOBF).

## Mathematical Context: Algebra and Linear Regression

Linear functions constitute a major focus of our curriculum, including the use of LOBF to model data. Our Algebra course also aims at general learning outcomes, including communication, problem solving, and multiple representations. In this activity, students organized "raw data" (number of songs each man produced) in tables and graphs, and they used lines of best fit to model the data. Then they predicted when Timbaland surpasses Dre, and when Timbaland's production reached twice that of Dr. Dre. In an extension activity, LOBF were used to motivate solving systems of linear equations.

## Implementation, Reflections, and Future Work

The activity was implemented in both authors' classrooms with similar results. Unlike some activities we have implemented, here students had significant knowledge of this context, and they eagerly suggested other quantities that could be used to compare the relative success of these producers. Some students struggled to organize the raw data, construct lines of best fit, and write the equations of the lines, likely because they lacked experience with such activities. However, the group work and whole class discussion components of the activity served as important sites for learning about linear equations, rates, graphs, estimation and prediction. Different groups necessarily graphed different lines, but were able to make similar predictions about future production and to interpret the slopes of lines as production rates. Future versions of the activity will include the examination of different quantities that measure relative success, as well as the investigation of other contexts and questions generated by students.

# MATHEMATICS LITERACY WORKERS' IDENEITY WITHIN A COMMUNITY OF PRACTICE

Denise Natasha Brewley-Corbin
Georgia Gwinnett College
dbrewley@ggc.usg.edu

*This study examined the identities of mathematics literacy workers of the Young People's Project (YPP) Chicago within the context of their mathematics literacy work. YPP Chicago is a youth-led organization and mathematics initiative that is an outgrowth of and in partnership with Robert Moses' Algebra Project. Wenger's (1998) framework, communites of practice (COP), was utilized in this study. Through the data, I found that there were several identitites constructed by MLWs and CMLWs due to their engagement within this COP. CMLWs and MLWs themselves as change agents, doers of mathematics, and an authority and role model in flagway trainings.*

In the past two decades there has been a major emphasis to increase understanding of rural and urban youths in mathematics. Proficiency in mathematics has become a fundamental requirement for students taking advanced mathematics courses in schools and "more influential on income at age 24 than 30 years ago" (Carpenter & Bottoms, 2003). As urban schools work toward improving student achievement in a variety of disciplines, like mathematics, some scholars have suggested a possible avenue for improving student outcome – allowing students to take a more active role in the mathematics teaching process. Research has shown that student involvement in school change impacts student learning (Mitra, 2003), youth development and produces new identities (Mitra, 2004).

Wenger's communities of practice espouses that learning requires extensive participation within a community where its members are engaged in a set of relationships over time. Communities of practice exist all around us, they are an important part of our everyday life, and individuals are part of a number of them both implicitly and explicitly. There are three dimensions of communities of practice: (1) mutual engagement, (2) joint enterprise, and (3) shared repertoire. Moreover, there are three modes of belonging in identity formation: (1) engagement, (2) imagination, and (3) alignment. For this study, the workshop training was the context for the community of practice. Through these modes of belonging, I was interested understanding mathematics literacy workers' formed their identities. The perspectives that guided this work were as follows: (1) Learning occurs by doing or through practices in social activity (Lave & Wenger, 1991); (2) Identity formation occurs in a social context and is contingent on ones levels of engagement in that context. I engaged participants in mathematical tasks and prompts to solicit their interpretations of how they were influenced by their work in YPP overall and the workshop training in particular. This paper describes how CMLWs and MLWs came to understand their own construction of identity as a result of their community outreach work and participation in the workshop training.

Results from data revealed a wide variety of experiences that influenced how mathematics literacy workers came to their work at YPP. Each of the participants' identity were constructed differently through various aspects of the outreach work they engaged in and the way they felt it came through in their overall purpose with the Young People's Project Chicago. Each participant's identity was displayed through very specific goals they had for themselves and for others in doing the outreach work. One of the ways that identity was constructed was mathematics literacy workers defined as authoritative figures. Math literacy workers as an authority were defined by participants aspiring to be role models, capable of shaping how children saw mathematics, and demonstrating a high level of understanding among peers. Mathematics literacy workers also saw themselves as change agents, capable of changing how others perceived mathematics in their community.

# SEX DIFFERENCES IN PERFORMANCE ON THE SAT I QUANTITATIVE SECTION

Bryan Nankervis
Texas State University-San Marcos
bn10@txstate.edu

*This theoretical paper demonstrates that gender gaps in performance on the SAT I quantitative section (about one third of a standard deviation) have little to do with college readiness, but rather are due to the misaligned content of the instrument as well as the environment in which the exam is administered. The findings of this research have far-reaching implications for the design and administration of standardized mathematics tests and in particular for the SAT, which is used for determining admission to many colleges as well as the awarding of scholarships.*

## Introduction

Performance differences between the sexes across mathematical content areas, problem types, and various instruments have been previously documented (Gallagher & Kaufman, 2005; Hyde, Fennema, & Lamon, 1990; McGraw, Lubienski, & Strutchens, 2006; Willingham & Cole, 1997) and generally attributed to biological and/or sociological influences. Also it has been demonstrated that stereotype threat can contribute to performance gaps by causing females to falter in the face of complex numerical reasoning tasks or to forego tedious calculations and opt to guess at an answer while their male counterparts are unaffected (Quinn & Spencer, 2001; Spencer, Steele, & Quinn; 1998). Since the SAT I is supposedly designed to predict the success of college freshmen, students' scores play a significant role in many institutions' admissions and scholarship decisions. However, the disparity in scores between college-bound males and females, particularly on the quantitative section, leads to inequities in terms of access. It is asserted here that the conditions under which the high-stakes SAT I is administered are conducive to stereotype threat. Further, this paper argues that the predictive validity of the SAT I quantitative section is questionable because it includes a significant amount of content that not only favors males, but also is not reflective of first-year college mathematical subject matter.

## Theoretical Perspectives

This literature review examines possible reasons for divergence in performance (biological and sociological), differences between the sexes' performance in particular mathematical content areas and problem types, differences in use of mathematical problem-solving strategies, and stereotype threat's effect on performance. The review then examines the validity of the SAT quantitative section in predicting college success.

*Possible Reasons for Divergence In Performance*

The literature shows three main lines of reasoning to explain the differences in male and female performance on mathematical tasks: biological and sociological (covered here) and psychological (covered later in the section on stereotype threat). While biological arguments have in recent literature largely been discredited, they still exert an influence in contemporary discourse and thus cannot be ignored.

*Biological*

In terms of sex differences in performance on cognitive tests, arguments have been made that males for biological reasons have a higher aptitude for mathematics than females, which would account for performance gaps on tests such as the SAT I quantitative section. Hormones may play a role in enhancing some abilities, as levels of testosterone in males have been shown to be causally linked to spatial-skills performance (Janowsky, Oviatt, & Orwoll, 1994), and female-to-male transsexuals have demonstrated marked increases in their spatial abilities after being given large amounts of testosterone (Van Goozen, Cohen-Kettenis, Gooren, Frijda, & Van De Pol, 1995).

Another line of reasoning is that males have greater variability in mathematical performance than females which leads to more males at the far right of the statistical distribution (e.g., at high levels of performance) than females. Studies conducted in the late 1970s and early 1980s with nearly 50,000 junior high students who had taken the SAT I quantitative section as part of talent searches, revealed that boys exhibited a “substantial” sex difference in mathematical reasoning, and further suggested, because the participants were adolescents, that genetic differences (e.g., deficiencies in female genetics) were the reason for this difference (Benbow & Stanley, 1980; 1983). Feingold (1992) found that 12th-grade males also exhibited more variable performance than females on the SAT I quantitative section, and suggested that this greater variability, combined with the medium effect size of central tendencies favoring males (moderate differences in average scores between the sexes), could lead to even greater effect sizes in the right tails of the ability distributions for the sexes (larger differences in average scores for high-ability males and females).

However, this domination by males at the far right of the ability distribution (e.g., at the high end of ability in mathematics performance) has diminished over the last two decades in the U.S. and internationally (Brody & Mills, 2005; Feingold, 1994; Monastersky, 2005; Willingham & Cole, 1997), which suggests that sociocultural factors may play a role in gender differences in achievement. In general, current evidence for a purely biological basis for differences in mathematical performance between the sexes has been described as “weak, at best” (Wilder, 1997, p. 14).

*Sociological*

A different argument is that sex-related differences in mathematics performance are due mainly to environmental influences. In this view, differential socialization of boys and girls via prejudicial treatment, social norms, and the expectations of parents, teachers, and fellow students, results in the divergent development of boys and girls and sex-role stereotyping (Baker & Jones, D. P., 1992; Eccles & Jacobs, 1986; Fennema & Peterson, 1985).

For example, in the area of spatial abilities (where males have a documented edge), it has been shown that taking part in related activities (especially those specific to completing spatial tasks) is essential to the development of the spatial ability, and that females tend to participate in these learning situations less often than males (Baenninger & Newcombe, 1989). Further, it has been demonstrated that when females are given the opportunity to train with visual-spatial tasks, their performance improves (Vasta, Knott, & Gaze, 1996). In addition, international studies have shown that sex differences in performance on mathematics tasks decrease as females are provided more access to advanced training and better jobs (Baker & Jones, D. P., 1992).

Therefore, the evidence suggests that sex differences in mathematics performance are not immutable. Instead, rather than a dichotomy of nature (biological) or nurture (sociological) as possible reasons for divergence in performance, it would seem that differences in performance are a result of a unique and complex blending of influences and opportunities.

*Differences between The Sexes’ Performance In Particular Mathematical Content Areas And Problem Types*

Sixth- and seventh-grade girls perform better in problems of number sense, problems of estimation, and those that involve patterns, while their male counterparts perform better in geometry and ratio/proportion, and on problems that employ figures (Lane, Wang, & Magone, 1996). These differences in performance continue through high school—for example, studies of students taking college entrance exams (e.g., the SAT and ACT) revealed that females perform better on algebra items that involve familiar algorithms or computation, while males perform better in geometry, mathematical reasoning, word problems, and items including figures, graphs, or tables (Doolittle & Cleary, 1987; Harris & Carlton, 1993).

In a review of studies up to 1985, the observed trend was that among high school students, males were somewhat better than females in solving word problems, and females were better or at least equal in computational skills (Stage, Kreinberg, Eccles, & Becker, 1985). A 1990 meta-analysis of 100 studies revealed "a slight female superiority in computation, no gender difference in understanding of concepts, and a slight male superiority in problem solving" (Hyde, Fennema, & Lamon, 1990, p. 147). Further, despite relatively similar male and female mathematical abilities at the elementary level, males' ability in geometry seems to accelerate past and beyond that of females by the end of high school (Leahy & Guo, 2001).

Differences in the ability of spatial visualization may be the key to differences in mathematical trajectories for the sexes. Males have been shown to outperform females on geometric tasks involving spatial visualization, but males and females exhibit roughly equal performance in logical reasoning ability and in the use of geometric problem-solving strategies (Battista, 1990). Males exceed females by some of the largest differences in performance on items that involve mental rotation of three-dimensional objects (Casey, Nuttal, Pezaris, & Benbow, 1995; Willingham & Cole, 1997), and also perform better on items based on measurement of two-dimensional and three-dimensional objects (perimeter, area, surface area, volume), which also involve spatial visualization (Garner & Engelhard, 1999; Li, Cohen, & Ibarra, 2004).

Higher ability in spatial visualization may also play a role in a higher ability to retrieve mathematics facts. College males (undergraduates from the 1996–97 academic year) have been shown to be faster at math-fact retrieval on an achievement test (the Computer-based Academic Assessment System, now known as the Cognitive Aptitude Assessment System) (Royer, Tronsky, Chan, Jackson, & Marchant, 1999). It has been suggested that this higher retrieval speed may be linked to males having greater flexibility in their choice of problem-solving strategies, because they have the option of employing a spatial approach that might be more appropriate for some items. On the same items, someone with limited spatial ability would be forced to rely upon a perhaps less effective approach (Casey et al., 1995).

Another possibility to explain the difference in male and female mathematics performance is that math-fact retrieval ability itself plays a pivotal role in solving more complex problems that require more cognitive load. That is, those who can retrieve information more quickly or more effectively would perform better on items requiring recall of a mixture of concepts and/or procedures (Paek, 2002; Royer et al., 1999). Further, it has been demonstrated that on SAT I quantitative items, males take less time to solve problems than females (Paek, 2002). But, regardless of whether math-fact retrieval ability is an effect that favors males (due to higher ability in spatial visualization) or is the cause for their better performance on certain mathematics tasks, it certainly would provide an advantage on a timed test.

*Differences in Use Of Mathematical Problem-Solving Strategies*

A study of high school students working problems from the quantitative section of the SAT I (Gallagher, 1992) found that females were more apt to rely on standard algorithms traditionally presented in classrooms, while males were more inclined to use insight. Females demonstrated less prior knowledge than males and used fewer mathematical strategies on SAT mathematics items, even when both groups had similar backgrounds in terms of mathematics courses taken and grades received (Byrnes & Takahira, 1993; Paek, 2002). It has also been shown that on SAT mathematics items, males use unconventional strategies (including logic, estimation, or insight) significantly more often than females, and females use conventional strategies (such as an algorithm, assigning values to variables, or "plugging in" numbers to a formula) significantly more often than males (Gallagher & De Lisi, 1994; Paek, 2002).

These findings would certainly tend to suggest that males would have the advantage in situations where problems cannot be solved by the more traditional strategies presented in school, and would help to explain why females generally have better grades in school but underperform on tests such as the SAT I quantitative section. One study that used course grades rather than standardized tests to measure differences in mathematics achievement between the sexes noted that "when differences are found, they almost always favor girls, and these differences are quite consistent across samples of varying selectivity for junior high through university mathematics courses" (Kimball, 1989, p.199). The study's findings, which are contrary to male and female achievement patterns on the SAT I quantitative section, suggest that situational variables (such as the testing environment or method of administration) might play a role in performance gaps between males and females.

*Stereotype Threat's Effect on Performance*

A landmark study that introduced the term *stereotype threat* (Steele & Aronson, 1995) suggests a plausible explanation for some of the differences in male and female mathematics achievement when measured by classroom test grades and by standardized tests. Stereotype threat is defined in the study as a feeling of "being at risk of confirming, as self-characteristic, a negative stereotype about one's group" and further, stereotype threat "may interfere with the intellectual functioning of these students [affected by stereotype threat], particularly during standardized tests" (Steele & Aronson, 1995, p. 797). The initial study focused on black students who were found to be burdened by the stereotype of having less ability than white students in terms of general intellectual aptitude.

Steele and Aronson's findings are relevant to this study of performance gaps between the sexes on standardized mathematics tests, because females may also deal with stereotype threat. In particular, females are susceptible to the stereotype threat that they are publicly perceived to be less able in mathematics than males. Steele and Aronson note the broad applicability of stereotype threat: "This threat can befall anyone with a group identity about which some negative stereotype exists, and for the person to be threatened in this way, he [or she] need not even believe this stereotype" (Steele & Aronson, 1995, p. 798).

In a later experiment, the effects of stereotype threat on female mathematics performance was confirmed among college females who excelled at math and identified strongly with the subject (Spencer et al., 1998). In that study, on an extremely difficult test (composed from the advanced GRE in mathematics), females underperformed compared to males when informed before they took the test of historic sex differences in test performance, but females achieved as well as males when told that the test was gender-insensitive. The results of the experiment contradicted the hypothesis of female genetic deficiency suggested previously by Benbow and Stanley in the early 1980s (Spencer et al., 1998). Additionally, the experiment's findings confirmed what Steele had concluded in an earlier study: that “stereotype threat may be a possible source of bias in standardized tests, a bias that arises not from item content but from group differences in the threat that societal stereotypes attach to test performance” (Steele, 1997, p. 622).

*The Effects of Priming Stereotype Threat*

Stereotype threat can be primed in various ways. One is the condition of *evaluative scrutiny.* In this situation test-takers know their results will be available to others, such as parents, teachers, administrators, or colleges. On a standardized test such as the SAT, some degree of evaluative scrutiny is always present. Another way to induce stereotype threat is the condition of *identity salience.* This condition can be thought of as “the likelihood that the identity will be invoked in diverse situations” (Hogg, Terry, & White, 1995, p. 257). Participating in a mixed testing environment (for example, males and females together) or having to identify one’s sex prior to a standardized test, as is the norm, can invoke identity salience.

The effects of these two causes of identity salience have been measured in studies conducted by the Educational Testing Service (commonly known as ETS) and the College Board. In one experiment, researchers administered the mathematics section of the Graduate Record Exam general test to males and females on an individual basis (GRE Board, 1999). In this study, the gap in scores between males and females was less than half of the gap from the regular administration of the GRE general test ($d$ =.40 versus $d$ =.97) that same year, in which students tested in a mixed environment.

Another study measured the effect on performance of identifying one’s sex before a test (College Board, 1998a). The experiment focused on students taking the Advanced Placement Calculus AB exam. For those who indicated their sex on a standard background information sheet *before* the test, the performance gap effect size ($d$ = .41) between males and females was more than triple that for the males and females who identified their sex *after* the test ($d$ = .12). This study, along with the ETS study, clearly demonstrates that the condition of identity salience, while subtle in nature, can play a major role in inducing stereotype threat.

*The SAT and Its Present Validity in Predicting College Success*

Approximately 92 % of four-year institutions require SAT/ACT scores from potential students and 75% routinely use these scores in making decisions on admissions (College Board, 2002). However, in Hyde, Fennema, and Lamon’s 1990 meta-analysis of gender differences in mathematics performance on various instruments (100 studies total), the effect size favoring males was by far the greatest on the SAT I, and this performance gap persists today.

The College Board has offered various reasons for differences in the performance of males and females on the SAT I quantitative section. Essentially, the College Board suggests that females are generally less prepared than males in terms of mathematics (College Board, 1998b). However, the validity of the exam is suspect, in terms of gender, as it has been demonstrated that the SAT I quantitative section consistently under-predicts the college success of females compared to males. Studies have shown that while males consistently score higher (a third of a standard deviation) than females with similar mathematical backgrounds on the SAT I quantitative section, females perform on par with males, later, in like college mathematics courses (Bridgeman and Wendler, 1991; Wainer and Steinberg, 1992).

One reason for the lack of predictive validity with the SAT I quantitative section may lie with the content of the exam, which is seemingly not well-aligned with college readiness standards. Approximately 40% of the test is devoted to geometry, measurement, and data analysis items (Achieve, 2007), content strands where 12th-grade males tend to outperform their female counterparts on the NAEP (McGraw et al., 2006). However, the typical core curriculum mathematics course required for students at universities is college algebra or its equivalent, a mathematical area where women perform on par with men (McGraw et al., 2006). Further, a recent national curriculum survey of post-secondary mathematics instructors (ACT, 2007) revealed that algebra skills were ranked as the most important, while measurement, geometry, and probability/statistics skills were considered least important for success in college.

Also, in another study on college readiness (AAU & Pew Charitable Trust, 2003), the content strands of geometry and measurement accounted for only seven out of 81 mathematics standards for success in college (the rest covered by algebra) and probability/statistics was not considered a necessary prerequisite for entry-level mathematics courses. Therefore, since the SAT I quantitative section contains a large percentage of items that are for the most part considered irrelevant to college freshman success and tend to favor males over females, the fact that the exam over-predicts the future success of males while under-predicting the same for females should not be unexpected.

## Conclusion

Evidence to date suggests that performance gaps between males and females on standardized mathematics tests, such as the SAT I quantitative section, are influenced by a complex mix of sociological, psychological, and (to a lesser extent) biological factors unique to each individual. However, the typical core curriculum mathematics course required by universities is college algebra or its equivalent, a content area where females perform on par with males (according to NAEP data). Yet, a large percentage of the SAT I quantitative section is devoted to other content areas which are not essential to freshmen success and favor males (also according to NAEP data), which in combination with a testing environment conducive to stereotype threat potentially lead to existing sex differences in performance on the exam.

Since high-stakes decisions involving admissions to colleges and awarding of scholarships are often based on the results of this single testing instrument, the College Board should reexamine the content of the exam to ensure that it is aligned with and accurately reflects the topics necessary for early college success in mathematics. Further, in order to lessen the effects of stereotype threat, ETS should consider shifting the administration of the SAT I to individualized (or same sex) testing and moving identification of one’s sex to after or well in advance of the exam.

*This research report examines patterns in middle-grades boys' and girls' written problem solving strategies for a mathematical task involving proportional reasoning. The students participating in this study attend a coeducational charter middle school with single-sex classrooms. 119 6th grade students' responses are analyzed by gender according to the solution strategy they used to arrive at their final response to the task. 42.7% of participating girls' responses are classified as either using a purely multiplicative strategy, as evidencing emergent proportional reasoning, or as evidencing mature proportional reasoning. 60.5% of participating boys' responses are thus classified. 52.5% of girls are classified as relying on a purely additive strategy for their final response, as compared with 29.5% of boys.*

## Objectives/Purposes of this Study

This research report examines patterns in middle-grades boys' and girls' problem solving strategies for a mathematical task involving proportional reasoning. The students participating in this study attend a coeducational charter school with single-sex classrooms. All of the students in this study attended 6th, 7th, or 8th grade mathematics classes (6th grade mathematics, pre-algebra, or algebra) in single-sex classrooms. Instruction in single-sex classrooms is a mandate of the charter for this school, formed by parents seeking an alternative to local public middle schools. The research reported in this paper is part of a more broad investigation of the impacts of single-sex middle-grades education on mathematics learning, mathematics achievement, student academic self-concept, and parent, teacher, and student perspectives of the experience of being educated at this charter school. For this paper, we are looking specifically at the written and, in some cases, video-recorded solution strategies of girls and boys as they attempt a mathematical task centered on proportional reasoning.

## Perspectives/Theoretical Framework

Equity issues in mathematics education are currently receiving much attention, as evidenced in part by the NCTM Board of Directors' emphasis on equity as a strategic priority and by the upcoming special issue of JRME on equity in mathematics education. Of the many aspects of equity to consider, this research report proposal contributes to understandings in mathematics education about gender and mathematical thinking. Much of the work in the mathematics education research community on gender and mathematics thinking focuses on a narrow, restrictive view of mathematics achievement by using mathematical performance on standardized tests to compare girls and boys. While such studies can provide insight about certain questions regarding girls' and boys' mathematical performance, one of the problematic issues with basing findings on students' mathematical performance on a standardized test is that results from such studies are easily (mis-)extrapolated to include implications about not just performance, but achievement, ability, and talent. In addition, findings resting on outcomes from an assessment in which answers are coded either right or wrong disregards students' thinking about the mathematical tasks on the assessment.

## Research Questions

1. How do girls' strategies for solving a mathematical task compare to other girls' strategies?
2. How do boys' strategies for solving a mathematical task compare to other boys' strategies?
3. How do the girls' strategies for solving a mathematical task compare to boys' strategies?

## Modes of Inquiry

*Participants*

The initial phase of this research involved selecting a sample of students to participate in a videoed task-based interview. 23 students (12 girls, 11 boys) were selected for this task, in which students attempted to solve and explain their strategies for solving a mathematical task involving proportional reasoning. Following these task-based interviews, a total of 162 students, grades 6-8, participated in writing responses to the mathematical task. Table 1 shows the distribution of these 162 students across gender and grade level. The reason there are so many $6^{th}$ graders relative to the $7^{th}$ and $8^{th}$ grade students is that the school has decided on a growth process whereby new classes are added at the $6^{th}$ grade level.

Table 1. *School Student Population by Grade and Gender*

| | Girls | Boys | Total |
|---|---|---|---|
| $6^{th}$ grade | 61 | 58 | 119 |
| $7^{th}$/$8^{th}$ grade | 24 | 19 | 43 |
| Total | 85 | 77 | 162 |

For the school's first year, there were about 20 $6^{th}$ graders, 20 $7^{th}$ graders, and 20 $8^{th}$ graders. At the time of our data collection, there were still about 20 $7^{th}$ graders and 20 $8^{th}$ graders, but a larger class of $6^{th}$ graders had been admitted. Because there are so many more $6^{th}$ graders than $7^{th}$ and $8^{th}$ graders, the data in this paper concentrate on $6^{th}$ grade students.

*Contexts*

Students participating in this research attend a public coeducational charter school in the southeast. Classes at this charter school are conducted in single-sex classrooms (the one exception is $8^{th}$ grade geometry, which is coeducational and offered before school so as to not violate the school's charter). The school currently has approximately 220 students in grades 6 through 8, and class sizes are at most 20, with class sizes from 15-20 being habitual. Thus, this charter middle school is atypical from local public middle schools in both school and class size. Further, this charter middle school has a homogenous student population both in terms of race and SES; more than 90% of the students are white and no students qualify for free and reduced lunches. Though this school is not representative of local public schools, it does offer a rare glimpse into single-sex education in non-private settings in the U.S.

*Data Collection*

The data of primary focus for this paper (written responses to a mathematical task) were collected in May, 2008, near the end of the academic year. Students participating in a task-based interview (in October, 2007) were selected by their mathematics teachers; researchers asked teachers to select several students in each of their classes. Upon completion of the initial analysis of these interviews, researchers distributed the task in written form and asked all students to respond to the task. Participating students responded to this problem:

> The capacity of an elevator is either 20 children or 15 adults. If 12 children are currently in the elevator, how many adults can still get in? (Johnson & Herr, 2001)

This particular problem was chosen for several reasons: first, this problem addresses one of the main ‘big ideas’ of middle grades mathematics, proportional reasoning. Second, this problem allows for many distinct solution strategies. Third, students only using the traditional algorithm of setting up two equal ratios and cross-multiplying to solve for the unknown quantity will not arrive at the correct response if they use only the numbers given in the problem. This is because the information given in the problem relates to the full capacity of the elevator and the capacity that is occupied, but the problem asks for the capacity still available for use. The fact that, when students only use numbers given in the problem with a traditional algorithm, they do not arrive at the correct answer facilitates analysis, as discussed below. Fourth, the context of the problem is one to which the participating students can all relate and which has a high degree of gender neutrality (no names are used, no one in the problem is referred to by gender, and both women and men frequently use elevators).

## Analysis

The student responses were analyzed in two ways: responses were first analyzed separately by gender and responses were sorted according to the students’ final answer. There were some students who did not have a clear final answer, and there were some students who offered an answer with no written strategy. The remaining task attempts were put into categories coinciding with the students’ final answer. For instance, all the 6$^{th}$ grade girls whose final response was 6 adults were placed into the same category. Once the range of final answers from 6$^{th}$ grade girls was established, each of the strategies leading to these final answers was examined, with researchers tracing students’ thinking according to the sequencing of the work on the page and the flow of the mathematical computations. In several cases, there were also illustrations which frequently gave insight into students’ thought processes. During this phase of analysis, researchers articulated students’ strategies for each response and noted similarities and differences in students’ strategies.

The second level of analysis occurred across final answers, and focused on the spectrum of student solution strategy from purely additive reasoning to appropriate use of proportional reasoning. This spectrum is based on Lamon’s (2005) work on levels of sophistication of student solution strategies. While we do not explicitly place students’ work samples in different levels of sophistication, we do place them on a spectrum from additive to multiplicative strategies, using a four-part scale: purely additive strategies, emergent proportional reasoning, purely multiplicative strategies, and mature proportional reasoning. This scale is admittedly problematic in a sense because the scale uses both strategies and reasoning as sorting variables. The rationale for this is that a student’s use of a multiplicative strategy (such as setting up a proportion and cross multiplying) is not necessarily indicative of proportional reasoning. Such students could have simply followed a memorized procedure. Thus, only those papers with clearly articulated reasoning and clear strategies are placed in the categories of emergent proportional reasoning or mature proportional reasoning.

## Results

Tables 2 and 3 show the results of the analysis of final responses by gender. Of the 61 $6^{th}$ grade girls, there were 11 different final responses. Of the 58 $6^{th}$ grade boys, there were also 11 different final responses. Looking at the $6^{th}$ grade as a whole, of the 119 students, there were 15 different final responses to the question.

Table 2. *Distribution of $6^{th}$ Grade Girls' Responses (n = 61)*

| Final Response (# of adults) | Number of Each Response | | Strategies for each response |
|---|---|---|---|
| No work/rationale | 4 | (6.6%) | 1 attempt at a multiplicative strategy, 3 papers have no work |
| 8 or 3 | 1 | (1.6%) | 1, an additive strategy |
| 4.6 | 1 | (1.6%) | 1, attempts a multiplicative strategy |
| 23 | 6 | (9.8%) | Additive strategies; several multiplicative strategies attempted and rejected |
| 9 | 9 | (14.8%) | All multiplicative strategies |
| 8 | 7 | (11.5%) | Additive strategies, although several multiplicative strategies attempted |
| 7 | 10 | (16.4%) | All additive strategies |
| 6 | 5 | (8.2%) | All strategies used proportions |
| 5 | 2 | (3.3%) | 2 purely additive strategies |
| 4 | 7 | (11.5%) | 1 purely additive strategy; 6 strategies involving multiplicative reasoning; 2 strategies using a 2:1 ratio |
| 3 | 7 | (11.5%) | Additive strategies; several multiplicative strategies attempted and rejected |
| 2 | 2 | (3.3%) | 2 proportions attempted |

Table 3. *Distribution of 6th Grade Boys' Responses (n = 58)*

| Final Response | Number of Each Response | | Strategies for Each Response |
|---|---|---|---|
| Unclear | 4 | (6.9%) | Mainly strategies involving multiplication and division; some additive strategies |
| No work/rationale | 2 | (3.4%) | |
| 25 | 1 | (1.7%) | 1 multiplicative strategy |
| 13 | 1 | (1.7%) | 1 additive strategy |
| 9 | 4 | (6.9%) | 4 multiplicative strategies |
| 8 | 5 | (8.6%) | 3 additive-only strategies |
| 7 | 7 | (12.1%) | 5 additive-only strategies |
| 6 | 10 | (17.2%) | Multiplicative strategies; two strategies used LCM (15,20); one strategy assigned a weight for children |
| 5 | 4 | (6.9%) | 1 multiplicative strategy; 4 additive strategies |
| 4 | 8 | (13.8%) | 4 strategies using a 2:1 ratio |
| 3 | 9 | (15.5%) | 5 multiplicative strategies, 3 additive strategies |
| 2 | 2 | (3.4%) | 1 strategy using a 3:1 ratio |
| 1.666… | 1 | (1.7%) | Divided 20 by 12 |

In Tables 2 and 3, the category of no work/rationale means that the student states a response but there is no mathematical work shown and no written rationale for the response. This category *does not* include those students who show mathematical work but do not give a written rationale.

Table 4. *Strategy Classification of Girls and Boys*

| Response Classification | Girls (n = 61)* | | Boys (n = 58)* | |
|---|---|---|---|---|
| No work/rationale | 3 | (4.9) | 4 | (6.6) |
| Purely additive | 32 | (52.5) | 18 | (29.5) |
| Emergent Proportional Reasoning | 12 | (19.7) | 18 | (29.5) |
| Purely multiplicative | 9 | (14.8) | 13 | (22.4) |
| Mature Proportional Reasoning | 5 | (8.2) | 5 | (8.6) |

*Quantities in parentheses indicate percentages.

In Table 4, the category 'No work/rationale' corresponds to the same category for Tables 2 and 3. That is, these papers gave a response but showed no work and stated no rationale for their response. The category 'Purely additive' refers to the strategy the student relied on to get their final response. As will be discussed in the presentation, there are several students in this category that attempted strategies involving multiplication and/or division, but ultimately resorted to strategies using only addition/subtraction for their final response. 'Emergent Proportional Reasoning' papers were classified as such because of their images, their words, and their use of ratios. These students indicated that they were aware of the necessity for ratios but were not quite sure how to find and/or use meaningful ratios for this problem. Several of these students assigned arbitrary ratios (like 2:1) and solved the problem using this assigned ratio. Many of these students indicated uncertainty in their response, but none resorted to purely additive strategies. 'Purely multiplicative' strategies are those whose responses include setting up a proportion and cross-multiplying to solve, or calculating a ratio and using multiplication to get a response. Many of these students got a response of 9 adults. Those students whose work is classified as 'Mature Proportional Reasoning' indicated an understanding of the process they were doing and what their results meant; further, their process was appropriate to responding to the question—that is, it made sense mathematically. This category of 'mature' does not mean that this is the highest level of proportional reasoning possible; rather, it indicates that, from the student work samples in this study, these responses were making sense of the problem.

## Discussion/Conclusion

There are many ways to analyze student work samples. In addition to the analyses above, we could also group student work according to the specific strategy employed, sorting those students who assigned a ratio of 2:1, for instance, in one group and those students who subtracted 12 from 15 in another. We could also analyze according to the strength of the rationale or reasoning indicated; this could help with the issue of hidden non-reasoning in the purely multiplicative category in Table 4. The problem with this type of analysis is that very few papers, particularly boys' papers, used words or other indications of their reasoning. On the other hand, many girls who used purely additive strategies still explained their thought process in words. In our presentation, we will share several examples of both girls' and boys' work for each category in Table 4.

The selection of the task became important to the types of analyses we could do and the insights we could get from those analyses. The fact that students who set up a proportion and solve (usually getting a response of 9 adults) do not get the correct result helped us to distinguish between students who were reasoning about whether their result made sense and those who were not. If you figure that more than half of the capacity of the elevator is already taken up, then it becomes clear that fewer than half of 15 (7 1/2) adults can still get on. That is one reason why students using multiplicative strategies are not necessarily assigned a category indicating proportional reasoning. Indeed, several student papers classified as emergent proportional reasoning evidenced a higher level of reasoning than many papers classified as multiplicative. Thus, the results in Table 4 should not be viewed as a spectrum from lower sophistication levels to higher sophistication levels.

Returning to our original questions for this study, comparisons of girls' and boys' strategies, we can see that 57.4% of the girls either showed no work or used purely additive strategies to arrive at their final response. By contrast, about 36.1% of boys either showed no work or relied on purely additive strategies for their final response. Some of the students who ultimately used additive strategies also attempted a multiplicative strategy but abandoned it; even still, this discrepancy between the portion of girls relying on purely additive strategies for their final response and the portion of boys doing so is the most striking discrepancy in our results.

Though more comparable, there is still a discrepancy between the percent of girls classified as emergent or mature in proportional reasoning and that of boys (girls had 27.9% so classified as compared to 38.1% of boys). Of the ten papers classified as Mature Proportional Reasoning, only 2, both of whom were girls, set up a proportion to solve the problem.

Findings from this study, involving student work samples from just one problem, are clearly not generalizable. We can make some inferences for these students for this mathematical context, but applying results from this study more broadly is problematic. Our results point to the importance of mathematical communication and having these students articulate their reasoning and their rationales. We say this because students clearly indicating some degree of proportional reasoning were also thinking about the problem in reasoned ways. Further, it could be that those strategies classified as purely multiplicative involved some degree of reasoning beyond following an algorithm; just because this reasoning was not evidenced on paper does not necessarily mean that the reasoning was not present at all.

Many questions remain: why did so many more girls use additive strategies to get their final response? What level of reasoning was evidenced in students' discarded strategies? How was the use of imagery related to gender and to reasoning level? What are the strengths and limitations of this kind of methodology for understanding students' reasoning more broadly than student standardized performance? We will share our reflections on these questions and invite discussion on these issues during our presentation.

# THE ROLE OF ADVISING IN THE ACADEMIC DECISIONS OF WOMEN MATHEMATICS MAJORS AT A LIBERAL ARTS COLLEGE

Central Michigan University
solle1ka@cmich.edu

*Research suggests that the support of "significant others" such as family, teachers, and professors plays a large role in women's participation in non-traditionally female careers. Using the method of case studies, we discuss the experiences of three undergraduate women mathematics majors at a small liberal arts college and describe the role "significant others" played in the development of their mathematics identities and their choices as undergraduates. Furthermore, we emphasize the role advising by college faculty played in these women's knowledge of career options and how this has influenced their future career plans.*

## Introduction

Research shows that the support of "significant others" plays a large role in women's participation in non-traditionally female careers. Women who are successful in mathematics and who pursue mathematical careers often cite having a family member who served as a role-model in mathematics or feel that they were directly encouraged in mathematics by family members or teachers beginning at a relatively young age (Fox & Soller, 2001; Zelden & Pajares, 2000). Furthermore, women who choose to leave the field of mathematics often describe a lack of mentoring or advising from their university professors (Herzig, 2004; Stage & Maple, 1996).

It is likely that the feedback women receive from significant people in their lives plays a rolein the development of their mathematics identity, i.e. their tendency to identify as a "mathematics person." Carlone and Johnson (2007) have developed a framework in which they use the concept of one's science identity as a lens for interpreting the science experiences and choices made by successful women of color in science. These scholars view one's science identity as consisting of three overlapping dimensions: *competence*, *performance*, and *recognition*. The dimension referred to as *recognition* is developed from both one recognizing herself, as well as one being recognized by others, as a science person. These scholars' work suggests that "recognition by others" played a critical role in these women's science identities and career paths.

It is clear from the literature that the encouragement and recognition of others plays an important role in the choices and career decisions of women in non-traditionally female careers. In this paper we describe a case study of three undergraduate women mathematics students at a small liberal arts college in the Midwest. We discuss how support from their professors and other significant people in their lives have influenced the development of their mathematics identities and their choices as undergraduates. We further note the role advising played in their knowledge of career options and how this has influenced their future career plans.

The study described in this paper is part of a larger study being conducted to look at what motivates undergraduate women mathematics majors to choose to earn a Bachelor's degree in mathematics and what factors influences their future career choices. Although participants from the larger study are from universities of differing types, we found that the emphasis on faculty advising at the small liberal arts school was worthy of closer investigation. As such, this paper focuses specifically on these women's experiences.

## Method

The participants in this study were undergraduate women mathematics majors at a small liberal arts college in the Midwest. All of the participants had either junior or senior class standing at the time of the interviews and were earning non-teaching, mathematics degrees. Given the small size of the college, all students at this school fitting these criteria were invited to participate in this study. We had approximately a 50% participation rate.

The main source of data for this study was a series of three in-depth, phenomologically-based interviews with each of the participants. "In this approach interviewers use, primarily, open-ended questions. Their major task is to build upon and explore their participants' responses to those questions" (Seidman, 1998, p. 9). We followed the Three-Interview Series protocol as suggested by Seidman (1998). During the first interview, we collected data on the participant's pre-college mathematics experiences. The second interview consisted of learning about the participant's mathematical experiences while in college. During the third interview, we asked the participants to reflect on their past experiences with mathematics and explored how these experiences may be influencing their future career goals. In addition to the data collected through the interviews, we also collected information about these students' college grades and ACT/SAT scores. The purpose of collecting this data was to compare their perceived academic achievement with their actual academic records. Previous research suggests that women frequently underestimate their accomplishments (Fox & Soller, 2001).

All of the interviews were audio and video-recorded. After the interviews were transcribed, each of the two researchers independently analyzed the transcripts and created profiles for the participants (Seidman, 1998). Once the profiles were created, we noted common themes emerging from the data and developed a coding scheme grounded in the data (Strauss & Corbin, 1998). This collaborative method allowed for researcher triangulation. Once the codes were agreed upon, the primary investigator coded and analyzed all of the data with respect to these themes. Because only one researcher conducted the final coding, consistency in coding between researchers is not a concern.

## Results

In this paper we will mostly focus on the role that advising played (or did not play) in these women's academic and career decisions. Furthermore, we will be utilizing the word "advising" rather loosely. The term "advising" may reference advice that these students received from family members, teachers, professors or other significant people in their lives. Moreover, advising may be done either formally or informally through casual interactions.

At this particular liberal arts college, formal advising is taken quite seriously. All incoming freshmen are assigned an academic advisor. If the student has chosen a major prior to beginning his or her college career, the student is assigned an advisor in that department. Otherwise, the student is encouraged to select one or two academic areas that they might have an interest in and the administration then assigns the student to an advisor in one of these disciplines. The role of this advisor is critical because each semester before the students are able to sign up for their classes for the following semester, they must meet with their advisor and have the advisor sign off on their choice of courses for the following semester. This method ensures that students are receiving proper advising with respect to their course selections.

We will now describe each student's case separately, focusing specifically on the role that significant others in their lives played with respect to the development of their mathematics identities, their choices with regards to mathematics, and their future career plans.

*The Case of Paige*

Paige developed a strong mathematics identity at a young age. As early as freshman year of high school, Paige knew that she would major in mathematics. She claims that she probably knew it subconsciously even before that. Mathematics was always considered "her subject" and she knew mathematics was what she wanted to do. She admits, however, "I didn't know what I was going to do with it, but I knew I was going to be a math major."

Many teachers encouraged Paige in mathematics through the years and in high school Paige remembers being the "math person" amongst her group of friends, but the person who clearly contributed the most to her mathematics identity was her mother. Paige recalls that her earliest memory of mathematics was her mother using candy to help her learn arithmetic. As the years went on, her mother continued to support her and encourage her in mathematics. Her mother felt that she, herself, was strong in mathematics and was happy to see her daughter choose such a field because she felt Paige would have more opportunities going into a non-traditional discipline for women. Paige claims that she never really received discouragement from doing mathematics from anyone, and jokes, "I'm pretty sure my mom would hurt them if they [did]."

Because Paige was so far advanced in mathematics, she had completed Calculus I by the end of her sophomore year in high school. For her junior and senior years of high school she commuted to the local community college for her mathematics courses. Her instructor at the community college was very supportive and even encouraged her one semester to take both Calculus III and Differential Equations at the same time.

When Paige began college as a freshman, she was already taking junior level mathematics courses. Both she and her mother were a little concerned about her taking such advanced courses as a freshman, but she had already completed all the freshman and sophomore level courses by then. During her first semester at college, she took a 300-level Linear Algebra course. She remembers feeling behind because she had not taken the "introduction to proofs" course yet, which was only offered during the winter semester, and the instructor did a number of proofs in the Linear Algebra class. Though this was a difficult transition for her, she remembers the professor never treating her like she was unable do it. Because this college is a small school, all of the mathematics professors know who the students are. Therefore, the professor knew that she was simply a freshman in a junior-level class and that she had just not taken the "proofs" course yet. He provided encouragement and positive feedback to her to ensure her that this was the source of her difficulties in the course.

Paige feels like her experience as a mathematics major was a positive one. She enjoyed her mathematics classes more than any of her other classes, for the most part, even though she claims she spent much longer doing homework for her mathematics classes than her other classes. Through her time in college, Paige decided that she preferred applied mathematics to pure mathematics, and she especially enjoyed statistics. As a result, Paige has decided to go to graduate school to earn a Master's degree in statistics. At the time of the interviews, she had been accepted to a number of programs but had not yet decided which program she would choose. After earning her Master's degree, Paige plans to find a job working for a company as a statistical consultant.

Initially, Paige had no idea of what to do with her degree in mathematics. She admits, "I know there's a bunch of … hidden jobs where it doesn't say Bachelor's in math or whatever on the requirements… but I don't know what I would actually be eligible for." Once she decided that she wanted a career in statistics, Paige started looking into possible jobs by searching the internet and claims that she realized that to get a good job in statistics, she would need to get a Master's degree.

At the beginning of her junior year, Paige says that she was encouraged by her professors to apply for REU programs for that summer. An REU (Research Experiences for Undergraduates) is an NSF-funded program in which undergraduate students are funded to spend their summer doing research. There are currently 57 REU programs in the mathematical sciences and these programs tend to be very competitive. Paige ended up participating in an REU program in statistics. Her particular project was done in collaboration with a company to help them solve a real-life problem, which allowed Paige to contribute to mathematics in a real way. Prior to this, Paige had already decided that she wanted to leave academia and be in the "real world" and she felt like this REU experience really gave her a taste of this. The experience helped her to decide that working for a statistical company would be a good career for her. She claims, "I didn't know that you could do statistical modeling before I did this."

In addition to being encouraged to participate in an REU by the mathematics faculty, Paige also has received substantial encouragement and support from her advisor in applying for graduate school. He advised her to apply to a wide range of programs, including some really prestigious ones. This made Paige feel really good because she said that even though he was encouraging her to have a "back up," by suggesting that she apply to some competitive programs too, it demonstrated to her that he saw her as being a strong candidate.

Although Paige spoke of both advantages and disadvantages of attending a small college, she feels like some of the advantages were that she got to know her professors really well. She says that she talks with her mathematics professors at least once a week, but not about mathematics. They talk more about what REU or graduate programs that she has gotten into. She feels like the professors have shown a sincere interest in her. The mathematics faculty also host a dinner once a year for all the mathematics majors, but Paige has always had a conflict and has not been able to attend. Paige says that she liked her experiences as a mathematics major on this campus and really appreciated that everyone in the mathematics department knew her. She further makes a point to emphasize that they did not just know *of* her, but they knew her personality, too.

*The Case of Mandy*

Unlike Paige, Mandy did not decide to be a mathematics major until sometime during college. In all actuality, Mandy never really consciously made the decision to major in mathematics; she sort of just "fell into a math major," as she puts it. When beginning college, Mandy did not know what to major in. Because she had expressed an interest in mathematics, the college gave her an advisor in the mathematics department. Each semester her advisor encouraged her to take more mathematics (and science) classes. By the end of her sophomore year, she was required to choose a major. She had never expected to major in mathematics, but at this point she had already completed so many courses for that degree that she decided that it just seemed natural for her to choose that as her major.

Though no one in her family has earned a degree in mathematics before, Mandy's family has definitely shown an interest in working with numbers, since many of her family members are accountants or engineers. Mandy claims that often at her parents' house, she, her sisters, and her parents all fight over the puzzles in the newspaper. She says they all enjoy Sudoku and jigsaw puzzles as well. Despite her family's interest in such things, Mandy credits her interest in mathematics to the teachers that she had in high school, especially her A.P. Calculus teacher. During her last two years of high school is when Mandy feels like her interest in mathematics really began to develop.

Mandy took Calculus II her first semester in college. This class went really well for her since she had learned most of the material in her A.P. Calculus class in high school. She recalls, "I think it was helpful and kind of kept my confidence up in my math ability." During her sophomore year of college, Mandy had a similar experience to Paige in that she took a proof-based course in cryptography prior to having taken the "introduction to proofs" course. She remembers studying with a friend a lot in that class and they both worked with the professor a lot since neither had learned how to write proofs before. Mandy recalls that the professor knew they were both in this predicament and feels like he went out of his way to help the two of them be successful in that class.

Mandy has had both good and bad experiences with some of her mathematics classes and admits to sometimes thinking about switching her major. At the same time, she figures that she is so close to finishing her degree in mathematics, she may as well just keep going. She says though that sometimes she is not even sure she likes mathematics anymore. She explains that one reason she feels this way is because she does not know what she can do with a major in mathematics. She believes that the biggest challenge of being a mathematics major is not knowing what to do with the degree afterwards. Mandy feels like with other disciplines it is more clear-cut; all of her friends know what they are going to do with their degrees after they graduate. She says it is also hard because when people ask her what she is going to do with her degree, she has to tell them that she still does not know.

Although this is frustrating to her, Mandy was completing her junior year at the time of the interviews, and is hopeful that she will figure out what she wants to do when the time comes. Her advisor suggested that she apply to REUs to get ideas of what she might like to do. She applied to four of them. At the time of the interviews, she had heard back from two of them and had been accepted to both. She has decided to participate in an REU that has a focus in using mathematics to model biology. At this point, Mandy does know that she does not want to focus on pure mathematics, but would rather apply mathematics to other disciplines, so she feels like this program will be a good fit for her. Mandy recalls that when she told her advisor in the mathematics department that she got into one of the REUs, he told all of the other mathematics professors the news. She was amazed at how excited he was for her and remembers thinking, "Oh wow, dude, they're awfully excited."

Being accepted into this REU has really made a difference in Mandy's mathematics identity. When asked, Mandy says that she would not say that she is "good" at mathematics, just "okay." She admits though that now that she has gotten into some REUs, it has made her feel more confident with her mathematics abilities. "I'm not sure if math is for me; if I should continue with it. But I guess like having something to do for the summer makes me feel like I can succeed, so I think that's helping a lot." She also says that she thinks the mathematics professors at her college would say that she is good at mathematics.

Mandy says that she really likes the professors in the mathematics department and claims that this is part of the reason she decided to major in mathematics. She says the professors are all very approachable and personable and that they all know her name. This makes her feel more comfortable to ask questions in class and to ask them for letters of recommendation. They give her advice on what classes to take and have encouraged her to apply for REUs for the summer. Mandy says that she drops by the mathematics faculty offices at least once a week and peeks her head in just to say "hi" to the professors. She also thinks it is really neat that her advisor sometimes tells her stories from when he was an undergraduate and that once she went to his house for a game-night as an event through her church.

*The Case of Nicole*

Nicole became interested in mathematics as early as elementary school. She claims that none of her K-12 teachers were ever really an influence on her. Rather, Nicole believes that her father, a high school mathematics teacher, played the largest role in her interest in mathematics. She remembers him bringing home puzzles and logic games for her to do as a child. Nicole is very close with her father and considers him to be her biggest role model. This gave her a close connection to mathematics at a young age.

By fifth grade, Nicole was put a year ahead in mathematics and by eighth grade she was being bussed to the high school to take a high school geometry course. During her senior year of high school, Nicole took Calculus I and II at the local college. She remembers this being the first time mathematics was ever difficult for her. She explains though that she did not think of this as a bad experience, but simply as an adjustment. It was actually during her senior year of high school that Nicole made the decision to major in mathematics. Prior to that, she had thought about majoring in one of the sciences, like biology. When she began taking mathematics classes at the college level, however, she really enjoyed them. She felt like she received a lot of encouragement from her father on this decision.

Nicole has a strong mathematics identity and considers herself to be good at mathematics. She claims that the material in mathematics classes can be challenging, but then follows up by saying, "I didn't really have a lot of trouble with getting grades and that kind of thing. But I think *other* people maybe had trouble with that." She says that she knows mathematics is a challenging subject for most people, but that it is not extremely challenging for her.

When thinking about specific classes, Nicole remembers certain mathematics classes that she did not enjoy very much, but thinking back on her entire college experience as a mathematics major, she claims, "It was *all* a good experience." The thing that Nicole enjoys the most about being a mathematics major is the feeling of being able to do well in mathematics classes, and being able to do something that most people are not good at. She feels like there really was not anything she did not enjoy about the experience. "Even when it was *hard* I, I wouldn't say that I was *not* enjoying it."

Unlike the other two participants, Nicole did not communicate much with her mathematics professors outside of class. She claims that she normally only went to office hours about once a semester. Nicole claims that she did not go very often because she really did not have the need to go; she generally did not have specific questions to ask. She also says that she would not consider any of her mathematics professors as mentors to her since she did not communicate with them much and did not ask them for help with decisions.

Similar to the other two participants, however, Nicole initially did not really know what she wanted to do after college. She claims there are so many things one can do with a mathematics degree that it is overwhelming. At the same time, she seemed very unclear as to what those careers might be. Her father had discouraged her from becoming a high school mathematics teacher in their home state because of job instability, and she really did not know where to go from there. She had thought about a lot of different career options, such as engineering, physics, or veterinarian school. She decided though that careers in engineering and physics would be boring and that she wanted a career with more public interaction. As for veterinarian school, Nicole knew that veterinarian school is really hard to get into and felt like she had not taken the right classes to get in. In the end, she decided that she wanted to stick with mathematics.

One day while on Facebook, Nicole saw an advertisement for a program called “Math for America.” The program consists of one year of schooling, which would conclude with her earning an MAT. After that she would be required to teach in New York City public schools for four years. The program also has professional development opportunities and hosts social activities. Since Nicole really did not know what else to do after graduation, she decided to apply for this program. She felt like this program would be good for her because she would be able to earn her Master’s degree for free, plus the program pays quite well. Also, she would not have to commit to a life-long career now, since she really did not know what she wanted to do with her life yet.

Originally, Nicole was determined not to go into teaching. She had thought if she ever went into teaching, she would teach at the college level. She says that she definitely does not see herself remaining as a public school teacher for a long period of time. Nicole sees this opportunity as just that, an opportunity, and does not see this program as leading to a future career. At one point Nicole says she almost sees it as being “a big, long camp.” It almost appears that she is using this program as a way of putting off trying to decide what to do with her degree.

Despite her uncertainty with what she wants to do with her life, Nicole really never has asked for advice or guidance from her professors. She has asked for letters of recommendation once she had decided where to apply, but did not solicit advice prior to that. Even with her father, she often told him what she was thinking about doing, but he never gave her much advice or further suggestions of what else she could do. She really feels like she made most of her decisions all on her own, and she appears to be happy with that.

It is interesting that though all three participants were students in the same department, Nicole did not utilize the advising that was clearly available to her the same way as the other two did. Nicole had the same advisor as Paige, and Mandy had a different advisor, so we know that the difference is not a result of an over-zealous advisor. Furthermore, of the three participants, Nicole had the highest mathematics grades, highest college GPA, and highest ACT/SAT scores, so we doubt that the professors did not show interest in advising her. From conversations with her, we believe that the lack of advising she received was completely her choice.

## Discussion

From our data, we can see that “significant others” played a large part in the development of these women’s mathematics identities. Each of these women began developing a strong mathematics identity prior to entering college, which seemed to formulate as a combination of being successful in mathematics and being perceived as good at mathematics by others. While in college, all three of these women felt like their mathematics professors viewed them as high achieving, which contributed to their views of themselves as a “mathematics person.” Some of the women even spoke of their achievements, such as their acceptance into an REU program or a

Master's program, as a form of being recognized by others as someone successful in mathematics.

The role that meaningful others played in these women's development of their mathematics identities is consistent with the findings of Carlone and Johnson (2007) who determined that recognition by others was a key factor in the formation of science identities of women of color. Furthermore, Adhikari and colleagues (1997) found that the women in their study were more likely than men to report valuing the support of others as important to their success in mathematics. Because women are often socialized to want to please people, it may not be surprising that women tend to place a large emphasis on the recognition and support of others in the development of their mathematics identities.

Although the mathematics faculty at this liberal arts college played a large role in the development of these women's mathematics identities, there is another critical role that they played for two of these students. The faculty provided useful suggestions that helped these women determine what career options were available to them. All of the participants clearly stated that originally they did not know what they could do with a degree in mathematics other than teach. Furthermore, they had each made a conscious decision that they did not want to pursue K-12 teaching. The two participants who utilized the advising available to them were able to expand their knowledge about future career options, leading them to more informed and purposeful future career decisions. The participant who did not utilize faculty advising chose to pursue teaching despite her initial decision against it. This choice appeared to be more of a "stalling tactic" until she figured out better what other career options were available to her.

It is not uncommon for college students graduating with degrees in mathematics to not know what career options in mathematics are available to them. Piatek-Jimenez (2008) found that senior-level mathematics majors often are not aware of many potential careers and that they had a very shallow understanding of the careers that they were aware of. Therefore, regardless whether or not a student has a strong mathematics identity, if he or she does not know what careers exist, it will be difficult to enter a career in mathematics. Consequently, it is important for students not only to receive encouragement in mathematics but also to obtain career advising. Furthermore, our work suggests that more research programs, such as REUs, and internships in industry would serve the discipline of mathematics well in retaining our majors in the field.

# GENDER DIFFERENCES IN LUNAR-RELATED SPATIAL UNDERSTANDINGS

Jennifer Anne Wilhelm
Texas Tech University
jennifer.wilhelm@ttu.edu

*Gender differences were examined in spatial understandings of 70 females and 53 males who studied the Moon through observations, journaling, and geometric spatial modeling. Understanding was measured through analysis of pre/post-test results of a Lunar Phases Concept Inventory (LPCI) and a Geometric Spatial Assessment (GSA). Results showed both genders making gains on five of eight science LPCI domains and on three of four mathematics LPCI domains. Males scored significantly higher than females on the Geometric Spatial Visualization LPCI domain items. Females made gains on GSA domains, Periodic Patterns and Cardinal Directions, while males made only Periodic Patterns gains. The GSA filtered out understanding that might normally be missed.*

## Background

This research concerns an examination of gender differences in geometric spatial understanding of 123 middle school students after participation in an inquiry unit. The lessons within this unit were adapted from an integrated mathematics and science curriculum called Realistic Explorations in Astronomical Learning (REAL).

## Objective and Theory

Research has shown that students have difficulty understanding the cause of lunar phases (Abell, Martini, & George, 2001; Baxter, 1989; Lightman & Sadler, 1993; Trundle, Atwood, & Christopher, 2002; Zeilik & Bisard, 2000). "Instructors believe they have successfully taught lunar phases, only to find that the majority of students cannot answer questions related to the concept" (Lindell & Olsen, 2002, p. 1). The most common misconception of the cause of phases is the belief that the Earth casts a shadow upon the Moon. Fanetti (2001) stated that there was a correlation between students' ignorance of Moon-size, Earth-size, and Earth-Moon distance that feeds this misconception. Some researchers examined links between students' understanding of phases and spatial ability. For example, Reynolds' (1990) and Wellner's (1995) claimed that students were more likely to report a correct cause of phases when they had well-developed spatial skills. Others reported findings connecting spatial ability to success on assessments, such as the Force Concept Inventory (Hake, 2002) and molecular rotation exams in Chemistry (Pribyl & Bodner, 1987).

Mathematics education literature has well documented that males outperform females on assessment tasks that focus on spatial visualization (Ben-Chaim, Lappan, & Houang, 1988; Battista, 1990; Casey, Nuttall, Pezaris, & Benbow, 1995). Sex differences with regard to spatial ability were found in preadolescent children by Kerns and Berenbaum (1991). "Boys again performed better than girls on all tests. The sex difference was significant on Geometric Forms, Mirror Images, and 3D Mental Rotations" (p. 391). Linn and Petersen (1985) determined that males outperformed females at all age levels on mental rotation tasks and to a lesser extent on spatial perception tasks. Black (2005) "hypothesized that mental rotation is the most important in understanding Earth science concepts that are associated with common misconceptions" and stated that “humans are handicapped by their single vantage point from Earth of the moving bodies in outer space” (p. 403).

Therefore, based on this mathematics education literature, if males have better spatial skills than females, then males should show higher scores on science assessments that have spatial components. *Few studies speak directly to gender differences on lunar phases assessments.*

I claim that one cannot completely understand lunar phases without a developed understanding of four mathematical spatial concepts. The four mathematical concepts are defined within the context of its relation to lunar understanding. They are: (a) *geometric spatial visualization* (visualizing the geometric spatial features of the Moon/Earth/Sun system as it appears in space above/below/within the Moon/Earth/Sun plane), (b) *spatial projection* (projecting one’s self into a different Earthly location and visualizing from that global perspective), (c) *cardinal directions* (documenting an object’s vector direction from a given position, i.e. North, South, East, West, etc.), and (d) *periodic patterns* (occurring at regular intervals of time and/or space, i.e. periodicity of celestial orbits, phases, percent illuminated).

The first spatial term, geometric spatial visualization, has a mental rotation component since as one visualizes the Moon/Earth/Sun three-body system in space above/below/within, one must also manipulate and consider the motion of the system itself. The second spatial identity, spatial projection, not only includes the idea of visualizing the environment from one’s own reference point, but also visualizing the environment of another from their reference point. Spatial projection also has a mental rotation derivative since one must also mentally manipulate the movement of the sky throughout a day’s viewing due to the rotation of the Earth on its axis. The final two mathematical terms that are instrumental in understanding lunar related concepts are cardinal directions and periodic patterns. Learners must be able to distinguish cardinal directions in order to document an object’s vector direction in space as a function of time from a given position. The final mathematical term is that of periodic patterns. For this paper, periodicity comprises the idea of something occurring at regular intervals of time and/or space. Within the lunar context, some examples of periodic patterns materialize in lunar orbital cycles, illumination, and in altitude angles.

Giedd, Blumenthal, Jeffries, Rajapakse, Vaituzis, Liu, Berry, Tobin, Nelson, and Castellanos (1999) conducted a study with 145 normal children where their brains were scanned using magnetic resonance imaging at two-year intervals. The researchers found that although 95 percent of each child’s brain structure was formed by the age of 6, a second wave of brain development occurred in preteens just prior to puberty (age 11 in girls, and 12 in boys). Giedd et. al (1999) as cited in Bryce and Blown (2007) showed in their research that “different anatomical regions of the brain mature differently in childhood and typically by several years, e.g. favoring earlier development in girls for those areas which handle verbal fluency, handwriting, and face recognition; favoring earlier development in boys for those which handle spatial and mechanical reasoning, and visual targeting” (Bryce and Blown, p. 1657). These varied rates of brain development in girls and boys are of particular interest since the subjects in my study were of this preteen age where this newfound wave of brain development occurs. The following study was conducted with 123 US preteen (average age of 12), seventh graders.

## Methodology

This paper reports the effect gender has on measurable learning via an integrated mathematics and science, inquiry Moon unit adapted from a NASA/IDEAS funded curriculum called *Realistic Explorations in Astronomical Learning* (Wilhelm & Wilhelm, 2007). A veteran female teacher enacted the unit within her seventh-grade science classrooms with 70 females and 53 males during the Fall 2007 term. All lessons and activities were drawn from the REAL curriculum to accommodate the school district's mathematics objectives regarding using two-dimensional representations of three-dimensional objects to visualize and solve problems; and applying geometric ideas and relationships in areas outside mathematics, such as science. The district's science objectives concerning the relationship of the Earth's movement and the Moon's orbit to the observed cyclical phases of the Moon were also addressed.

In this seven week unit, which purposefully included spatial geometric activities, students explored the lunar phases through observation, journaling, sketching, two- and three-dimensional modeling, and classroom discussions. The lunar unit began with students conducting daily Moon observations. Students were expected to record in a journal at least two sentences per daily entry to communicate what they viewed regarding the Moon and sky. Further explorations focused on geometric configurations and scaling of the Earth/Moon/Sun system, where students modeled these geometries in both two and three dimensions. In-class lessons were conducted where students, working in groups, used modeling techniques and ratio concepts to discover the number of Earth diameters between the Earth and the Moon. The general method of teaching was inquiry-based, and most student groups were self-selected and gender-mixed.

After daily Moon observations had ceased, student journals were completed and a guest instructor guided the students through a "Moon finale". The Moon finale was a hands-on modeling activity in which students were asked to create the geometric configuration of the Earth and Moon (Styrofoam balls), given a fixed Sun (overhead projector light), for a number of chosen Moon's phases. This three-dimensional (3-D) modeling was followed with a two-dimensional (2-D) drawing activity where students represented their 3-D configurations within a 2-D (paper and pencil) space.

This study was quantitative where data collection involved the administration of the Lunar Phases Concept Inventory (Lindell & Olsen, 2002) and the Geometric Spatial Assessment (Wilhelm, Ganesh, Sherrod & Ji, 2007), pre- and post-implementation. The LPCI assesses eight science and four mathematics domains (see Table 1).

Table 1. *LPCI Domains*

| Scientific Domains | Mathematical Domains |
|---|---|
| **A-**Periodicity of Moon's orbit | Periodic Patterns |
| **B-**Periodicity of phases | Periodic Patterns |
| **C-**Moon's direction around Earth | Geometric Spatial Visualization, Spatial projection |
| **D-**Moon Motion | Cardinal directions |
| **E-**Phase and Earth/Moon/Sun positions | Geometric spatial visualization |
| **F-**Phase-sky location-time | Cardinal directions |
| **G-**Cause of phases | Geometric spatial visualization |
| **H-**Phase effect with location change | Spatial projection |

This research focused on the development in students' mathematical and scientific content knowledge from pre- to post-implementation. Questions pursued were:

1) What lunar-related mathematics and science content knowledge will be developed by students through inquiry experiences?

2) What gender differences will be observed in learned, lunar-related mathematics and science content knowledge?

The GSA (a 16-item, multiple choice test) was administered pre and post implementation for the purpose of filtering out mathematical spatial understandings of the same four math domains shown in table 1, *but not posed within a lunar context*. Example GSA test items are shown in figure 1.

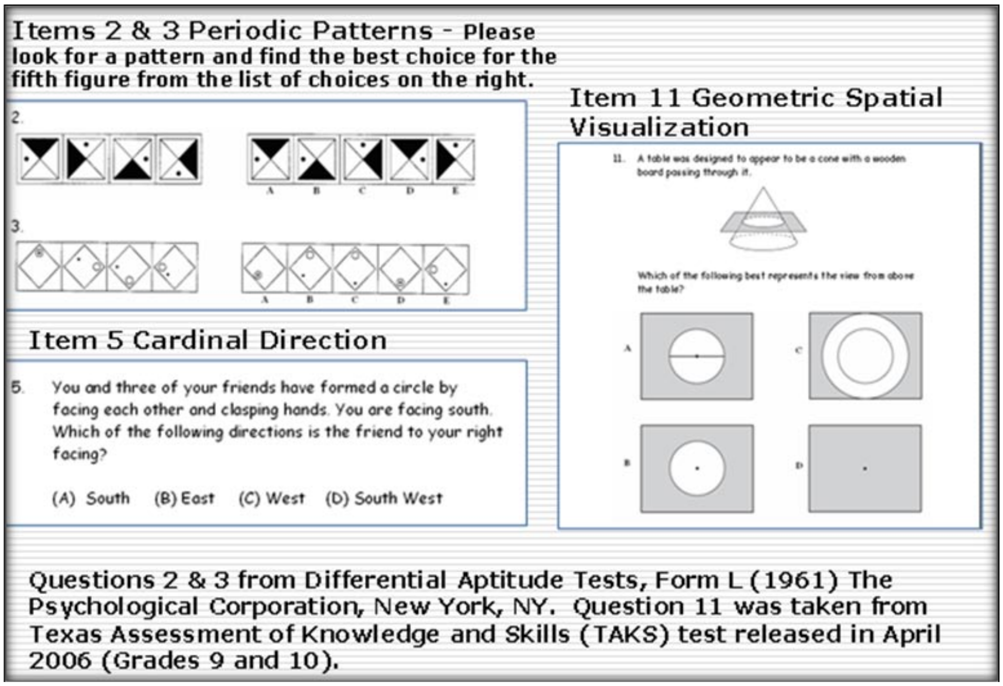

*Figure 1*. Example Geometric Spatial Assessment Test Items – Items 2 & 3, 5, and 11 that assess math domains periodic patterns, cardinal directions, and geometric spatial visualization, respectively.

## Data & Analysis

*LPCI Results*

The LPCI pretest was given to 53 males and 70 females prior to any observations and the posttest was administered seven weeks after the initial lunar viewing. The mean pretest score was 31.2% correct and the mean posttest score was 52.9% correct. A repeated measures ANOVA revealed a significant increase in the mean values from pre to post on overall test scores, $F(1,122) = 288.5$, $p < 0.001$, partial $\eta^2 = 0.703$. A one-way ANOVA showed no significant difference between groups on the pre-LPCI scores, $F(1, 122) = 3.816$, $p = 0.053$. Both groups made similar significant overall gains from pre to post. The significant percentage gain score for males and females were 23.6% and 20.2%, respectively. A one-way ANOVA showed a significant difference between groups on the post-LPCI scores, $F(1, 122) = 10.133$, $p = 0.002$, mainly due to males scoring 24.8% higher than females on domain E (science-*phase and*

*Sun/Earth/Moon positions*, mathematics-*geometric spatial visualization*) of the posttest (see Table 2).

To test for significant differences from pre to post on individual domains, a repeated measure ANOVA was conducted. Results showed males and females making similar significant gains on science domains: A (*period of orbit*), B (*period of phase cycle*), C (*direction of orbit*), and G (*cause of phases*); and on mathematics domains: *periodic patterns* and *spatial projection* (Tables 2&3).

The largest gender gap was found to exist within the LPCI-domain E (science-*Phase-Earth/Moon/Sun positions*, math-*geometric spatial visualization*). No significant increase in understanding by any group was observed on concept domains F (science-*Phase-sky location-time*, math-*cardinal direction*), D (science-*Moon motion*, math-*cardinal direction*), or H (science-*Phase effect with location change*, math-*spatial projection).*

** $p < 0.001$

*GSA Results*

The purpose of the GSA was to filter out spatial understandings that were not posed within a lunar context. The GSA pretest was given to 54 males and 67 females prior to any observations and the posttest was administered eleven weeks after the initial lunar viewing. The mean pretest score was 49.4% correct and the mean posttest score was 56.2% correct. A repeated measures ANOVA revealed a significant increase in the mean values from pre to post on overall scores, $F(1,120) = 21.29$, $p < 0.001$, partial $\eta^2 = 0.151$.

A one-way ANOVA showed a significant difference between gender groups on the pre-GSA scores, $F(1, 120) = 6.322$, $p = 0.013$. The significant percentage gain scores from pre to post for males and females were 5.8% and 7.5%, respectively. A one-way ANOVA showed no significant difference between groups on the post-GSA scores, $F(1, 120) = 3.125$, $p = 0.08$.

To test for significant differences from pre to post on individual GSA domains, a repeated measure ANOVA was conducted (Table 4). Results showed males and females making similar gains on geometric spatial visualization and spatial projection, although neither was significant. However, with genders combined, there was a significant increase in means from pre to post for geometric spatial visualization. Males and females achieved significant gains on periodicity where males made a 7.9% gain while females scored a 10.5% gain. Females' gain score nearly doubled that of males' for cardinal direction (males-insignificant 7% gain; females-significant 12% gain). While the interaction effect between gender and time was not significant, one cannot help but notice a closing gap from pre to post between males and females. Although females scored lower than males on every pre-GSA domain, females made gains that brought each of their post-domain items up to or beyond those of the males' pre-scores.

There appears to be inconsistency when comparing the results of the LPCI- and GSA-mathematics domains. For example, all LPCI mathematics domains showed both groups making significant gains from pre to post *except* for the math domain, cardinal direction. However, females made significant gains from pre to post on the GSA-domain, cardinal direction. In order to understand how this might be possible, one must examine the LPCI items that have the embedded cardinal direction domain. For example, LPCI item-1 requests the learner to consider a waxing crescent Moon in the sky immediately after sunset. One would need to know the Sun had just set in the west and that since the crescent Moon was still visible, it would be close to setting in the western sky as well. In order to choose the correct response, the learner would have to take into account the moving setting Sun and Moon, and realize the rise and set times of a waxing crescent Moon. The GSA did its job of filtering out the mathematics of only cardinal direction (i.e., not posed within a lunar context) and assisted in showing measurable understanding of this concept whereas the LPCI did not.

Table 4. *Percentage Correct on Pre-Post by GSA Domain*

| Mathematics Domain | All % | | | Male % | | | Female % | | |
|---|---|---|---|---|---|---|---|---|---|
| | Correct Pre (SD) | Correct Post (SD) | Gain | Correct Pre (SD) | Correct Post (SD) | Gain | Correct Pre (SD) | Correct Post (SD) | Gain |
| Periodic Patterns | 52.9 (23.3) | 62.2 (25.2) | 9.3** | 58.8 (22.8) | 66.7 (24.3) | 7.9* | 48.1 (22.7) | 58.6 (25.6) | 10.5* |
| Geometric Spatial Visualization | 55.8 (29.9) | 61.8 (28.3) | 6.0* | 58.8 (28.0) | 64.8 (30.5) | 6.0 | 53.3 (31.3) | 59.3 (26.4) | 6.0 |
| Cardinal Directions | 46.5 (27.3) | 56.2 (26.3) | 9.7* | 49.5 (29.3) | 56.5 (26.2) | 7.0 | 44.0 (25.4) | 56.0 (26.5) | 12.0* |
| Spatial Projection | 42.6 (23.2) | 44.6 (23.7) | 2.0 | 45.8 (23.7) | 48.2 (24.2) | 2.4 | 39.9 (22.6) | 41.8 (23.2) | 1.9 |

*$p < 0.05$; **$p < 0.001$

The other apparent contradiction concerns spatial projection. Both genders made significant gains from pre to post on this LPCI-domain. However, the GSA-domain of spatial projection showed neither males nor females scoring significantly higher from pre to post. Upon examination of the GSA questions assessing this domain, it was found that the questions did not appropriately filter out the spatial projection concept. For example, GSA test item-13 requests the learner to consider two boats approaching a Texas flag (one approaching from the east and the other from the west). "*The captain on the boat approaching from the east saw the star on the Texas flag to be on the right side of the flag, what side of the flag would the captain of the other boat observe?*" This question not only had the spatial projection domain embedded, but also cardinal direction. The question was easily modified by replacing east/west with right/left.

## Conclusions and Importance

No significant increase in understanding by any groups was observed on concept domains F (science - *Phase – sky location-time;* math - *cardinal direction*), D (science - *Moon motion;* math - *cardinal direction*), and H (science - *effect of lunar phase with change in Earthly location;* math – *spatial direction*). This needs to be considered as the integrated unit within the REAL curriculum is modified.

This research indicates that mathematics and science learning of lunar related concepts can be significantly improved by both sexes in an inquiry environment. Even though the males scored significantly higher (from pre to post) than females on the LPCI domains concerning geometric spatial visualization, both groups made the highest gain scores in this LPCI mathematics domain. Males and females made similar significant gains on science domains: A (*period of Moon's orbit around Earth*), B (*period of Moon's cycle of phases*), C (*direction of Moon's orbit*), and G (*cause of lunar phases*), and on LPCI mathematics domains*: periodic patterns* and *spatial projection*. The LPCI pre-tests showed no significant difference between gender groups at the $\alpha = 0.05$ level; however, the LPCI post-tests did show a significant difference between groups. This significant difference between groups was mainly due to science domain E (*phase and Sun/Earth/Moon positions*) where males scored an 18.1% higher gain score than females, and due to the mathematics domain, *geometric spatial visualization*, where males scored a 10.3% higher gain score than females. More research is needed to better understand why males seem to perform significantly better than females on this particular domain, but this finding also seems to be consistent with the Bishop (1996) research results. Perhaps this finding can be explained by the faster maturation rate (during these particular years of development) of the male brain's anatomical regions which handle spatial visual reasoning as reported by Giedd et. al (1999). Both males and females achieved significant gain scores on the GSA periodic patterns domain, while only females scored significantly higher from pre to post on GSA cardinal direction domain. Females had scored significantly lower than the males on the pre-GSA, but the gap narrowed by the time of post-GSA where no significant difference between gender groups was observed.

This research is unique because it will further the literature concerning students' lunar related mathematical and scientific understandings, especially regarding gender differences. The development of the GSA helped to filter out understanding that might normally be missed within a science classroom.

# BLENDING PERSPECTIVES: STUDENT MEDIATIONS OF GEOMETRIC AND NUMERIC REASONING TO MAKE SENSE OF SIMILARITY AND SCALE

Dana C. Cox
Miami University
dana.cox@muohio.edu

*Although studies have documented student difficulties with similarity, a gap exists between documented visual insights of younger children and the quantitative inadequacies of older ones. This study investigated the intermediate strategies used by middle school students to construct rectangular and non-rectangular similar figures. Seven types of construction strategies were identified which indicate that multiple types of reasoning were used. Results suggest that visual perception is not entirely primitive and the consideration of visual perception as a powerful indicator and supportive extender of conceptual understanding is warranted. Experiences with scaling complex figures may encourage students to bridge intuitions and numeric strategies.*

## Rationale and Purpose of the Study

Research studies have shown repeatedly that similarity is one of the most difficult contexts for proportional reasoning (e.g. Kaput & West, 1994). Even young students have useful visual intuitions about proportion (e.g. Lehrer et al., 2002). However, studies also document the quantitative inadequacies of the older ones (Hart, 1988). Karplus, Pulos, & Stage (1983) highlighted this disconnect by documenting that students struggle to remember and utilize procedures and symbolism for numeric strategies, which seem to replace rather than extend visual perceptions and intuition. Studies have been done to characterize the nature of this student difficulty (Chazan, 1987), but the gap remains.

In strictly numerical contexts for proportional reasoning, this gap between useful intuitions and mature proportional reasoning has been narrowed, and work has been done to identify intermediate qualitative strategies such as building up, norming, or unitizing (Lamon, 2007). The identification of these strategies gives us some power to hypothesize about intermediate conceptions of similarity; however, these strategies are not entirely translatable to a geometric context. Given the position of similarity at the crossroads of geometric and proportional reasoning, it is likely that the progression of students from visual to *proportional thinker* (Cramer & Post, 1993) can be better described if, in addition to attending to numeric proportional reasoning, we acknowledge that students also bring geometric and spatial understanding (van Hiele, 1986) to bear on similarity tasks. In a review of middle-grades texts, it was found that similarity tasks often include only simple polygons such as rectangles or triangles (Lo, Cox & Mingus, 2006). In further study (Cox, Lo & Mingus, 2007), it was hypothesized that scaling these figures did not help students understand the continuous all-directional nature of scaling but instead focused on isolated instances of scaling.

Although the research literature suggests that students struggle to develop abilities to reason proportionally and to make sense of similarity, the fact remains that some students actually do develop these abilities. How these students advance from using visual and additive reasoning strategies to using multiplicative proportional reasoning on similarity tasks is an open question. Before we can study the transition, however, we must admit that we have only incomplete theories about what intermediate student strategies would look like on these tasks. Lamon (1993) argues for

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

research that identifies the ideas that students have that contribute to proportional reasoning, and investigates the contexts and models that "offer more explanatory power" (p. 42) to students in their work.

This study is focused on identifying and describing potential extenders for visual intuitions about scale by analyzing the strategies that students use during clinical interview to construct similar figures. Results are shared here in answer to the questions:

1. What strategies do students use to construct similar figures and what types of geometric and numeric reasoning are indicated by these strategies?
2. How does the complexity of the figure to be constructed influence student reasoning about construction?

## Theoretical Perspective

This study assumes a constructivist perspective on the inquiry into student conceptions and the modeling process. This has two implications for the study at hand. First, there is the direct implication that without observations of students themselves, no theory can stand apart from the limitations of the mathematical understanding and biases of the researcher (Cobb & Steffe, 1983). By observing students interacting with the ideas behind the theory, we open the theory up to the unexpected (Cobb & Steffe, 1983). Thus, the method of clinical interview (Cobb & Steffe, 1983) was chosen as the primary method of data collection.

The second implication is in registering the significance of the data that are collected. It is possible to have as a goal the empirical vetting of a theory, marking instances where the predictive power is great and where it is not. However, another goal, responds to Vergnaud's (1987) challenge to "understand better the processes by which students learn, construct or discover mathematics and to help teachers, curriculum and test devisers, and other actors in mathematics education to make better decisions" (as quoted in Confrey & Kazak, 2006, p. 311).

## Theoretical Framework

Proportional reasoning has been investigated through two major types of tasks: comparison tasks and missing value tasks (Lamon, 1993, 2007). Lamon (1993) outlined a conceptual progression for the development of proportional reasoning that stemmed from visual and intuitive solutions growing through successful preproportional strategies up into mature proportional reasoning. This progression was useful in describing and organizing the numeric strategies that were used by students during interviews. However, because students begin with a visual intuition about similarity, it is insufficient to focus only on instances of numerical proportional reasoning in student strategies. In order to capture other forms of reasoning that students may use on similarity tasks, it was imperative that a geometric lens also be used. van Hiele's descriptions of reasoning at levels 0 and 1 provided such a lens while analyzing student strategies on these tasks.

## Methodology

*Population*

A population of students in a Midwestern, urban school district was identified to target racial, economical, and academic diversity. The inclusion of diversity in the sample for study was not intended to highlight differences between groups of students, but rather to ensure that a broader extent of prior student experience and knowledge is included in the results. For example, students from urban areas may have significantly different experiences related to geometric proportionality (such as reading bus maps) that influence conceptions of scale or correspondence. Alternatively, lower socio-economic status may indicate a more limited access to technology, photographic or otherwise, and a different repertoire of imagery that others take for granted. Furthermore, because the majority of student data related to research on proportion and similarity are more than a decade old (Lamon, 2007), it is likely that technological advances, such as the availability of publishing software, photo enlargement machines, and multi-dimensional video gaming systems may alter potential student imagery and visual acuity, and provide a more fertile ground for developing quantitative strategies.

*Data Collection*

An assessment, the revised Similarity Perception Test (rSPT), was administered to a group of 91 seventh-grade students for sampling purposes. This instrument provided information about students' visual perception of shape, correspondence, and size transformation and helped to divide students into subgroups according to their responses. A stratified purposeful sample (n=21) that included the most common as well as unique response patterns was selected for task-based interviews. This method of sampling intentionally included individuals who exhibited varying abilities, perceptions, and strategies.

During the interview, students were given up to six construction tasks. Each task involved one of three different shapes shown in Figure 1: a rectangle with an embedded square, an L-shape, or a heart. Students were asked to draw an enlarged or shrunken version of the figure with a given scale factor (*k*) and in most cases were given a scale factor, generally 2. All students started with the rectangle with the embedded square task. If successful, students were given another version of the task. In this case, students were asked to draw another version of the figure "somewhere in the middle" of the original size and the size of the image. It was notable that many students applied different strategies to scaling the rectangle and scaling the square embedded in the rectangle. Thus, during analysis, tasks involving this figure were analyzed in two distinct parts: scaling the rectangle (Double Rectangle/Middle Rectangle) and scaling the embedded square (Embedded Square (*k*)/Embedded Square(M)).

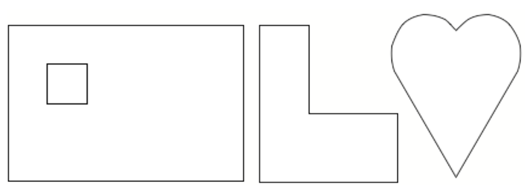

*Figure 1.* Figures depicted in construction tasks.

*Data Analysis*

Interviews were transcribed using Transana (Fassnacht & Woods, 2005), a software package used to transcribe and organize data. Student constructions, including drawings and measurements, were all digitally scanned. Analysis started with individual responses to individual tasks. It is possible that one student used two distinct strategies on one task. In this event, both strategies were analyzed separately. Descriptions of each strategy used by each student on each assigned task were written. All of the strategies used by an individual student were compared, noting similarities and differences in particular uses. Then, all of the strategies used on each individual task were compared in the same way. In order to validate these general descriptions and types, they were compared again to original student responses and revised when necessary. General strategy types were then devised to organize the strategies. The theoretical framework described above also helped to order the types with respect to the sophistication of implied reasoning.

## Results

In this section, I will provide the results relevant to the research questions stated earlier. I will first describe the seven identified types of construction strategies. Although defined here, there is not space here to elaborate on each of the strategies observed. More detailed illustrations will be provided during the presentation. Second, I will present an overview of the strategies used on each of the tasks to gain insight into how the figure may influence the strategies selected and reasoning used.

*Strategy Types*

Seven construction strategy types were observed in this study: Avoidance (AV), Additive, Visual, Betweening, Pattern Building (PB), Unitizing, and the Functional Scaling strategy (FS). Two of the seven strategy types, *Avoidance* and *Additive*, were similar to strategies documented for proportional reasoning. Reponses that indicated no meaningful engagement with the problem were considered indicative of an avoidance strategy. Responses that featured students scaling lengths using a constant additive approach were considered indicative of a classical additive strategy resembling those documented by Lamon (1993) and many others.

There were other strategy types described in the literature that diverged from standard in the case of similarity. For example, a *visual* strategy was identified by Lamon (1993) as a primitive approach to proportional reasoning and was aligned with the additive strategy as non-constructive. However, in the context of similarity, there was cause to differentiate this strategy more from an additive approach. The main distinction between additive and visual strategies is that visual strategies in this context can indicate sophisticated conceptions of proportional growth, and can be quite constructive. While it is true that for some students, a visual strategy is more akin to a guess, this is certainly not the case for all students. Visual strategies can incorporate a range of simple to sophisticated concept imagery regarding the constant of proportion, correspondence, and dilation. The additive strategy is more accurately depicted as primitive and non-constructive.

Elaine's construction of an enlarged heart in Figure 2 is an illustration of how intuitive conceptions of proportional growth can be constructive. In this image, the original heart was traced and a larger version was constructed around the outside like a frame. Elaine's image was reasonably similar to the smaller original heart and was based on only visual measurements. *"All I did was look at the heart; the design of what it was drawn. I looked at it while I was drawing, too. I was trying to make it exactly like it was."*

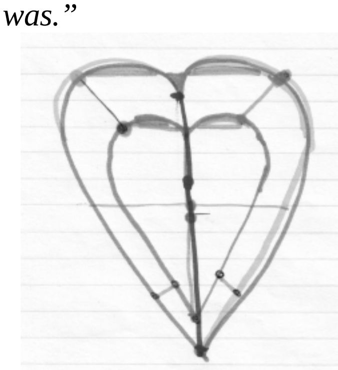

*Figure 2.* Elaine scales the heart.

Elaine's concept imagery related to dilation was robust and did not occur accidentally or by chance. This was not the only instance where Elaine demonstrated her intuitions about geometric proportion and dilation, which were remarkably reliable. Elaine's drawings, Figure 2 included, illustrated intuitions she has about correspondence and the implications of this intuition on the way she visualized scaling. The correspondence lines between the two hearts that Elaine drew in Figure 2 were not constant in length. While not made explicit during the interview, this might illustrate an informal understanding of proportion—the distance between corresponding points on the original and image depends multiplicatively on the distance the original is from the point of dilation. Elaine suggested in another situation that when this distance was held constant, the result was visually displeasing to her and that the original and scaled figures did not look like the same shape. This type of intuition was not evident when a student took an additive approach and accepted the result.

In some cases, it was apparent that students were making use of visual judgment to mediate numeric strategies. This combination of numeric and visual reasoning was indicative of a new type of strategy, *Betweening*, which is characterized by the remediation, both during and post-construction, of a numeric strategy so that it conforms to visual expectations. Betweening was used primarily, though not exclusively, to remediate a constant additive construction. Students, noticing distortion in their constructions, adjusted side lengths so that they varied by different additive amounts.

*Pattern-building* is an umbrella term for the use of oral or written patterns without indicating an understanding of the functional nature of the scale factor. In the context of construction, three pattern-building strategies were observed: Angle-matching, Median Length Finding, and Tiling. All of these strategies require the use of existing angles, lengths and shapes as tools in constructing a new shape. In the case of Median Finding, the lengths of a shape become numeric tools by which a student can interpolate intermediate lengths of similar figures. In all three cases there were limitations of the applicability and reliability of the strategy.

*Unitizing* and *Functional Scaling* were the most sophisticated strategies observed. Unitizing, as observed in this study, is closely related to tiling, but differs in that a student acts on lengths as units rather than entire figures. In addition, it is not limited to use with figures that tile the plane. Students using the Functional Scaling strategy multiplied select original lengths (dimensional, secondary, and space) by the identified or indicated scale factor to determine corresponding image lengths before construction. Students knew how long the lengths would be before they even began drawing them. This is not always the case when students used pattern-building strategies or even unitizing strategies.

*Overview of Strategy Use*

If a student was successful with a given strategy, it is possible to imagine that they would continue to use this strategy regardless of the figure they were constructing. This was not the case. Students who were successful using a Functional Scaling strategy on the first task did not necessarily do so on all of the tasks. In fact, most ($n=17$) students were able to apply the Functional Scaling strategy on the double rectangle task yet only four out of twenty-one students used Functional Scaling exclusively. As the figures became more complex and as the scale factors were changed from whole numbers to non-whole numbers to numbers less than 1, fewer students applied the strategy and began to use other types tempered by visual judgment. At the point where the strategy broke down, students utilized less sophisticated strategies, or made modifications to their constructions using visual judgment. Visual judgment, used in concert with other strategies, was used as a tool for mathematical reflection and evaluation.

For example, Andre applied the strategy on three out of five tasks, but resorted to a visual strategy when embedding the square in the medium rectangle and when scaling the heart figure. Andre's drawing of the embedded square is shown in Figure 3. His difficulty is more related to spatial reasoning rather than a lack of proportional reasoning. He applied a scale factor (1.5) functionally to all edges of whole-number lengths, but did not transfer that strategy to the space between the square and the rectangle. All attempts at placing the square within the rectangle were done visually, and the square changed in dimension to accommodate his visualization as he made three attempts at moving the location—each attempt shown in this figure.

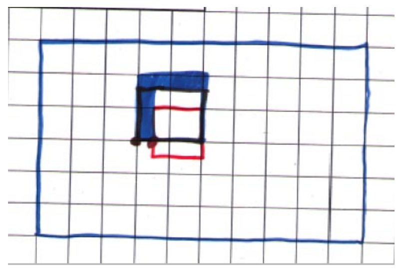

*Figure 3.* Andre attempts embedded square (M).

This leads us to the second research question regarding the influence of the complexity of the figure. In Figure 4, profiles of the strategies used on each task are compared. When organized by task rather than individuals, the strategy profiles are also varied in both unexpected and expected ways. For example, the two L-shape tasks should have skewed results. Only students who indicated using an additive strategy on some or all of their previous responses were asked to double the L-shape. Thus, it is expected that the profile for this task would be skewed toward less sophisticated strategies. Only students who had shown proficiency on other tasks or who finished tasks more quickly were asked to reduce the size of the L-shape. Thus, it is expected that the profile for this task would be skewed toward more sophisticated strategies. In fact, neither skew is observed. Reducing the L-shape inspired the greatest variety of strategies with no single strategy dominating student responses. Doubling the L-shape did have the highest frequency of additive strategy use, but this is to be expected. A few students used a visual approach, but students tended to favor the Functional Scaling strategy—even if, like Chris, they did not use Functional Scaling on previous tasks.

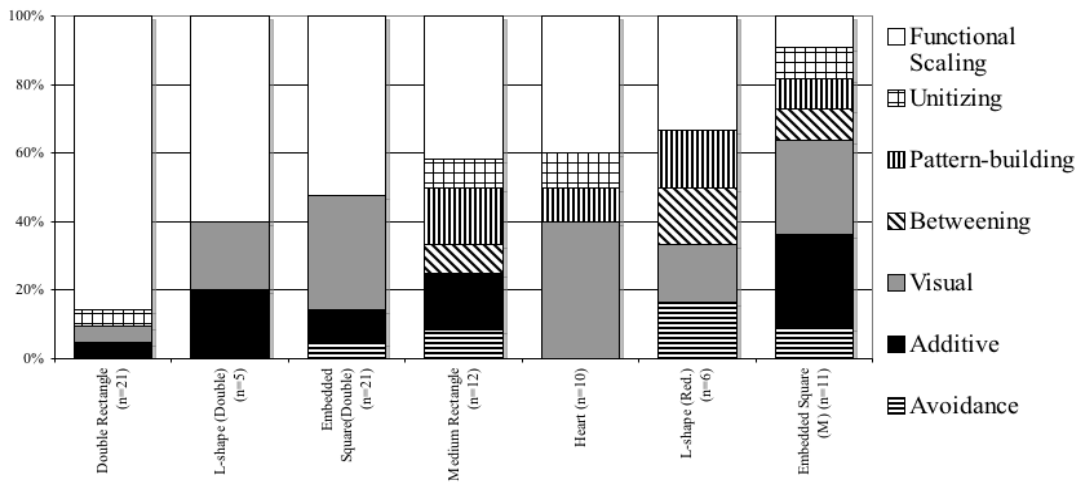

*Figure 4.* Summary of strategy by task.

The tasks incorporating whole scale factors (DR, L-shape [Double], Embedded Square [Double]) are clustered at the top end when the profiles are ranked according to the percentage of students utilizing the functional scaling strategy. As the scale factors change to non-whole numbers, fewer students utilized this strategy in lieu of a variety of other strategies. A smaller percentage of students (42%) utilized the functional scaling strategy on the Medium Rectangle (MR) task, a task that is different from the DR task only in scale factor. No students avoided solving the DR task, but this behavior emerged in the MR profile along with the pattern building strategy. Pattern building emerged as a strategy on the MR task even though it was not used on the DR task; it was a strategy used by students to reduce the L-shape but not to double it. In fact, on the L-shape Reduction task, a task that incorporated non-whole factors less than 1, there was much variety in student strategies. No particular strategy type seemed more prevalent than any other.

On the other end of the proposed spectrum were students who utilized a visual strategy. The number of students who utilized a visual strategy did not seem to be impacted by a non-whole scale factor. On tasks where students used whole and non-whole factors to scale the same figure, the frequencies of visual strategies were remarkably close. However, more variation is noticed when tasks of differing figure type are compared. Very few students used visual strategies to scale each of the rectangles, but 40% of students used a visual strategy on the heart task, 27% of students used a visual strategy to embed squares inside the double rectangle, and 36% to embed squares inside the medium rectangle.

## Discussion

To return to the original research questions regarding the strategies students choose to use when constructing similar figures and the influence of the complexity of the figures on reasoning used, two conclusions are possible. First, students in this study used a variety of construction strategies that have not been previously classified according to existing research frameworks including some that seemed to mediate numeric strategies with visual judgment or reasoning. The seven types of strategies are related to the literature on intermediate strategies for proportional reasoning, but as hypothesized, indicate as well the use of geometric and spatial reasoning.

Second, the complexity of the figures to be scaled did influence the strategies and reasoning types used by students. Depending on the nature of the figure being constructed, students were required to attend to a variety of characteristics including angles and different lengths of different varieties. The three figures (rectangle with embedded square, L-shape, and heart) used incorporate *primary*, *secondary,* and *gap* lengths. Primary and secondary lengths are both measurements of drawn lines within the figure, generally edges. A *primary* length is a length that defines the height or width of the entire figure. In the case of the rectangle, all four edges were defined as primary because they frame the figure and determine both horizontal width and vertical height. All other lengths including edges or drawn lines within the figure are *secondary*. A *gap* length measures the width of a gap in the figure not represented by a drawn line.

By increasing the complexity of the figures in the interview protocol, it was possible to manipulate the characteristics that students are required to attend to. One interpretation of the variance in the use of visual strategies is based on this complexity. As the lengths to be scaled became more oriented toward secondary and space lengths and away from primary lengths, the visual strategy was used more frequently. Furthermore, students who began with a numeric strategy—whether additive or multiplicative—utilized their visual judgment to mediate these strategies when the resulting image did not match their expectations.

These conclusions suggest that visual perception is not entirely guess-related or primitive in this context for proportional reasoning. Two implications follow. First, the consideration of visual perception as a powerful indicator and supportive extender of conceptual understanding in this area might be warranted. Second, there is strong evidence that providing students with complex figures to scale may encourage students to mathematise their visual perceptions and increase their ability to attend to the quantifiable features of shape and the numeric relationships between then.

# ELEMENTARY CHILDREN'S 3-D VISUALIZATION DEVELOPMENT: REPRESENTING TOP-VIEWS

Jacqueline Sack
University of Houston Downtown
jackiesack@gmail.com

Irma Vazquez
University of St. Thomas
irmavazquez@sbcglobal.net

*The Spatial Operational Capacity* (*SOC*) *framework* (*Yakimanskaya, 1991; van Niekerk, 1997*) *guides a long-range design research study to develop spatial skills in elementary-age childrenusing Geocadabra, a dynamic computer interface. Learners engage in activities that move among 3-D models, 2-D conventional and semiotic* (*abstract*) *representations, and verbal descriptions of figures. In this presentation, we focus on children's development of top-view coding as they engage in activities that move among the SOC representations, their extension of this knowledge to invent non-conventional numeric coding systems and their spontaneous connections to their daily mathematics programs. Social-constructivist instructional approaches undergird the classroom ecology.*

## Introduction

This paper, written in the voice of researcher, A, demonstrates how 3rd and 4th grade children developed mastery at top-view coding to create assembly puzzles to challenge each other and invented their own coding systems to account for holes and overhangs in figures they constructed using loose cubes and Soma pieces (Weisstein, 1999). We share how they continued to use the coding to create assembly diagrams for 3-D figures and recognized connections to other strands in their everyday mathematics curriculum. The ongoing study is conducted in a dual-language urban elementary school within one of the largest public school districts in the mid-southwestern United States.

## Theoretical Frameworks and Perspectives

*Spatial Visualization*

The National Research Council's report, *Learning to Think Spatially* (2006), identifies spatial thinking as a significant gap in the K-12 curriculum, which, they claim, is presumed throughout but is formally and systematically taught nowhere. They believe that spatial thinking *is* the start of successful thinking and problem solving, an integral part of mathematical and scientific literacy. The National Council of Teachers of Mathematics' *Principles and Standards for School Mathematics* (NCTM, 2000) supports this view. In their early years of schooling, students should develop visualization skills through hands-on experiences with a variety of geometric objects and use technology to dynamically transform simulations of two- and three-dimensional objects. Later, they should analyze and draw perspective views, count component parts, and describe attributes that cannot be seen but can be inferred. Students need to learn to physically and mentally transform objects in systematic ways as they develop spatial knowledge. From a purely academic perspective, the importance of visual processing has been documented by researchers who have examined students' performance in higher-level mathematics. For example, Tall et al (2001) found that to be successful in abstract axiomatic mathematics, students should be proficient in both symbolic and visual cognition; Dreyfus (1991) calls for integration across algebraic, visual and verbal abilities; and, Presmeg (1992) believes that imagistic processing is an essential component in one's development of abstraction and generalization.

*Spatial Operational Capacity Framework*

The spatial operation capacity (SOC) framework (Yakimanskaya, 1991; van Niekerk, 1997) that guides our study exposes children to multiple representations through activities that require them to act on a variety of physical and mental objects and transformations to develop the skills necessary for solving spatial problems.

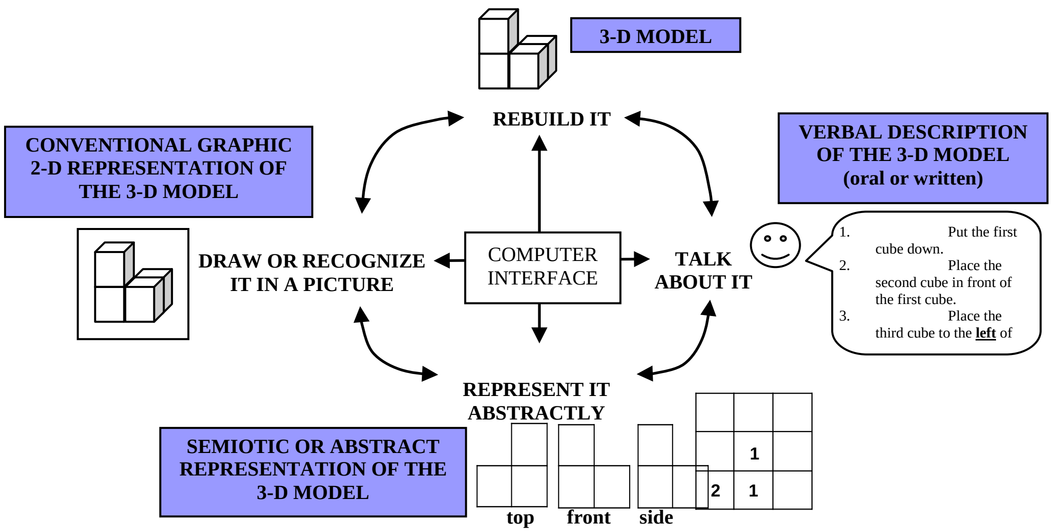

*Figure 1.* Multiple representations within 3-D visualization.

The SOC model (see Figure 1) uses:

- *full-scale* figures, that, in our study, are created from loose cubes or Soma figures, made from 27 unit cubes glued together in different 3-cube or 4-cube arrangements (see Figure 2);
- *conventional-graphic* 2-D pictures that resemble the 3-D figures;
- *semiotic* representations (Freudenthal, 1991) such as front, top and side views or numeric top-view codings that do not obviously resemble the 3-D figures; and
- *verbal* descriptions using appropriate mathematical language (Sack & Vazquez, 2008).

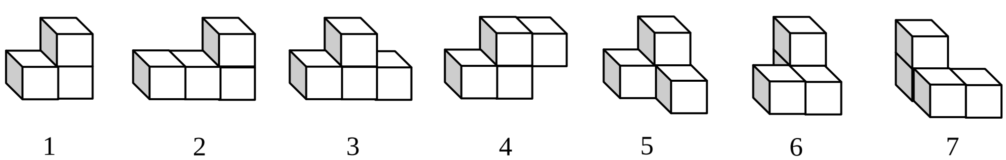

*Figure 2.* The Soma set can be made by gluing unit cubes together.

We also utilize a *dynamic computer interface*, Geocadabra (Lecluse, 2005), a tool that was not available when the SOC framework was originally developed. Through the Geocadabra Construction Box module, complex, multi-cube structures can be viewed as two-dimensional conventional representations or as top, side and front views or numeric top-view diagrams (see Figure 3). Whereas one can move around a three-dimensional model to see it from other vantage points, one may see various views of a dynamic computer-generated figure through its ability to be rotated in real time. The Geocadabra computer interface serves as a mediator of knowledge (Borba & Villarreal, 2005) rather than as a unique form of representation.

*Design Research Methodology and Data Sources*

Instructional decisions are guided by the design research methodology of Cobb, Confrey, diSessa, Lehrer, and Schauble (2003). Our intent is to support and give an account of young children's development of spatial reasoning and ultimately to create curricular resources that may be integrated into the elementary-level mathematics curriculum. Each lesson we enact is part of a design experiment in which the research team hypothesizes learning outcomes, designs instructional activities to support the outcomes, and enacts the lesson. Social constructivist approaches provide us access to student understanding in that we encourage verbal explanation and justification orally and where appropriate, in writing. During the retrospective analysis following each lesson, the research team determines the actual outcomes and then plans the next lesson, which may be an iteration of the last lesson to improve the outcomes, a rejection of the last lesson if it failed to produce adequate progress toward the desired outcomes, or a change in direction if unexpected, but interesting, outcomes arose that are deemed worthy of more attention. Data sources include formal and informal interviews, video-recordings and transcriptions, field notes, student products and lesson notes.

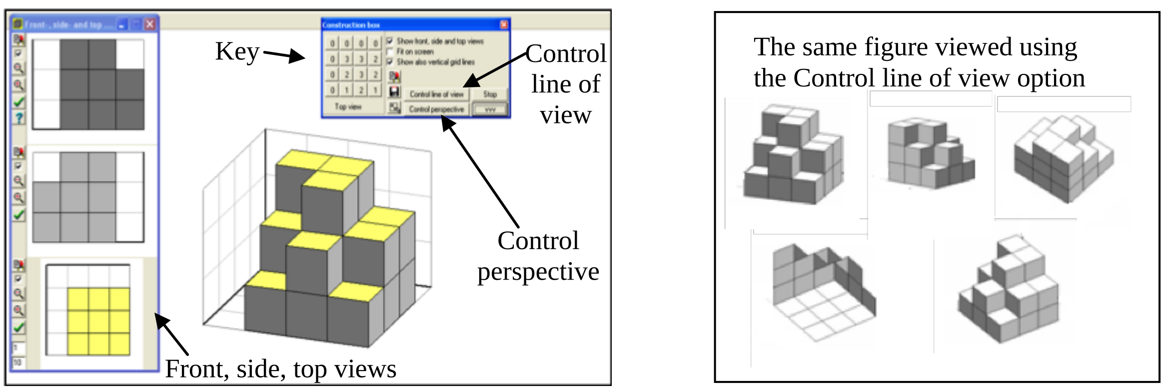

*Figure 3.* The Geocadabra Construction Box.

*Context and Classroom Ecology*

During the 2007-2008 academic year, teacher-researcher A, teacher B, and co-teacher C formed the research team that worked with a third-grade and then a fourth-grade group of children weekly (one hour per group) in teacher B's classroom during an after-school program. English and Spanish parent/guardian and student consent-to-participate forms were sent home to parents of all after-school third and fourth graders. All respondents were accepted into the program. Teacher B had taught mathematics and science to all fourth-grade participants during their entire third-grade year. Due to staffing changes for the third-grade class, she taught all core subjects to half of the school's third-grade students. Consequently, some of the third-grade participants in the after-school SOC program were not her students during the school day. However, all participants became attuned to her behavioral and communal expectations very quickly during the first month of the research program. She expected all students to develop independence by asking each other for help or support before asking the teacher, and to treat each other respectfully. Students expressed their understandings, justifications, confusions or frustrations safely in front of their peers. We rarely gave away answers or explanations. Students constructed meaning and representations for themselves. Furthermore, our design incorporated learning experiences that challenged each child according to particular readiness, interest and learning profile. Our strong attention to differentiated instruction ensured "processes and procedures that ensure effective learning for varied individuals" (Tomlinson & McTighe, 2006, p. 3). This environment supported problem-solving and fostered creativity in our participants while as researchers we were able to make sense of student understanding of 3-D structures.

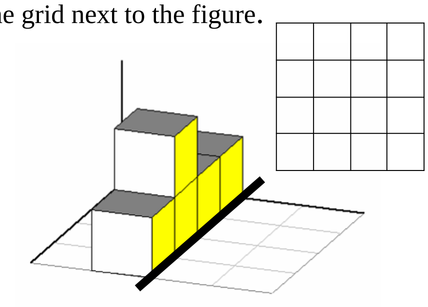
The stimuli presented to students began with simple reproductions of any of the given SOC representations into any or all of the others using single Soma figures. Later we concentrated on figures assembled with combinations of Soma figures together with rigid, congruent transformations. Activities included various game components and tasks using Geocadabra in which students had to identify the individual Soma figure(s) that made up the figure, or (de)code a top-view mapping to (re-)construct an assembly of Soma figures.

In the next section, we focus on how the children's interest in top-view coding led to invention and connections to other aspects of their daily mathematics work.

## Results

Over the course of six lessons spanning November-December, 2007, students worked with the Geocadabra Construction Box to master numeric top-view coding of 2-D conventional images. Students initially rebuilt the figures shown in a customized manual (van Niekerk, 2008) using loose cubes and then created the complete structure on the computer using Geocadabra. For an example, see Figure 4. They coordinated the top-view codings with the 2-D figures that emerged on the computer's screen. To check for understanding, we de-selected "Hide spatial model." The student then entered his or her predicted top-view coding on the screen and then clicked to un-hide the computer figure to compare with the printed 2-D figure.

Build the following figure and its mirror image on your screen. Write the correct numbers in the grid next to the figure.



Geocadabra screen for this task:

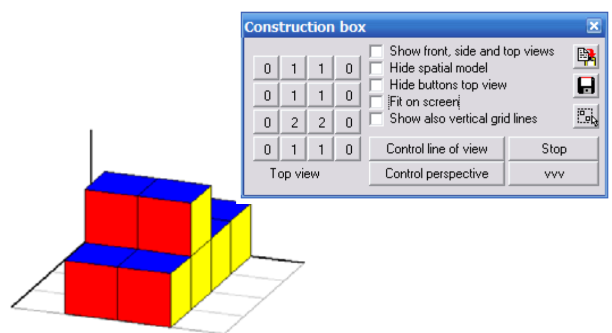


*Figure 4.* Mirror image task

A custom-created Geocadabra module, the Extended Construction Box, allowed students to construct figures with spaces and overhangs (see Figure 5). One places individual cubes or linked combinations of cubes along axial lines in a 3-dimensional octant. We challenged the children to create a numeric top-view coding system that included holes and overhangs since we were not aware of a conventional coding system of this nature. In this problem setting, students tested each other's invented codings to see if they could re-create the corresponding 3-D figures; challenged each other and offered suggestions for improvement in writing, to engage the verbal representation; and, compared and rated the invented codings. These activities provided the children opportunities to tackle open-ended problems without known solutions.

We had discovered that our students ascribed to two different but conceptually appropriate interpretations of the conventional top-view coding system (as in the original Construction Box). For example, in Figure 6, some children said that the 2 in the front left position represented a stack of 2 cubes. Others said that the 2 represented a cube on the second level, implicitly knowing that there is a cube (or a stack of cubes) supporting that cube from below. These interpretations came into conflict when students tried to decode someone else's invented coding for structures with empty spaces or overhangs especially if one's initial interpretation of a grid number was different from the coder's interpretation. For example, one student used (↑2), where the arrow meant one empty space and two cubes above the empty space, which aligns with the first interpretation described above. Another used (**3) to mean two empty spaces and one cube

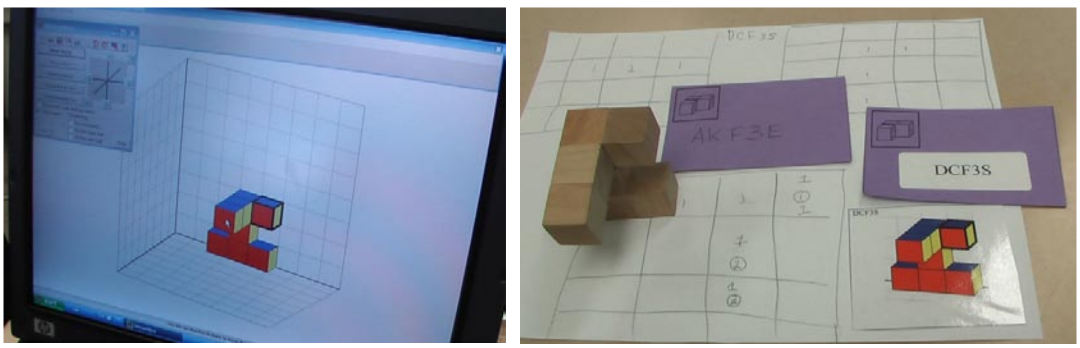

*Figure 5.* Extended Construction Box, student-created task card, coding and 3D figure.

on the third level. His coding sprang from the second interpretation of the conventional coding described above. The plethora of invented codings created class-wide confusion. Our video clips show how Teacher B and the class negotiated to select and refine a new class-wide convention that reflected the conventional coding and included holes and overhangs. Examples of various student-created codings are shown in Figure 8. Sarah's code (Fig. 8(c)) was selected with a modification to change the square to a circle to denote the number of empty spaces.

*Figure 6.* Conventional coding system developed through the Construction Box.

The traditional and class-wide coding conventions continued to be used to create assembly plans for multi-Soma figures. By presenting this as a puzzle-creation and solving activity, the children challenged each other and checked each other's work against the task cards they created using the Extended Construction Box. They set their own levels of difficulty and carefully recorded their assembly diagrams carefully. See Figure 7 for examples of student work.

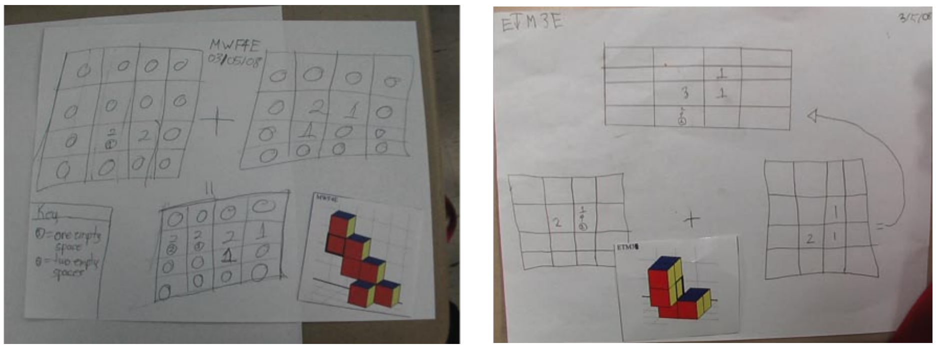

*Figure 7.* Student-created task cards and assembly puzzles.

For the end-of-year party, we decided to order a cake designed by the children, by combining all seven Soma figures into a rectangular base shape. Considering factor pairs, they determined possible dimensions for the base. Everyone was successful creating patterns on 3x8 or 4x6 bases. Vena, a third-grader, believed she would be able to construct a figure on a 2x12 base. We encouraged her to explain why this was not possible. She simply shrugged. When the program resumed the following year, Vena immediately returned to her self-created problem of building the cake on a 2x12 base. She generally finds mathematics difficult but this problem is hers and she will probably wrestle with it until she convinces herself that it cannot be solved. In separate incidents, Sarah (third grade) and Debra (fourth grade) noticed that Somas #1, #5, #6 and #7 all had the same 3-square footprint and that these pieces could be interchanged within their cakes to produce many more different patterns. This observation became an opportunity for the two groups to transfer to their academic class-work. They successfully completed tabular representations to show how many different permutations these interchanges would produce. In our presentation, we will share examples of students' assembly diagrams and a video-clip of a particularly interesting "cake" in which the ends of the student's rectangular base rotate up to lock into the 27-unit cube.

## Discussion/Conclusions

*Re-invention and Invention*

In this learning environment, through small-group and whole-class discussion, students formalized, or re-invented concepts that later became the foundation for further mathematization. Although these concepts may be new to these students, they generally constitute age-old mathematics that form the basis of school mathematics curricula. Freudenthal uses the term "re-invention" (1973, p. 120), sometimes known as discovery-based instruction for this approach to learning mathematics. Through debate and negotiation, the children adopted a particular system to be the class-wide convention for all to use. More than re-inventing mathematics, our students invented a new mathematical coding system. Our confidence in managing such an approach comes from cumulative years of providing our students opportunities to share problem-solving strategies and solutions with their peers in order to deepen their knowledge of the concepts at hand.

*Connections to Classroom Concepts*

The permutations connection that arose out of the cake-designing activity is one example of how our activities integrated with classroom-mathematics concepts. Others include figures created using loose cubes or Soma figures that exhibited repeated or step-wise patterns. These presented opportunities for children to calculate how many unit cubes were in the structure. Finding the total number cubes by in multiple ways, such as by horizontal and then vertical slicing, developed students' number and spatial senses symbiotically. A final check was established by looking at the totals of the numbers in the top-view coding grids. These activities helped establish a foundation for the concept of volume. When the children returned the following year, we extended the permutation connection from the cake activity to finding and representing as many 24-cube rectangular boxes as possible. We expected students' records-of-action to be tables showing length, width and height, but they immediately reverted to drawing their figures using top-view numeric coding. They all agreed that the numbers in the top-view grid represented the heights of the boxes. In reflection, the connection to volume was implicit during our first year of the study, especially when the children were developing mastery with conventional top-view coding. Now in our second year of the study, as we work with a much larger group of third-graders, we are making the volume and top-view grid connection explicit by asking "how many" in almost every activity. We concur with Tall et al (2001), Dreyfus (1991) and Presmeg (1992) in the importance of integrating spatial visualization with symbolic forms at the concept-development stage of mathematical learning.

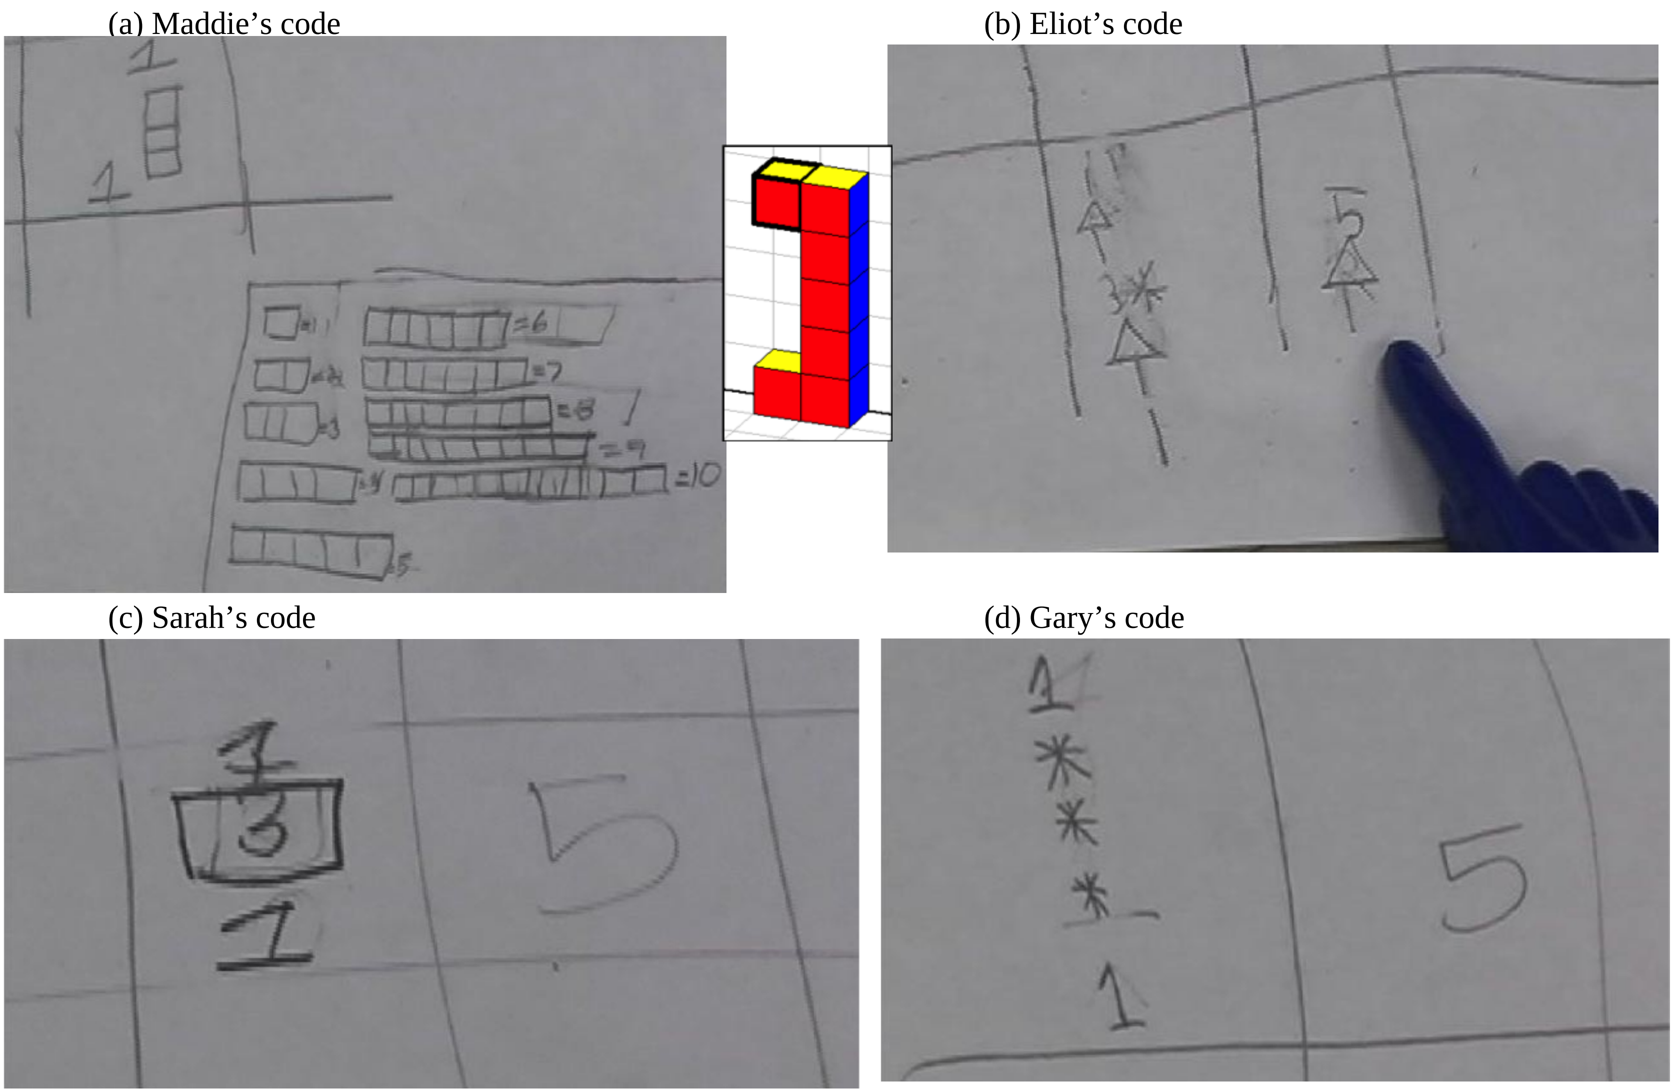

*Figure 8.* Top-view numeric coding systems to represent holes in cube figures.

# ELEMENTARY PRESERVICE TEACHERS' AREA CONCEPTIONS INVOLVING THE NOTION OF PERIMETER

Hyung Sook Lee
Eastern Washington University*
hslee@ewu.edu

*This study investigated elementary preservice teachers' conceptions about the area of parallelograms through the processes of shearing and squashing. When asked to compare areas of parallelograms, the preservice teachers revealed two opposite misconceptions along with lack of a dynamic understanding of the quantity of area: 1) increasing perimeter decreases area and 2) increasing perimeter increases area.*

## Introduction

When asked about the area of a two-dimensional shape, do you first focus on the boundary of the shape or the region that the shape covers, or both? Regardless of whether the question is about the area or the perimeter, both the boundary and the region covered may be in our primary consideration rather than either of them in an exclusive manner. Interestingly, when asked to compare areas of parallelograms, many of the elementary preservice teachers in our mathematics content course paid attention to the boundaries, more specifically, to the changes in the boundaries from a related rectangular shape. Similarly, in response to the question about the perimeter of a shape, many of the preservice teachers attempted to change the shape so that they could easily produce the area and use the changed shape to find the perimeter measure. This paper shows elementary preservice teachers' various attempts to relate area and perimeter.

## Lessons Taught and Theoretical Background

This study is based on the lessons for the second mathematics content course that is required for those who pursue or major in elementary education (K-8). The author taught two sections of the course where 43 students attended in total. Most of these students were learning the school geometry that was planned and instructed especially for elementary preservice teachers for the first time.

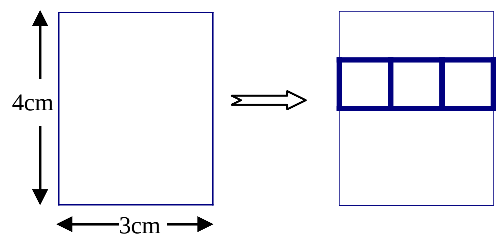
We began by describing how the topic of area measurement was introduced in our mathematics content course for elementary preservice teachers and what research results contributed to shaping our lesson. The preservice teachers in the course were first asked to find the area of a 3cm by 4cm rectangle. Every student answered 12[i] and many of them justified the answer using the area formula $length \times width$ or $base \times height$. The use of the area formula, especially starting with the area formula from the very beginning stages of the topic, has been criticized as leading to difficulties and poor understanding of area measurement (Zacharos, 2006). Three salient shortcomings were reported with respect to the use of the area formula (Baturo & Nason, 1996): reinforcing the perception of area based on the boundary of a shape; avoidance of generating the unit of area; and likely disregarding of the array notion of multiplication due to the dominant notion of multiplication as repeated addition. Along with

* I would like to thank Diane Dowd for her reading of this manuscript.

these concerns, three research ideas affected our lesson plans: (1) Schwartz's idea of area as an attribute of a quantity: "The confounding of these two attributes [perimeter and area] of shape is a serious obstacle to the learning of area measure" (Schwartz, 1996, p.9); (2) Simon and Blume's idea of the quantitative reasoning involved in the evaluation of the area of a rectangle: "Important aspects of this [quantitative] reasoning include the anticipation of a rectangular array of units as the structure of the area quantity" (Simon & Blume, 1994, p. 472); and (3) Steffe's idea of multiplicative reasoning as a way to coordinate two levels of units (Steffe, 1994).

*Area of a Rectangle*

To address the preservice teachers' dominant use of the area formula when justifying their answer of 12, the instructor started her instruction on the topic of area by focusing on the following questions: Why do you multiply 3 by 4 to determine the area? Where can you see the answer of 12? What does your answer refer to? These questions intended to encourage the preservice teachers to generate a unit of area while differentiating it from a unit of length and to produce the measurement of area based on a multiplicative way of thinking (Figure 1).



- There are four rows and each row has three squares.
- There are four rows of three 1 by 1 squares.
- 12 is the number of squares.
- When 4 is multiplied by 3 to find the area, 3 represents the number of squares in each row.

Figure 1

*Area of a Triangle*

Based on the conceptual understanding of the area of a rectangle, our preservice teachers were asked to produce the area measure of a triangle and explain why they need to know the length of the segment perpendicular to the base of the triangle in order to produce the area (Figure 2).

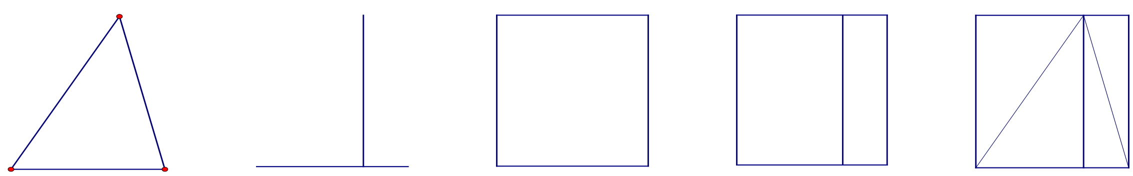


Figure 2

*Area of a Parallelogram*

The preservice teachers were then asked to find a way to determine the areas of parallelograms by relating the parallelograms to rectangular shapes. One student produced a rectangle that shares one side with a given parallelogram by applying a moving and combining principle (Figure 3).

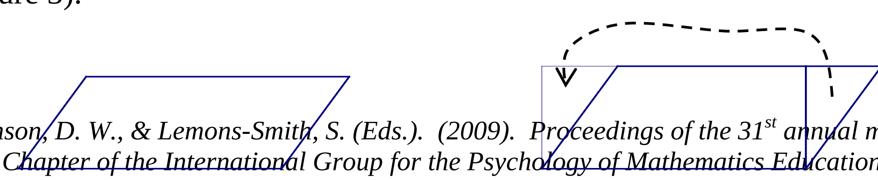

Figure 3

As another way to relate a rectangle to a parallelogram for finding the area measure, a shearing process was introduced using toothpicks. The shearing process is illustrated in Beckmann's textbook (2008) as follows: "Start with a polygon, pick one of its sides, and then imagine slicing the polygon into extremely thin (really, infinitesimally thin) strips that are parallel to the chosen side. Now imagine giving those thin strips a push from the side, so that the chosen side remains in place, but the thin strips slide over, remaining parallel to the chosen side and remaining the same distance from the chosen side throughout the sliding process" (p. 601). According to Cavalieri's principle for areas, the sheared shape has the same area as the original shape.

### Emergence of the Notion of Area Measurement with a Concern about Perimeter

Our preservice teachers seemed to have no problem in recognizing that changing a rectangular shape into a parallelogram that is not a rectangle through the shearing process results in preserving the area but changing the perimeter. However, many of the preservice teachers had difficulty implementing the inverse way of shearing, which is transforming a parallelogram that is not a rectangle into a rectangular shape. They desired to keep the perimeter of the parallelogram when shearing, which is referred to as squashing[ii].

Such a way of confounding shearing and squashing seemed to lead them to conjure up the *same A-same B* intuitive rule[iii] with respect to the process of squashing. That is, assuming that shearing preserves the area of shapes, they proceeded to the process of squashing and concluded that if a shape is changing while preserving its perimeter, the changed shape must have the same area as the original (Figure 4).

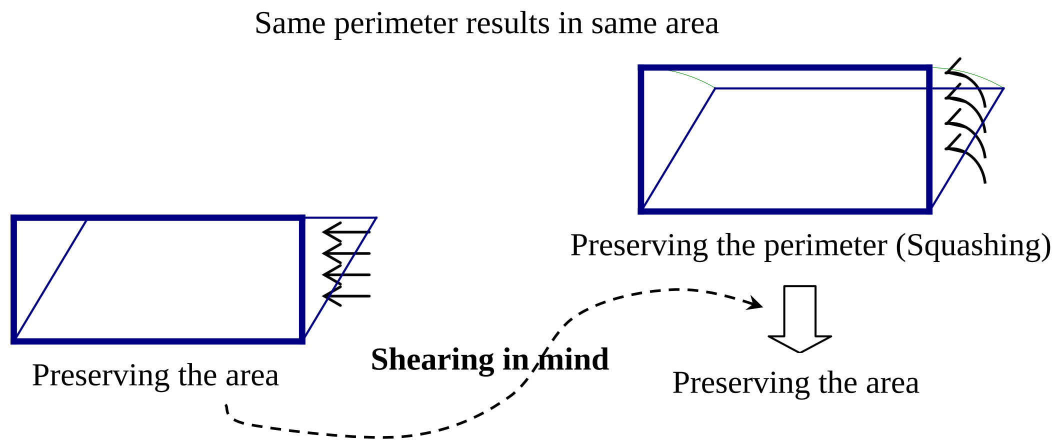

Figure 4

In addition, many of the preservice teachers showed a perception that area determines perimeter, which is the opposite of the above idea that perimeter determines area. In response to the question about determining the perimeter of a shape, they seemed comfortable using a *same A-same B* intuitive rule. That is, they changed a given shape into the one that has the same area as the original and determined the perimeter of the changed shape (e.g., Figure 5), or they calculated the perimeter by applying the procedure they would have followed to determine the area of the shape (e.g., Figure 6).

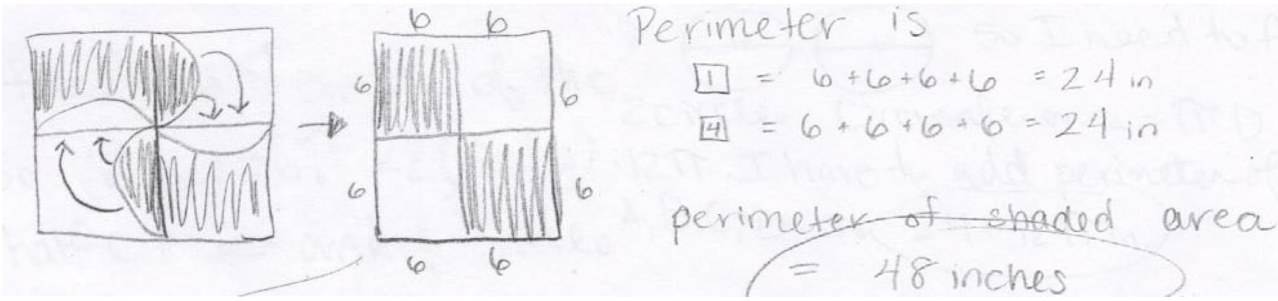

Figure 5

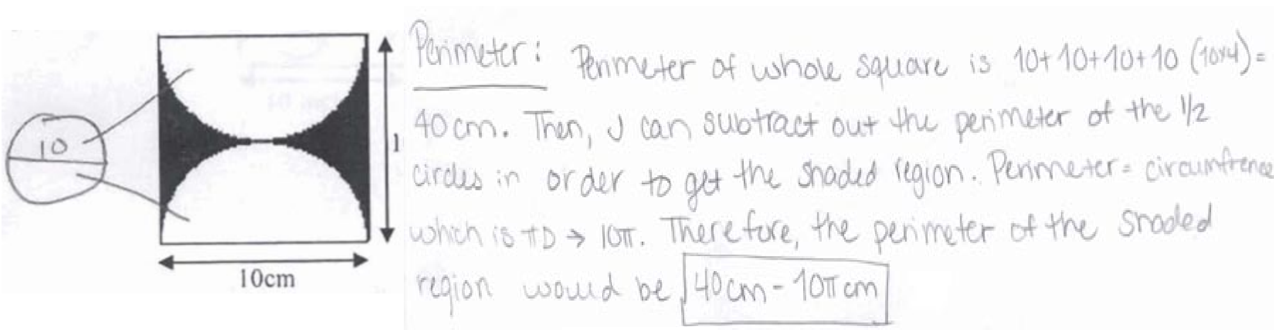

Figure 6

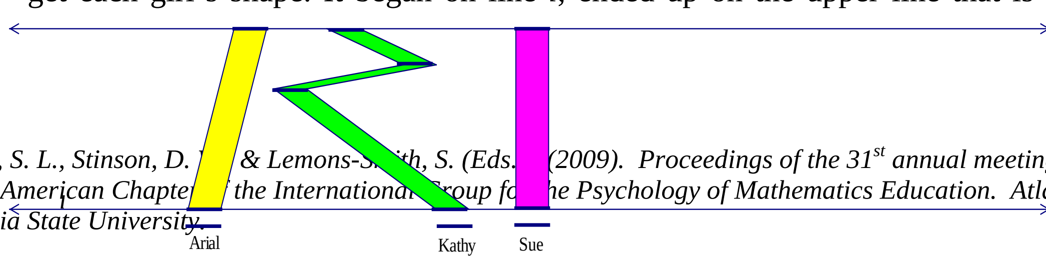
**Investigating Changes in Area by Looking at Changes in Perimeter**

In order to further investigate preservice teachers' conception of the relationship between perimeter and area, we proposed the following problem to the students in our mathematics content course for elementary preservice teachers.

> Arial, Kathy and Sue were planning to create a shape for planting on an empty plot. They were told to make a shape using a 3-foot long stick. Arial created her region by sliding the stick slightly toward the right, as shown at left below; Kathy made one by sliding her stick using a zigzag motion, as shown in the center; and Sue created a rectangle by sliding her stick straight forward, as shown at right below. When sliding their sticks, all of the girls kept their sticks parallel to the line *l*. The girls were wondering which region (if any) has a larger area than the other. Elaborate your reasoning as you comment on the girls' wondering about the regions. [Note: The stick is represented by the horizontal segment show below line *l*. This stick was slid directly upward, as shown in this picture, or upward and to the left or right, to get each girl's shape. It began on line *l*, ended up on the upper line that is



*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

parallel to line *l*, and remained parallel to line *l* throughout its journey.]

We found a group of preservice teachers had difficulty visualizing using the given stick to create two-dimensional shapes. Many of the preservice teachers in the group thought each shape itself represented the 3-foot long stick. This kind of response suggests a static perspective of area (Baturo & Nason, 1996), which is perceiving area as an amount of region that is enclosed within a boundary. In other words, the boundary of the shape is needed to determine the region for which the area is being asked, so the preservice teachers would need to have the boundary specified before investigating areas of each shape.

There was another big group of preservice teachers who attempted to compare the areas of the shapes based on a relationship between the boundaries of the shapes. Interestingly, two opposite ways of thinking emerged: "Increasing or preserving the perimeter decreases the area" vs. "Increasing the perimeter increases the area". Let's closely look at theses two ways of reasoning.

<u>Argument 1:</u> Increasing or preserving the perimeter decreases the area

- Anne: "Sue's stick [rectangular shape] would be a bigger area because it is fattest. The more you shorten the height the less the area is. Below (Figure 7), each shape has a base of 7 but the height changes every time because it is getting more slanted. This causes the area shrink."

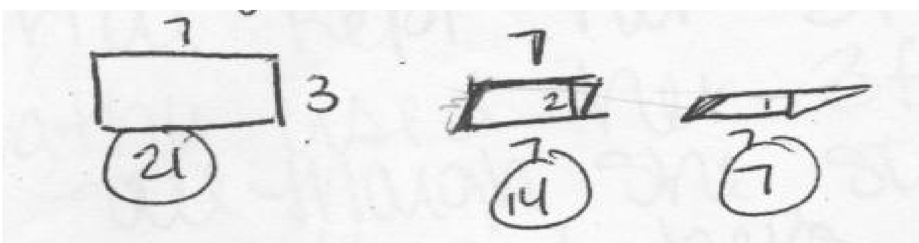


Figure 7

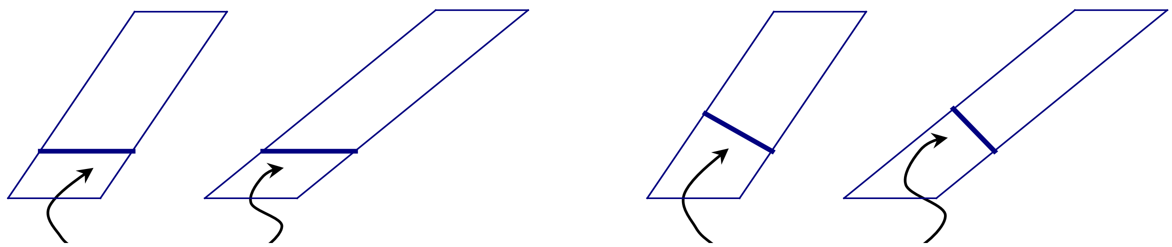
- Molly: "Kathy's [zigzag shape] is smaller because it is zigzagged. … Kathy's stick got much thinner and therefore having a smaller area in those smaller parts."

Both Anne and Molly's reasoning suggests that they are perceiving that (1) shape gets thinner as its sides become slanted and (2) a thinner shape has a smaller area than a thicker shape. However, they also took opposite positions in that Anne seems to have preserved the perimeter while Molly seems to view it as having changed. That is, Anne implemented squashing, instead of shearing, with respect to Sue's plot [or rectangular shape] in order to produce Arial's shape [a parallelogram that is not a rectangle]. On the other hand, Molly seemed to employ the shearing process properly, in that she did not express any view of the height decreasing. Anne and Molly's mentioning about being thinner as the rectangular shape slanted indicates they may have viewed the *width* of the shape as a segment that is perpendicular to each slanted side, and this view of a thinner *width* caused them to determine that Arial's area was smaller than Sue's. Notice that the term *width* can be interpreted two ways in a parallelogram (Figure 8).

Suppose a student perceives a parallelogram as getting "thinner" through the shearing process as it becomes more slanted. That may suggest the student is focusing on the segment that is perpendicular to the slanted sides of the parallelogram as the width of the parallelogram (e.g., Figure 8 (b)). In that case, the student is likely to think the thinner shape has the smaller area unless the student notices that the two measures—of the "thinner" perpendicular width and a slanted side—will be used to determine the area. On the other hand, if a student sees the width of a parallelogram in terms of the segment that maintains the distance between the two slanted sides, she or he would not have trouble noticing that the degree of the slant does not affect the area unless the student confounds shearing and squashing.



(a) The width is a segment that maintains the distance between the slanted sides

(b) The width is a segment that is perpendicular to a slanted side

Figure 8

<u>Argument 2:</u> Increasing the perimeter increases the area

- Crystal: "Kathy [zigzag shape] has a larger area than the others. All 3 sticks are covering the same distance. However, Kathy's if you were to lay it out straight is much longer than the other two. They all have the same width, but different length so Katy's has a larger area."
- Maggie: "Sue [rectangular shape] would have the smallest area because the shortest distance between two points is a straight line. We calculate the area of their plots by multiplying 3 by the length of their plot (Kathy we would have to use segments). So the 3 is constant. Arial's [parallelogram that is not a rectangle] length is a little longer because she goes at a diagonal. Lastly Kathy's length would be the longest because she zigzags back and forth. So it would go smallest to largest area respectively, Sue, Arial, and Kathy."
- Joel: "Arial's area is bigger than Sue's area because the line *a* is bigger than line *b* in my picture [shown at the right, Figure9]. The area of *a* is $1\times\sqrt{2}$ whereas the area of *b* is $1\times 1$ which is less. As for Kathy the same logic should hold for her as well and she should be bigger than the other 2, so long that the width of all the lines are the same."

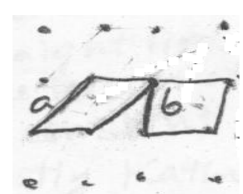


Figure 9

All of the students holding Argument 2 focused on the changes of the lengths of each shape. By length, they meant the side or the measurement of the side of each shape that goes from the line *l* to the other line that is parallel to *l*. It is interesting that they all considered the width as remaining the same in every shape; that is, unlike the previous group of the students who thought

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

increasing or preserving the perimeter decreases the area, they were not concerned about the shapes getting “thinner” as they become more slanted. Therefore, the lengths became the only factor they considered to compare the areas between the shapes. They reached conclusions about the area comparison only by looking at the lengths of the sides that are not width, the given 3 feet, and by squashing the shapes into a rectangular shape. Joel’s drawing clearly shows his confounding of shearing and squashing.

## Results

This study researched elementary preservice teachers’ conceptions about area through investigating their ability to implement the shearing process and to differentiate it from the squashing process. Three different ways of confounding shearing and squashing were found. The following table summarizes how those ways of thinking led the preservice teachers to mistakenly both conceive the areas of parallelograms and relate the areas to the perimeters.

| Original shape | What is the width of the new shape? | What is considered in order to determine the area of the new shape? | Which process is being intended, shearing or squashing? | Misconception involved in the process employed. |
|---|---|---|---|---|
|  |  |  | - Mixing squashing and shearing<br>- The width of the sheared strip was changed but the same height was assumed for the area comparison. | Preserving the perimeter decreases the area. |
| |  |  | - Shearing<br>- The conception of the width of the sheared strip changed. | Increasing the perimeter decreases the area. |
| |  |  | - Squashing<br>- The width of the sheared strip was preserved. | Increasing the perimeter increases the area. |

## Discussion

This study shows that investigating the shearing and squashing process while differentiating them can provide a good ground for students to develop a dynamic and static perspective of area at the same time. Baturo and Nason (1996) argued that “Area needs to be considered from two perspectives, namely static (a description of something at a certain point in time) or dynamic (a mapping or function from one thing to anther). … Underlying this dynamic perspective of area is the notion of the definite integral of differential calculus. However, the dynamic perspective is often not included in curriculum documents, thus limiting students' understanding of area." (p. 238-239). Many of our elementary preservice teachers had difficulty implementing the shearing process flexibly. We suggest that it may be due to an inability to generate two-dimensional shapes (plots shown in the stick-plot problem, especially the zigzag plot) using a one-dimensional attribute (the given definite length of stick) because the study reveals that our preservice elementary teachers do not have a good picture in their minds of what is to be sheared. In addition, confounding of and difficulty in differentiating the shearing and the squashing indicate that our preservice teachers' perspectives of area are inflexible in that the squashing process requires them to perceive area through reasoning about the perimeter, whereas shearing permits them to conceive perimeter through reasoning about the area. The impact of balancing these two perspectives of area on preservice teachers' conceptual understanding of area measurement needs to be investigated further.

# THE ROLE OF PRIOR KNOWLEDGE IN THE DEVELOPMENT OF STRATEGY FLEXIBILITY: THE CASE OF COMPUTATIONAL ESTIMATION

Jon R. Star
Harvard University
jon_star@harvard.edu

Bethany Rittle-Johnson
Vanderbilt University
Bethany.Rittle-Johnson@vanderbilt.edu

*The ability to estimate is a fundamental real-world skill where strategy flexibility is particularly critical. Here, we consider the role of students' prior knowledge of estimation strategies in the effectiveness of interventions designed to promote strategy flexibility across two recent studies with 5th and 6th grade students. Results indicated that students who exhibited high fluency at pretest were more likely to increase use of estimation strategies that led to more accurate estimates, while students with less fluency adopted strategies that were easiest to implement.*

## Introduction

Estimation is a critically useful skill in everyday life and in mathematics, as encapsulated in the "Adding It Up" report from the National Research Council: "The curriculum should provide opportunities for students to develop and use techniques for mental arithmetic and estimation as a means of promoting deeper number sense" (2001, p. 415). Unfortunately, current instructional methods have not been particularly effective at supporting estimation knowledge. It is well documented that a large majority of students have difficulty estimating the answers to problems in their heads (e.g., Reys, Bestgen, Rybolt, & Wyatt, 1980). Given the challenges of mentally computing estimates, it is especially important to have a broad repertoire of estimation strategies and to select the most appropriate (often, computationally easiest) strategy for a given problem and goal. Thus, students' difficulties with computational estimation partially results from a lack of strategy flexibility in this domain.

Strategy flexibility is defined as (1) knowledge of multiple strategies and (2) adaptive use of strategies, based on accuracy and efficiency. Knowledge of multiple strategies has clear benefits for learning and performance; for example, learners with knowledge of multiple strategies at pretest are more likely to learn from instructional interventions (e.g., Alibali, 1999). People who know multiple strategies also learn to choose among them based on their accuracy efficiency; adaptive choice is a fundamental feature of problem-solving expertise and is also a fundamental mechanism supporting learning and development (Siegler, 1996).

### *Flexibility and Strategies for Estimation*

There are numerous strategies that can be used to compute estimates. Of particular interest here are students' knowledge of and use of three strategies for estimating two-digit multiplication problems. One commonly taught strategy is *round both*, which involves rounding both numbers to the nearest multiple of ten. Another strategy that can be used is *round one*, which involves rounding only one number to the nearest ten. Finally, a third strategy that we explore here is *truncation, or trunc*, which involves covering up or ignoring the ones digits and multiplying the tens digits and subsequently adding two zeros to the resulting product. Note that *trunc* is a less familiar strategy than the other two, but it is relatively easy and fast and has been advocated for by researchers on computational estimation for these reasons (e.g., Sowder & Wheeler, 1989).

Flexibility in estimation includes choosing the most appropriate strategy for computing an estimate for a given problem. Choosing an appropriate strategy in estimation is complicated by the

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

presence of multiple, at times competing goals. On the one hand, it may be desirable to generate an estimate that is close to the exact answer. However, on the other hand, one may seek to compute an estimate using the strategy that is computational easiest. Ease is particularly important for estimation because one often must estimate mentally. (Note that it could be argued that ease of computation is a subjective and individual judgment; however, in our prior work with middle-school students (Star & Rittle-Johnson, in press), we have shown that *trunc* and *round one* are both easier (e.g., faster) strategies to implement than *round both*.)

The studies described here explore the development of students' flexibility for computing estimates. We were interested in students' learning of *round both*, *round one*, and *trunc*, and when and how students began to use these strategies to optimize for ease and/or for proximity for given problems.

*Prior Knowledge and Flexibility*

In our prior work, we have identified interventions that reliably lead to gains in flexibility. Our interventions built upon cognitive-science research suggesting that comparing multiple examples is a fundamental pathway to flexible, transferable knowledge (e.g., Gentner, Loewenstein, & Thompson, 2003). However, in a recent study, it became clear that students' prior knowledge may impact the effectiveness of interventions designed to promote flexibility (Rittle-Johnson, Star, & Durkin, 2008). We found that students who were not initially familiar with one of the target problem-solving strategies learned less if they were exposed to multiple strategies simultaneously, rather than sequentially. This study raised an interesting question that is not well explored in the existing literature on flexibility. If an instructional goal is to promote flexibility, then is it more effective to teach novice students multiple strategies from the beginning, or should learners develop initial fluency with one strategy before increasing their repertoire to include multiple strategies?

Our prior work would suggest that learners need initial familiarity with one strategy before they can become flexible in the use of multiple strategies (Rittle-Johnson et al., 2008). Research on analogical reasoning also provides indirect support for this position: learning from comparing unfamiliar examples is often difficult for young children (e.g., Gentner, Loewenstein, & Hung, 2007) and for college students who do not receive additional instructional support (Schwartz & Bransford, 1998).

*Present Studies*

The goal of the present paper was to continue our exploration of the role of prior knowledge in the effectiveness of interventions designed to promote flexibility, this time in the case of computational estimation. In Study 1, 65 fifth graders began the study as fluent users of the *round both* strategy, while in the Study 2, 157 5th and 6th graders began the study with moderate to low prior knowledge of strategies for computing mental estimates. Note that elsewhere we report on the effects of the intervention on improving flexibility (Star & Rittle-Johnson, in press); here, our interest is in prior knowledge and flexibility.

## Method

*Participants*

In both Study 1 and Study 2, participants were 5th and 6th grade students. Study 1 was conducted in an urban, private school (School A), and Study 2 was conducted in the same school as well as in a small, rural school (School B).

In Study 1, students in four classes of 5th graders (n = 65; 33 girls) participated. Students' mean age was 10.88. The fifth grade was comprised of a majority of Caucasian students and 25% minority students, of whom 18% were African-American. Approximately 10% of students at School A receive financial aid. All students were taught by the same mathematics teacher and had received some prior instruction on estimating answers to multiplication problems.

In Study 2, participants were fifth- and sixth-grade students from two schools. In School A, 69 fifth-grade students participated (32 girls). There were four fifth-grade mathematics classes (all taught by the same teacher) at the school. Students' mean age was 10.6 years; a majority were Caucasian (23% minority, with 13% African-American). At School B, 45 fifth graders and 46 sixth graders participated. At School B, 5th grade students' mean age was 10.7 years (range: 10.0 years to 11.8 years) while sixth grade students' mean age was 11.8 years (range: 11.0 years to 13.1 years). There were two fifth grade classes (taught by the same teacher) and two sixth grade classes (taught by the same teacher). Most of participating students were Caucasian. Approximately 36% of students at School B received financial aid. Across schools in Study 2, teachers had not taught computational estimation in any of the classes, although some students had received limited instruction on computational estimation in previous grades. Three students were dropped from Study 2 because they were absent from school and missed more than one intervention session. Thus the analysis below for Study 2 includes data from a total of 157 students.

*Materials*

*Intervention*. The interventions in Study 1 and Study 2 were largely the same. Students were presented with a packet of worked examples, showing hypothetical students' estimates and estimation strategies for multiplying two-digit integers. The worked examples focused on the three estimation strategies discussed above. Each packet contained 32 worked examples, with questions at the bottom of each page prompting students to reflect on the estimation strategy or strategies demonstrated on that page. In addition, practice problems were integrated into each packet, where students were asked to compute estimates and answer questions about their choice of strategy. Students also received a brief whole-class lesson and a brief homework assignment each day.

*Assessment*. The assessments for Study 1 and Study 2 were very similar. Within a study, the same assessment was used as an individual pretest and posttest and was designed to assess procedural knowledge, flexibility, and conceptual knowledge. The *procedural knowledge* measure assessed knowledge of how to estimate, using both whole-number multiplication problems (six problems, such as 12 x 24 and 113 x 27) and transfer problems that involved decimal numbers or division (six problems, such as 1.19 x 2.39 and 102 ÷ 9). *Flexibility* was assessed in two ways. First, flexible *use* of strategies was assessed by examining students' strategy use on the six whole-number multiplication problems. Second, flexible *knowledge* of strategies was assessed by items designed to tap students' ability to recognize, implement, and evaluate multiple strategies for computing estimates. Flexibility *knowledge* items fell into three categories: (a) Knowledge of multiple strategies; two questions asked students to compute estimates in three different ways; (b) Recognize and evaluate ease of use; two questions assessed whether students knew which strategies were computationally easier to implement; and (c) Recognize and evaluate closeness of estimate; four questions assessed whether students knew which strategies resulted in an estimate that was most proximal to the exact value. Finally, *conceptual knowledge* items assessed students' knowledge of core concepts related to estimation. The items focused on definitions of estimation as well as acceptance of multiple strategies of estimation and multiple values of estimates and were modified from past research (Sowder, 1992; Sowder & Wheeler, 1989).

*Procedure*

In both Studies 1 and 2, the study occurred during one week of students' regular mathematics class. The procedures for the two studies were very similar. On the first day, students completed a 30-minute written pretest and then were provided with a 10-minute introduction lesson by a member of the research team. On Days 2 and 3, students were divided into pairs to work on the intervention packet. During the partner work, the pairs of students were asked to first explain their answers to the explanation prompts verbally to one another and then write down a summary of their answer on the packet. At the conclusion of each class, students were given the same brief homework assignment to practice estimating. In Study 1, students received a wrap-up lesson and completed the posttest on Day 4. In Study 2, students received the wrap-up lesson on Day 4 and completed the posttest on Day 5. Students in Study 2 were given additional time to work on the packets because they were expected to need more time given that they were less familiar with the target content.

## Results

We begin by describing students' prior knowledge of estimation strategies at pretest and then explore the extent that students' prior knowledge impacted the development of strategy flexibility.

*Knowledge and Strategies at Pretest*

*Measures of conceptual knowledge, procedural knowledge, and flexibility*. In Study 1, students' scores at pretest were quite high on all measures, indicating substantial knowledge of estimation strategies prior to our intervention. At pretest, students had quite advanced levels of both procedural knowledge of estimation and procedural flexibility, as well as some conceptual knowledge of estimation. In contrast, students in Study 2 began the study with substantially less knowledge of estimation strategies and concepts. For example, Study 2 students on average were able to generate accurate estimates for 4 or 5 of the 12 pretest procedural knowledge items, whereas students in Study 1 on average were able to generate accurate estimates for 12 of these items.

*Students' strategies on familiar procedural knowledge items*. Differences in prior knowledge could also be seen in students' estimation strategies at pretest on the whole-number multiplication problems. In Study 1, almost all students began with considerable fluency with the *round both* strategy; 92% of participants used *round both* on at least one problem. Over one-third of Study 1 students were also familiar with *round one*. In contrast, only 49% of students in Study 2 used *round both* on any problem at pretest, and only 17% used *round one*.

*Flexibility Knowledge at Posttest*

In both Studies 1 and 2, students made gains in their flexibility knowledge as well as in procedural and conceptual knowledge. The similar gains in flexibility knowledge came about despite the stark differences in prior knowledge of estimation. In Study 1, students' scores on the flexibility knowledge measure rose from 73% to 89%, while in Study 2 the gains were from 46% to 68%.

However, looking more closely at the three subscales in the flexibility knowledge measure, a more complex picture of the differences between Study 1 and Study 2 emerged. First, consider the multiple ways subscale, which assessed students' knowledge of multiple strategies for generating estimates. Study 1 students' score rose from 75% to 92%, while Study 2 students' scores improved much more dramatically, from 24% to 62%. For example, one question in this subscale asked students to generate an estimate for 12 x 36 in three different ways. At pretest, 77% of Study 1 students were able to generate an estimate for this problem in at least two ways; at posttest, 98% were able to do so. On the same problem, only 11% of Study 2 students were able to generate an estimate in at least two ways at pretest, while 45% were able to do at posttest. Study 1 students were almost at ceiling at pretest in their knowledge of multiple strategies, while Study 2, who began the study knowing fewer strategies, experienced much more substantial gains.

A somewhat different picture emerged when examining the ease subscale, which assessed students' knowledge of which strategies led to estimates that were the easiest to compute. Students' scores on the ease subscale were comparable at pretest across the two studies, but Study 1 students' scores grew substantially from 62% to 89% while Study 2 students' gains were more moderate, from 58% to 72%. For example, one question on this subscale asked students to evaluate whether *round both* or *round one* was easiest to use for computing an estimate for 27 x 39. (*Round both*, 30 x 40, is easier to mentally compute than *round one*, 27 x 40.) Study 1 students' scores on this item grew from 67% correct to 91% correct, while Study 2 students' scores grew only from 70% correct to 73% correct. The other question on the ease subscale asked students to evaluate whether *round both* or *trunc* was easiest to use for computing an estimate for 172 x 234. (*Trunc*, or 1[redacted] x 2[redacted], is easier than *round both*, 170 x 230.) Study 1 students' scores on this problem grew from 59% to 86% correct, and Study 2 students' scores went up comparably, from 45% to 71%. Students in both studies made comparable gains in their recognition of the relative ease of the *trunc* strategy, but Study 1 students made greater strides in their ability to identify the relative ease of *round one*.

Finally, consider students' evaluation of which strategies provided more proximal (i.e., closer) estimates. Students' gains from the two studies were quite similar, from 76% to 86% (Study 1) and from 56% to 69% (Study 2). Thus, students in both studies made similar strides in their ability to evaluate strategies based on which yields the closer estimate. For example, students were asked to evaluate (without computing the exact value) whether *round both* or *round one* gave the closer estimate for 34 x 42 and 9 x 48 (*round one* is closer for both problems; 92% and 83% of Study 1 students answered these two questions correctly at posttest, as compared to 74% and 65% of Study 2 students at posttest) and whether *round both* or *trunc* gives a closer estimate for 21 x 39 (*round both* is closer; 86% correct at posttest in Study 1 and 72% correct in Study 2) and 31 x 73 (*round both* and *trunc* give the same estimate; 96% correct at posttest in Study 1 and 66% correct in Study 2). While Study 1 students' performance was higher on all of these items in this subscale, gains from pre- to posttest were quite similar for Study 1 and Study 2 students, indicating similar growth in students' ability to think about estimation strategies and proximity.

Our comparison of students' scores on the independent measure of flexibility knowledge suggests the following with respect to the role of prior knowledge in the development of flexibility. First, students with low prior knowledge in Study 2 made the greatest gains in their knowledge of multiple strategies. Study 2 students began with relatively little knowledge of strategies other than *round both*, and as a result of the study, increased their knowledge of *round both* as well as *trunc* and *round one*. Second, in addition to learning new strategies, Study 2 students also gained an appreciation of the relative ease of *trunc* over *round both* for some problems. In contrast, Study 1 students made relatively small gains in their knowledge of new strategies (likely due to a ceiling effect), but showed superior performance on all subscales and greater gains on questions relating to which strategies were easiest for computing estimates for given problems.

*Flexibility Use at Posttest*

To further explore the role of prior knowledge in the development of flexibility, we examined students' *use* of estimation strategies on the whole-number multiplication problems at posttest. Below we consider students' use of multiple strategies, as well as their ability to select the most appropriate strategy for a given problem on the posttest.

*Use of multiple strategies*. Study 1 students chose to use *round both* quite frequently on the posttest. Recall that 92% of Study 1 students used *round both* on at least one pretest problem; 100% of students used this strategy on at least one problem on the posttest. Use of *round one* on the posttest also increased; 51% of students used this strategy on at least one posttest problem. Interestingly, use of *trunc* fell among Study 1 students; while 14% of students used *trunc* on at least one problem at pretest, only 5% did so at posttest. Among Study 2 students, use of *round both* jumped to 77% of students at posttest, from 49% of students at pretest. Similarly, use of *round one* increased to 17% of students, and use of *trunc* increased to 23% of students. In addition, Study 1 students were more likely to use multiple strategies on the posttest. 53% of participants used at least two of the three target strategies (*trunc*, *round one*, *round two*) on at least one problem on the posttest, as compared to only 29% of Study 2 students.

*Choice of appropriate strategies*. In addition to use of multiple strategies, we also considered whether students switched to a more appropriate strategy on a given problem. Of interest were two potential switches that students could have made.

First, students could have switched from *round both* to *round one* on problems where *round one* was more appropriate. On two problems, *round one* was easier to implement than *round both*. In addition, for problems 1 and 2 in Study 2, *round one* yields a closer estimate than *round both*. To what extent did students in Studies 1 and 2 who used *round both* on problems 1 and 2 at pretest switch to *round one* at posttest? For this analysis, we only considered those students who showed some fluency with *round both* at pretest -- those who used this strategy on at least one pretest item (92% of Study 1 students and 49% of Study 2 students). Within this subset of participants, 25% of Study 1 students switched from *round both* to *round one* on problem 1 and/or 2, as compared to only 5% of Study 1 students.

Second, we also investigated whether students switched from *round both* to *trunc* on problems where *trunc* was appropriate. In our prior work, we have shown that *trunc* is easier to implement than *round both* (Star & Rittle-Johnson, in press). We coded whether students switched from *round both* (at pretest) to *trunc* (at posttest) on problems where *trunc* was easiest. As above, we only considered students who showed some fluency with *round both* at pretest. Results indicated that only 3% of Study 1 students switched from *round both* to *trunc* on one or more problems, while 19% of Study 2 students made this switch. Note that our interpretation of students' decision to switch or not to switch to *trunc* is complicated by the fact that, while *trunc* is easier to implement in problems 3-6, *round both* produces the most proximal estimate on problems 4, 5, and 6 (and the same estimate as *trunc* on problem 3). Study 1 students' reluctance to switch to *trunc* can be seen either as a reflection of these students' prioritization of proximity goals or their strong preference for *round both* in spite of the greater ease of *trunc*.

## Discussion

The goal of the present paper was to explore the role of students' prior knowledge of estimation strategies in the development of strategy flexibility. We report the results of two very similar studies, conducted with students with quite different prior knowledge profiles. Study 1 students began with significant fluency with the *round both* strategy, while Study 2 students had substantially less fluency with *round both* or with any estimation strategy. Our results indicated that prior knowledge did impact the development of flexibility, but in rather complex ways that these studies did not fully explicate, as we elaborate below.

First, there is some evidence that prior knowledge can be a boon to the development of strategy flexibility. Students from both studies made comparable gains on the independent measure of flexibility, but Study 1 students made greater improvements in their ability to identify the relative ease of *round one*. Although Study 1 students relied heavily on *round both* at pretest, they also showed greater familiarity with *round one* than did Study 2 students, which likely supported their ability to learn the relative merits of *round both* and *round one* in terms of ease. These results are consistent with our prior work suggesting that learners may need initial familiarity with one strategy before they can become flexible with multiple strategies (Rittle-Johnson et al., 2008). In addition to these gains in terms of flexibility *knowledge*, Study 1 students also were superior in flexibility *use*. Study 1 students used a greater diversity of strategies on posttest estimation problems, and they were more likely to switch from *round both* to *round one* on posttest problems 1 and 2—problems where *round one* is the most appropriate strategy.

However, in other ways, the impact of significant prior knowledge was not as widespread as we might have hypothesized. Students with lower prior knowledge made greater gains in their knowledge of multiple strategies and made comparable gains in learning the relative merits of the *trunc* strategy in terms of ease and closeness. In addition, Study 2 students were more likely to switch strategies from *round both* to *trunc*, which we interpret as a choice to optimize strategies based on ease of computation.

These findings have important implications for the assessment of flexibility and for interventions designed to promote flexibility. First, our results underscore the value of including measures of both knowledge and use in assessing flexibility. Our prior work indicates that knowledge develops prior to use (Star & Rittle-Johnson, 2008), suggesting the importance of knowledge measures to tap emerging flexibility. Similarly, in the present study, our investigation of students' strategy use showed that Study 1 students used a limited repertoire of strategies for solving posttest problems, yet our independent flexibility measures indicated that these students did develop sophisticated knowledge about the relative ease and closeness of various estimation strategies that was not reflected in their strategy choices.

Second, when considering the role of prior knowledge in the development of strategy flexibility, there are intuitive explanations for how prior knowledge can help or can hinder learning. On the one hand, students with high prior knowledge may be reluctant to adopt new strategies, given their fluency with (and likely preference for) a small set of known strategies. On the other hand, students with minimal prior knowledge may be overloaded by attempts to teach multiple strategies (and the pros and cons of each) at the onset of learning. Our results do not fall into one or the other side of this issue. Rather, an important take-away is that students' prior knowledge plays an important role in the development of strategy flexibility but in ways that are subtle and not completely understood. In particular, prior knowledge did not make students more or less willing to learn about or to adopt new strategies, but rather prior knowledge served as a filter through which students attend to or failed to attend to strategic information about problem solving methods. Study 1 students, who already possessed an easy-to-implement strategy for computing estimates, seemed driven to switch because of the proximity appeal of *round one*, while Study 2 students, who did not have an easily executable strategy at pretest, were attracted to the ease of execution offered by *trunc*.

In conclusion, our results indicate that prior knowledge plays an important but complex and nuanced role in the development of strategy flexibility. Flexibility can and should be an instructional goal for all students, but efforts to promote this outcome must carefully consider students' prior knowledge and the ways that such knowledge might promote or hinder students' knowledge of multiple strategies and their ability to select the most appropriate strategy for a given problem.

*In this paper we present a case study where middle school children, working in an after-school setting, develop knowledge (a) about their community and (b) about mathematics and use digital media to create and share literacy-based and mathematics-based digital stories as community service—that is, as a way of sharing knowledge with, and for the benefit of, others outside of educational settings.*

## Introduction

The role of community in education, and the sharing of knowledge as community service, is not a new idea. Educational institutions typically develop programs that encourage school-community and school-home connections. For example, the Ontario Ministry of Education has published booklets such as *Helping your Child Learn Math – A Parent's Guide* and *Helping your Child with Reading and Writing – A Guide for Parents* that help make home-school connections. Also, all Ontario high school students are required to complete a minimum of 40 hours of community involvement activities as part of the requirements for an Ontario Secondary School Diploma. In addition, high school students in Ontario can apply two co-operative education credits towards their core graduation requirements. However, despite such programs, it is probably fair to say that for the most part students see and experience their learning as a school-based activity, done within and for school, rather than for the purpose of sharing their knowledge with or for the benefit of others.

There are important implications for education if we view knowledge generated in educational settings as something to be shared with others in our community: (a) it enhances a sense of audience, motivating and giving purpose to student learning; (b) it increases the importance of skills needed to communicate with wider audiences; (c) it provides an opportunity for students to give voice to the things that concern them; (d) it creates school-community links by opening public windows into school learning; (e) it creates self-community links; and (f) it creates a setting for a meaningful application of the multimodal broadcasting capacities of digital media.

## Theoretical Perspective: Narrative and Agency/Identity

The case study positions middle school students as community storytellers of personal learning and growth, and offers opportunities for them to experience "narrative reconstruction" as they reflect on their lives, their learning, their choices, their past experiences and their goals for the future (Hull, 2003, p. 232). As Hull points out, "The ability to render one's world as changeable and oneself as an agent able to direct that change is integrally linked to acts of self-representation through writing" (p. 232). When adolescents are given opportunities to share their "identity texts" with peers, family, teachers and the general public through media, they are likely to make gains in self-confidence, self-esteem and a sense of community belonging through positive feedback (Cummins, Brown & Sayers, 2007). Hull (2003) urges collaboration among

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

educators, researchers, and community organizations to "find space and time to think expansively about the interface of literacy, youth culture, multi-media, and identity" (p. 233).

There is ample research on the role of narrative in the construction of personal agency and identity (cf. Ochs & Capps, 2001). Bruner's (1994) studies of narrative indicate that changes in conceptions and representations of self are typically associated with "turning points" in personal narratives. Bruner identifies turning points as "thickly agentive … whose construction results in increasing the realism and drama of the Self" (p. 50). There is a dialogical relationship between narrative and self: to shape our narrative is to shape ourselves, and vice versa. There is also a dialogical relationship between narrative/identity and community. Narratives are social artifacts and "the narrated self is constructed with and responsive to other people" (Miller & Goodnow, 1991, p. 172). Stories change depending on the audience, and a personal knowledge story aimed for a school-based audience can change when the audience is the wider community. When the audience is the community, the narrative becomes more of a public performance. Hull & Katz (2006) note "the power of public performance in generating especially intense moments of self-enactment" (p.47). Digital (unlike oral or solely print-based) stories potentially enhance the power of narrative to transform as they can be easily broadcast, creating a stronger sense of audience and performance.

In this research we also consider parallels between the arts and mathematics: between what makes for "a favourite book or movie" and what makes for "a favourite math idea or activity". This leads us to look to the performing arts to understand students' repertoires for organising and expressing the mathematical ideas they seek to communicate to one another and to their worlds outside of the classroom (Gadanidis & Borba, 2008; Gadanidis, Hughes & Borba, 2008). Bauman & Briggs (1990) suggest that digital stories, because they are forms of social interaction, are best analyzed from a framework that recognizes the dialectical relationship between performance and its wider social context. Hull & Katz (2006) add that "digital stories, because they of necessity layer multiple media and modes, complicate our understandings of textual performance as it is linked to the development of identity and agency" (p.47).

It should be noted that the knowledge shared by students is framed as "identity texts" (Cummins et al, 2005). That is, they are seen less as impersonal documentaries of knowledge and more as personal narratives of experience. The goal is to give students voice and agency in the context of community, and thus provide opportunities for students not only to learn subject matter but also to explore its and their place in the world around them. Thus, even stories that seem to be subject-based, like a new way of understanding a mathematical concept or problem, can also be seen as identity texts. Students who engage in developing a conceptual understanding of mathematics are also engaging in developing their mathematical identities (who they are and what they do when doing mathematics) as well as their view of mathematics (what mathematics is and how/why one engages with it). And when students author stories about experience and share them with the wider world, they are developing their identities within community.

## Methodology

*Setting for the Study*

The case study involved twelve middle school students at the Alderville First Nation Learning Centre, which had a lab of 10 desktop computers. Two additional laptops were provided by the research team for student use. Photo Story 3, a free download from www.microsoft.com, was installed on all computers.

The students typically attended a daily afterschool program organized by the Alderville First Nation Student Services, from 3:30 to 5:30, where they worked on homework and other educational activities. The research team was made up of two researchers and one research assistant. At least one of the researchers and the research assistant were present at all sessions. Also present at all sessions was one of the teachers from the Alderville First Nation Student Services and an educational assistant.

The twelve students participated in an afterschool program in which activities were designed by the research team, consisting of seven two-hour sessions and a culminating public performance of their work. During the first four sessions, students learned about and created digital stories of (a) various Alderville First Nation themes (like the Black Oak Savannah ecological sanctuary or the life of Ojibway marathon runner Fred Simpson) and (b) their experiences with rich mathematical tasks. Then students worked for three sessions to write poems and song lyrics based on the themes of their digital stories. They also worked with Aboriginal recording artists Tracy Bone, J.C. Campbell and Dave Mowat to add melodies to their poems and turn them into songs. In the last evening of the program, the students and recording artists performed the songs and digital stories for the students' community, at the Alderville Community Centre.

In this research we purposely involved students in the creation of both digital stories about their community and digital stories about their mathematics experiences. We assumed that students would have a better sense of story in the context of their community compared to the context of mathematics, and we wanted to draw parallels between the two contexts, to help students transfer their narrative skills about community to their mathematical storytelling. To reinforce this paralleling, we used George Ella Lyon's "Where I'm from" poem as a model for telling personal stories about community and about mathematics.

*Data Collection and Analysis*

Given that the case study involves only seven two-hour sessions with students, this research is exploratory in nature. Our general research interest in this case study is to investigate the elements that come into play when an educational program orients learning as community service and to develop a nascent conceptualization of "learning as community service". More specifically, we are interested in: (a) how community-oriented learning shapes what students learn and how they communicate their knowledge, and (b) how the public performances of students' knowledge shape the relationship between the educational institutions and the community.

We used a case study method, which is suitable for collecting in-depth stories of teaching and learning. The case study method is also appropriate for studying a 'bounded system' (that is, the thoughts and actions of participating students or the learning/community connection of a particular education setting) so as to understand it as it functions under natural conditions (Stake, 2000). The 12 students (along with the researchers, teachers, and recording artists) constituted a case. As well, individual students, and their digital stories, were considered as individual cases. The analysis was qualitative, in keeping with the established practice of in-depth studies of classroom-based learning and case studies in general (Stake, 2000). Case study data consisted of (a) field notes, (b) students' writing, (c) interviews with students, (d) interviews with one of the teachers, (e) interviews with one of the recording artists, (f) the digital stories created by students, and (g) the lyrics written by students. Because of the complex blending of multimodal data elements, we used the digital storytelling analysis method of Hull and Katz (2006) of developing a "pictorial and textual representation of those elements" (p.41)—that is, columns of the spoken words from recordings juxtaposed with original written text, the images from digital stories, and data from interviews, field notes and lyrics. This facilitated the "qualitative analysis of patterns" (p.41). The analytic methods included thematic coding (Miles, 1994) and critical discourse analysis (Fairclough, 1995). The data was read and coded for major themes and sub-themes across data sources, and the codes were revised and expanded as more themes emerged. In the authoring of the digital stories, we were particularly interested in moments that might be interpreted as "turning points" (Bruner, 1994) in the representation of identity and/or the conceptual understanding of subject-based knowledge. Part of the analytic process was to use "turning point" moments to construct narrative lines, based on diverse sources of data (Hull & Katz, 2006). Like Hull and Katz (2006), who also researched cases of digital storytelling, we relied on the work of linguistic anthropologists Bauman and Briggs (1990) and their "agent-centred" view of verbal performance (pp. 67-71), and adapted their framework to characterize the ways in which speakers can establish textual authority. A cross case analysis was conducted to compare/contrast the cases of individual students and to compare/contrast digital stories about Alderville and about mathematics.

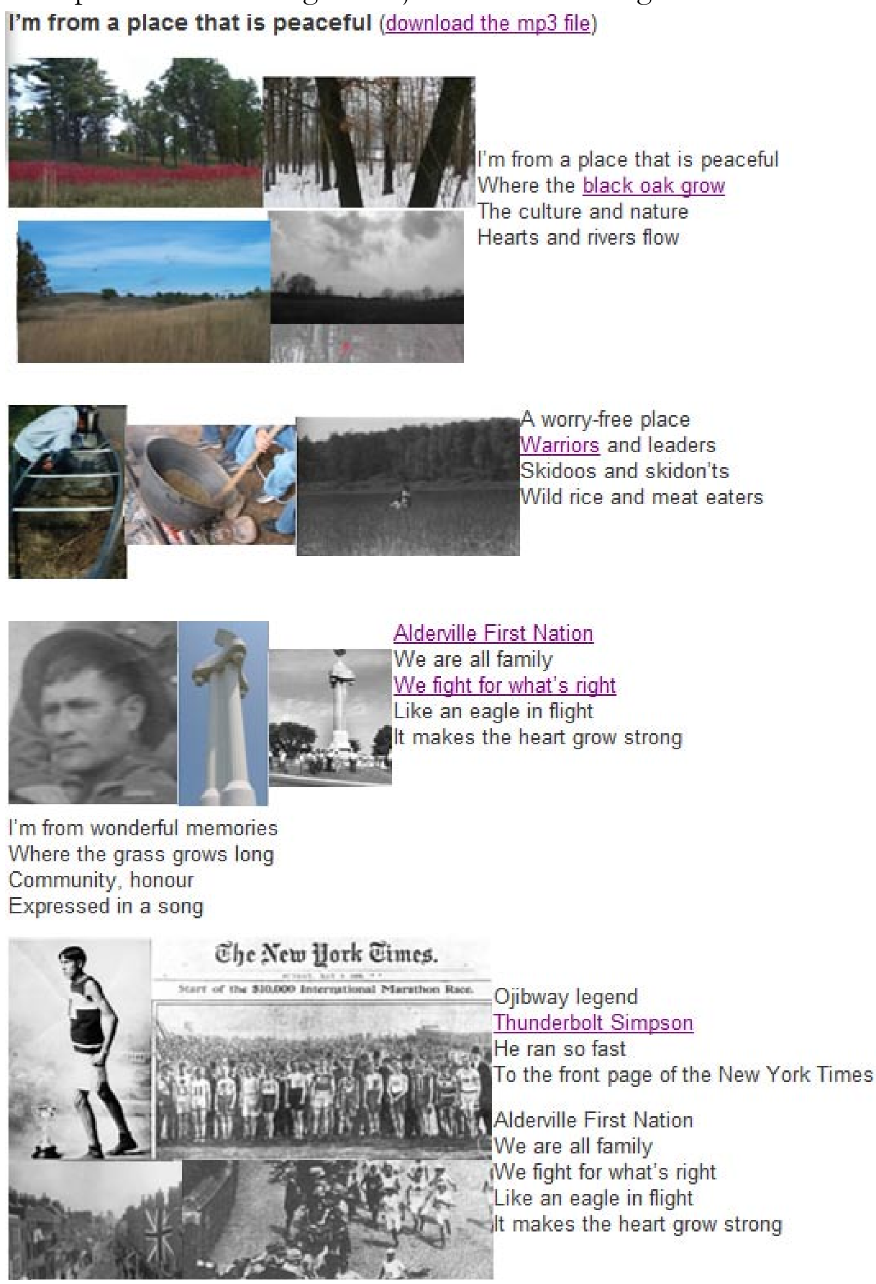

*Figure 1.* Alderville song.

## Findings and Discussion

A more complete discussion will be provided at the PMENA conference. Given the space restriction, we limit our discussion to a subset of the results. We will discuss the case study in terms of three themes that are evident in the data collected and are also key ideas in our theoretical approach: identity, community and turning points.

*Identity*

*Alderville.* Aboriginal identity was a theme identified by the Alderville Student Services staff. There were significant problems here twenty years ago. The language was lost, there was really no tradition and there were a lot of social problems that went along with that. So this community has really worked at it. In the last 15 years there has been a real momentum. There is a real effort to bring some of that back. And it translates into I think they have a better sense of who they are and because of that they want to achieve, not necessarily be a straight A student but be proud of who they are. One of the recording artists commented on the students' sense of identity as aboriginal children.

> It educated me. I was never brought up in the culture. I'm just learning myself. So they know a lot more than I do. I learned a lot through their lyrics, about things they do in their community and how proud they are, and it really brings me a lot of joy and hope for our future because they are so proud of who they are because when I was young, the years that I was young and in school I didn't feel as proud.. I was very moved by the kids and how proud they are of their community, very proud of it.

In the song *I'm from a place that is peaceful* (see Figure 1), the students describe some of the Alderville themes we discussed in Session 1: the Black Oak Savanna, the wild rice harvest, the cenotaph erected to honour the Alderville soldiers who died in First World War, and the marathon runner Fred Simpson. Some of the pictures that students used to create their digital stories were part of the historical archive of one of the Alderville councilors. Many of these pictures were used to illustrate the themes in the song. Not all of the students were familiar with all of these themes, and not all to the same degree.

> I think most of them know about the Black Oak Savanna, that it's a protected area, and it's important to the community. They wouldn't be able to tell you what grows there, how big it is, all the details but they know something, they have an idea. They all know about the Pow Wow, some traditions. Some families get really involved with it. Five of them have outfits and they dance the Pow Wow. They have been brought up to know that. About half of them are strongly involved with different traditions that are going on in the community. These kids would feel quite comfortable talking to you about what the traditions are. Maybe a little less about Fred Simpson, they would know a little less about him. On Remembrance Day I lay down a wreath on behalf of Student Services, every year since I started working here and a lot of the kids would be there, doing the drumming or they are coming with their parents. Now the kids from Roseneath would know more, they have a native liaison there, but not all the others. So they were learning. They were learning and sharing.

*Mathematics.* The authoring of "Where I'm from" digital stories and poems about Alderville set the stage for students writing similar poems about mathematics experiences (see Figure 2). Students responded well to a mathematics that involved hands-on activities and dramatic interpretations of concepts and ideas. In the sum of odd numbers activity, students used linking cubes to represent odd numbers as a growing L pattern. The fitting of consecutive Ls to form a growing square offered students a visual and tangible representation of the proof that the sum of the first N odd numbers in NxN. They used a similar pattern to explore the sums of consecutive even numbers. In the spherical geometry activity, they also used balloons to model a sphere and used pens to draw lines on the balloons to explore straight and parallel lines on a sphere. Students also used drama to communicate some of their ideas. One of the Alderville Student Services staff commented:

> It's no surprise to me that kids will respond more to hands-on, dramatic interpretations of math, as opposed to math out of the textbook. We did none of that but we did a lot of drama, using the computers, trying to access math in a different way. So that's quite interesting.

Parents reported that students enjoyed the math sessions. "The parents thought that the kids seemed like they were really enjoying it. They were looking forward to it. 'Oh, my child really likes math'.

The mathematics activities also involved problem solving and opportunities to explore and experience complex mathematics. The sum of odd numbers activity, which can also be found in upper high school mathematics (sequences and series), was made accessible to middle school students through the use of concrete materials. The spherical geometry activity is one that is typically not in the public school mathematics curriculum. Although we live on a sphere, the geometry of school mathematics is typically limited to flat surfaces. The combination of complex and imaginative mathematics offered students new ways of looking at what mathematics is and what it means to do mathematics. One of the student services staff noted:

> I think they learned to be open to new ideas. I think that's always a good thing. They're receptive to let's give it a try. I like to see that in our kids, they're willing, to give it a shot. And they were at least willing to look at the idea of math in this way. They didn't really question it. They showed up, and 'alright, what are we doing tonight?'

One of the recording artists commented:

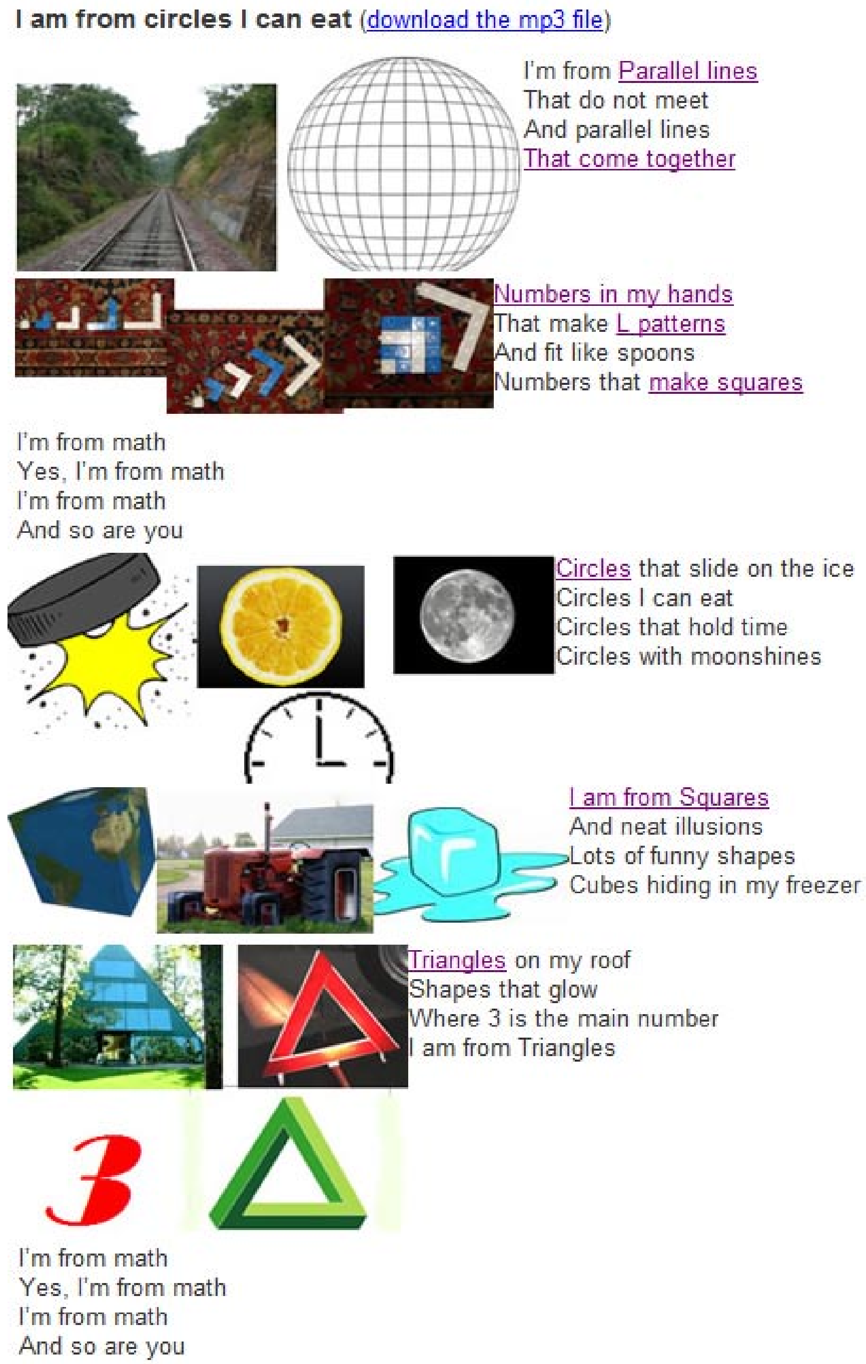

*Figure 2.* Math song.

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

> But I look at it different now. I look at math totally differently. I was looking at one of the towels upstairs and they have lines and I was thinking about parallel lines (laughter). It makes me look at the world and things differently.

*Community*

When asked what role community service played in the program for students, one of the student services staff commented that "I honestly believe that that's the biggest part of what we did."

One of the recording artists expressed the opinion that the experience would have a lasting effect on the community. "They'll be talking about this with their friends and their families. And they talk about it to other people."

In the evening following the 7th and last session of the program, students, along with the performance artists, performed their songs for their community at the Alderville Community Centre. Videos of their performance are available at http://www.edu.uwo.ca/mpc/alderville.html. It should be noted that our initial *community service* plan was that students would create digital stories and share these through the project website. However, our intent to *share* students' work beyond the classroom setting also meant that we were open to opportunities that emerged to share students' work in other ways. The opportunities that emerged included the following: Dave Mowat, who was our local resource for the history of the Alderville First Nation was also a recording artist; the research assistant on the project had both a mathematics and a music background; we had recently worked with aboriginal recording artist Tracy Bone on another project; the Alderville Learning Centre was adjacent to the Alderville Community Centre, which had a stage and sound system; and one of the researchers (second author) has a drama background.

*Turning Points*

We identified a number of turning points during the course of the project.

- *The performative pull of community oriented learning.* As discussed above, our initial plan was for students to create digital stories and share these through a website. Our community focus led us to unexpected community collaborations that expanded the project's performative orientation.
- *Seeing math differently***.** The mathematics activities and their integration with the arts help shift teachers', students' and recording artists' views of math. This shift is evident in the poems and digital stories authored by the students, where mathematics incorporates playfulness and imagination. As one of the recording artists commented, "I look at it different now. I look at math totally differently."
- *Strengthening identity***.** Although the (Alderville or mathematical) themes expressed in the poems and songs came from various individuals, the final product was appropriated by all students. As one of the recording artists commented, "It educated me. I was very moved by the kids and how proud they are of their community, very proud of it."
- *New relationship for the community***.** The project created a new relationship between two universities and a First Nation community. Past research relationships with the community focused on research based on surveys. As one of the teachers commented, "This is something different that we haven't done before. We've partnered before but we've never had a university come in and try that with the kids and it was really a lot of fun. People are sick and tired of doing surveys."

- *Raised expectations of what students can do***.** The teachers expressed surprise at both the artistic and mathematical ability of students. One teacher commented, “I was surprised with the lyrics they came up with … the way they looked at math and music and how they incorporated them.”

## Looking Ahead

The learning as community service focus of the Alderville First Nation project, although small in scope, offers some potential for new ideas in mathematics education. The community focus, and the community as audience for school learning, has the potential of drawing classroom teaching and learning towards performative directions. One question in our minds is how the methods of this project might be used in the more structured environments or regular classrooms. Towards this end, we are presently using the methods of this project in mathematics classrooms in a K-8 elementary school, over a more extended period of time and with seven different classrooms.

*In this research we take the view (as an elementary school teacher noted) that mathematics "can be discussed with your family and friends just like you would a favourite book or new movie". Such a view—rather uncommon in our culture, where mathematical ideas are rarely shared or discussed beyond the confines of mathematics classrooms or communities of mathematicians—leads us to consider parallels between the arts (whose aesthetic qualities support social and imaginative interactions) and mathematics: between what makes for "a favourite book or movie" and what makes for "a favourite math idea or activity." It also leads us to look to the performing arts to understand students' repertoires for organising and expressing the mathematical ideas they seek to communicate to one another and to their world outside of the classroom.*

## Introduction

When parents ask children "What did you do in math today?" it is not uncommon for children to reply: "Nothing" or "I don't know", or to mention a topic like integers or geometry, without elaborating. To change this situation, we imagine that we would need to work on at least two fronts, which we discuss below: (a) mathematics experiences worth talking about, and (b) skills for communicating mathematics beyond the classroom.

Mathematics Worth Talking About

In our experience in mathematics classrooms, as teachers and as researchers, we have found that mathematics activities that have a low floor and a high ceiling often tend to create mathematics experiences worth talking about. By a low floor we mean that the mathematics knowledge prerequisites for engaging with the activity are kept to a minimum. By a high ceiling we mean that the mathematics activities lead to or can be extended to include much more complex mathematical ideas and relationships. For example, the L pattern shown in Figure 1 can be used as a starting point for exploring the following questions, which (a) range from patterning in grade 2 to the study of sequences and series in grade 11, and (b) for the most part can be made accessible to younger students using concrete representations (Gadanidis, Hughes & Borba, 2008):

- How does the pattern grow, and what would the $10^{th}$ stage look like?
- Notice that the first 5 stages fit together to form a 5x5 square. What is interesting about this?

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

- If we were to construct the first 10 stages, how many blocks would we need?
- What is the sum of the first 5 odd numbers? The first 10? The first N?
- What if we added 1 block to each stage? What changes?
- If we were to construct the first 10 stages of this new pattern, how many blocks would we need?
- What is the sum of the first 5 even numbers? The first 10? The first N?

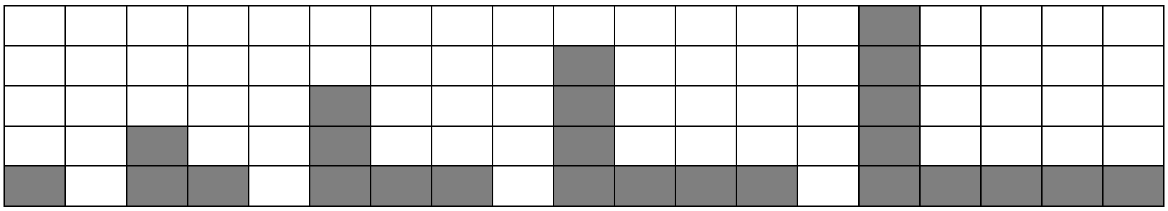

*Figure 1.* L pattern.

Gadanidis and Borba (2008) have looked at mathematics through a performing arts lens, using the performance model by Boorstin (1990) for analyzing movies. Boorstin suggests that we get three distinct pleasures from watching a movie, which we will paraphrase to suit our mathematics context: (a) the pleasure of experiencing the new, the wonderful and the surprising in mathematics; (b) the pleasure of experiencing emotional mathematical moments (either our own, or vicariously, those of others); and (c) the visceral pleasure of sensing mathematical beauty.

*The pleasure of experiencing the new, the wonderful and the surprising in mathematics.* The L pattern activity offers a number of surprises. Isn't it neat that the pattern also represents the odd numbers? Isn't it neat that the sums of these odd numbers are square numbers, and that these can be represented physically as squares? Isn't it neat that we can also add the odd numbers by pairing the first with the last, the second with the second last, and so forth? And this world can grow, by imagining variations on the original pattern.

*The pleasure of experiencing emotional mathematical moments (either our own, or vicariously, those of others).* Students who engage with this activity become excited about the patterns they are noticing and share their ideas and their excitement with others. Students may also experience moments of frustration or anxiety, or other feelings, and share these feelings as well. One student commented, "I felt like I was a lot younger because I haven't played with these blocks for a very long time." Another said, "I liked this more because I was more challenged than regular math." We can imagine a classroom where emotional moments become visible and valued, making mathematics more of a human (thinking + feeling) endeavour.

*The visceral pleasure of sensing mathematical beauty***.** We recently did the L patterns activity with 180 elementary preservice teachers in an auditorium setting (using blocks in small groups). When we showed them a digital simulation of the Ls fitting together, there was an audible visceral reaction from the teachers ("ooh", "ah", and laughter). We witnessed a similar reaction in a fourth-grade classroom. Zwicky (2003), commenting on this square pattern formed by the Ls—this visual proof that the sum of the first N odd numbers is $N^2$—says that such patterns draw our attention, and invite us to "Look at things like this" (p. 38). Sinclair (2001) notes that an aesthetic math experience often involves a sense of pattern or a sense of fit.

*Communicating Mathematics beyond the Classroom*

Our research objective is to explore the concept of elementary school students as "performance mathematicians" (Gadanidis & Borba, 2008; Gadanidis, Hughes & Borba, 2008).

Our research questions are: (1) how might classroom mathematical ideas and experiences be structured to increase their performative potential? (2) how might (a) performance arts methods and (b) digital communication affordances (like the multimodal nature of new media and the read/write capabilities of wikis) be used by students for organizing and expressing the mathematical ideas they seek to communicate to one another and to the wider world? We intend to create a parallel between the classroom focus on performance and the methods and methodology of our research, by relying on performance ethnography methods (Denzin, 2003, 2006; Dicks, Mason, Coffey & Atkinson, 2005; Madison, 2006; McCall, 2000).

When we see a movie we like or read a book we enjoy, we typically share our experience with others. When we do this, we don't retell the whole story. Rather, we might share what was new or fresh about the story, how the plot's turns might have surprised us, and how the movie or book made us feel. In other words, we concisely relate some of the *pleasures* of the experience identified by Boorstin. In our work with students, we aim to focus students' retelling (or performance) of math experiences on the pleasures of (a) the mathematically new, wonderful and surprising, (b) their emotional moments, and (c) the sensing of mathematical beauty.

## Examples of Math Performances

The construct of "students as performance mathematicians" is new in mathematics education and offers a fresh perspective on what school mathematics might be and how students might experience the subject. Some mathematical films do exist (like the 1960's short films produced by filmmaker René Jodoin at the National Film Board of Canada: *Spheres* (Jodoin, 1969), *Dance Squared* (Jodoin, 1961) and *Notes on a Triangle* (Jodoin, 1966)) and some mathematical songs are used in schools (like *Zero, My Hero* by Schoolhouse Rock (Schoolhouse Rock, 1973)). There do exist popular movies about mathematicians, such as *Good Will Hunting* and *A Beautiful Mind*; however, these movies are not performances of mathematics but rather narratives of the social adventures of mathematicians. Some digital examples of student "artistic" mathematical performances can be found on the Web, particularly images of geometry art (typically using tessellations), and student-produced mathematical videos that are just starting to appear on the Web (on YouTube, for example). For the most part, however, it is fair to say that the idea of students creating mathematical performances—digital or otherwise—as a way of communicating their ideas within the classroom and to the world beyond is new. In today's mathematics classrooms "mathematical performance" is associated with testing and standards and "digital mathematics" is associated with using technology to model mathematical concepts or with eLearning, not with students' aesthetic experiences and artistic expressions of mathematics.

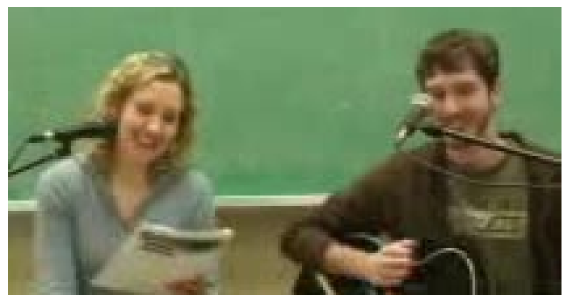
A recent venue for math performances is the Canada-wide *Math Performance Festival* (available at http://mathfest.ca). Below we briefly describe and discuss three math performances submitted to the *Festival.*

*Little Quad's Quest*

*Little Quad's Quest* (available at http://www.edu.uwo.ca/mathscene/lq/lq1.html) is a five-part shadow theatre performance created by a class of fifth-grade students. Little Quad, the protagonist, is in search of his identity. All of Little Quad's quadrilateral friends (Square, Rectangle, Rhombus and Trapezoid), unlike Little Quad, have their own special names.

How do we find instructional time to help students create such performances? Creating a performance like *Little Quad's Quest* takes much longer than 'covering' the concept of quadrilaterals in a more typical fashion. However, the process of creating such a performance integrates mathematics concepts with language arts, visual arts, and drama. The extra time spent is valuable and meaningful instructional time. Perhaps more importantly, such settings offer students opportunities to think creatively and imaginatively about mathematical concepts. They also afford personal and emotional connections to mathematical ideas.

*Measuring the Millimetres to YouMeasuring the Millimetres to You* (available at http://www.edu.uwo.ca/mathscene/pst/pst5.html) is a song written and performed by preservice teachers at The University of Western Ontario. In this romantic ballad, two friends are saddened because of the great distance (100,000 mm) that separates them. Then, they realize that 100,000 mm is the same as 10,000 cm. And, if they divide by 10 and by 10 again, they are really not that far apart: only 100 m.



This song provides insights into the Metric system in ways that are humourous, emotional and difficult to forget.

*Now I'm a Trapezoid*

*Now I'm a Trapezoid* (available at http://www.edu.uwo.ca/mathscene/geometry/geo1.html) is a song by a triangle that lost her head. Saddened by this loss, the triangle laments that it's now a trapezoid. The song is one of three songs in a Geometry Idol contest setting. The second song is *Triangles Rock*, and the third song is *Hexagon*.

A triangle loses its 'head' and becomes a trapezoid. Does this view of shapes and their relationships make a difference, for students, for teachers, for you? How might the student who sings the song see triangles and trapezoids differently? How might she 'feel' differently about these shapes, and about mathematics in general? What if the triangle lost all three of its vertices? What might it become? What if the triangle was created by cutting vertices off of another shape: what might this shape have been?

## Methodology

*Setting*

The study is, at the time of writing, in progress and involves seven teachers and students in grades 2, 5 and 8. The study uses mathematics activities that engage their imagination and motivate them to share their learning with others. Starting with the same core mathematical ideas (one of which is the L pattern exploration discussed above), teachers work with the project team to develop activities suitable for students at the different grade levels (2, 5 and 8). Students are provided with models and opportunities to 'perform' (communicate) complex mathematical ideas in compelling ways, using the Arts (story, drama, poetry, song, and artwork). Some models we have used so far include: (a) retelling experiences that students find surprising, (b) embedding the core activity in a fairy tale (where the Big Bad Wolf tempts Little Red Riding Hood with chocolate bar pieces in the shape of Ls), (c) rewriting George Ella Lyon's poem *Where I'm From*, using their math experiences as a base to write *I'm From Math*, and putting some of the poems to music to create songs.

*Timeline*

*Table 1*

Research Plan for January to May of 2009

| **2009 DATES** | **DESCRIPTION** | **NOTES** |
|---|---|---|
| January | Full-day math/planning session<br>• Teachers engage in (1) doing mathematics and (2) in artistically performing what they have learned/experienced<br>• Teachers collaboratively plan the first set of activities | |
| January-March | Teachers engage students in the first set of activities<br>• Each activity consist of 3-5 math classes (or approximately 3-5 hours of mathematics instruction)<br>• Students are provided with models and opportunities for communicating their ideas and knowledge in artistic ways | The research team will observe classroom activities and may also assist with instruction as needed by the teachers. |
| End of March | Half-day math/planning/reflection session<br>• Teachers reflect on classroom experiences<br>• Teachers engage in doing more mathematics<br>• Teachers collaboratively plan the second set of activities | |
| March-April | Teachers engage students in the second set of activities<br>• The activities consist of five math classes (or approximately 5 hours of mathematics instruction)<br>• Students are provided with models and opportunities for communicating their | The research team will observe classroom activities and may also assist with instruction as needed by the teachers. |

| | | |
|---|---|---|
| | ideas and knowledge in artistic ways | |
| May | Public performance<br>• Students perform their math performances during a afternoon where parents and the public are invited<br>Half-day math/planning/reflection session<br>• Teachers reflect on classroom experiences<br>• Research team presents preliminary data analysis for discussion and feedback<br>• Teachers and research team create a performance to communicate some of the ideas and/or results of the project | |

The research team, in collaboration with the teachers in the study, will design mathematical experiences that afford students opportunities to engage imaginatively with mathematics. Such mathematics "activities" are treated as drafts, to be adapted for use in each classroom and then revised based on teacher/researcher reflection for future use. The culminating student task in each activity will be the creation of a mathematical performance that depicts some of the mathematical and aesthetic qualities of students' real or imagined experiences. We are thinking about a performance mindset that spends proportionally longer on exploration (called rehearsal in theatre) that is not about "getting it right" but about exploring the possibilities of the text, stage, setting and characters. This approach to learning borrows from Frye (1988, 1990) whose understanding of the aesthetic was located in such considerations as "what if" "let's pretend" – those aspects of the psyche not usually valued at anything but the earliest levels of education. The performances will in some cases be created by individual students, in some cases by small groups, and in other cases by a whole class. The performances may take the form of a poem, reader's theatre, role play, improvisation, song, drawing or painting, or a combination of some of these forms. These live performances will occur in the classes and also at a culminating afternoon, where parents and the public will be invited to attend. All performances will be videotaped, and some (with student and parental permission) may also be shared publicly through the Math Performance Festival website.

Ethnographic data will be collected through classroom observation and field notes, audio or video recording of selected classroom activities, and individual and focus group interviews of students and teachers.

We intend to create a parallel between the classroom focus on performance and the methods and methodology of our research, by relying on performance ethnography methods (Denzin, 2003, 2006; Dicks, Mason, Coffey & Atkinson, 2005; Madison, 2006; McCall, 2000). The research team will use content analyses (Berg, 2004) of research data to build up piece by piece coherent, data-centred "stories" (Emerson, Fretz & Shaw, 1995). McCall (2000) (building on the work of Emerson et al) suggests that in writing an ethnographic performance script, the researcher "must read and reread their field notes or transcripts" to "create and elaborate analytic themes" and "organize some of these into a coherent story" (p. 427). Our ethnographic performances will take either digital form, for example, as video recordings of the performances we script, cast and perform, or as multimedia stories using digital storytelling tools like Photo

Story or iPhoto, which use zooming and panning on still pictures accompanied by narration and/or music. These ethnographic performances will then be shared with teachers and students, thus returning these "stories" to the classrooms from which they emerged (McCall, 2000; Denzin, 2003). We also intend to post our performance ethnography scripts in the project wiki and encourage teachers and students to edit these scripts to add their own interpretations of events—to add their own voices, perspectives and stories, leading to the creation of new digital performances. We will also invite teachers and students to become cast members in these performances.

An ethnographic approach is appropriate for our research as we seek to enter into "close and relatively prolonged interaction with people … in their everyday (classroom) lives" (Tedlock, 2000, p. 456) in order to investigate a community of mathematical performance in each of the schools as well as their relationships of participants across schools, and over a three-year period. The reliance on performance for (a) students to communicate mathematical ideas and (b) researchers to communicate research ideas about mathematics teaching and learning in a performance-rich setting provides a way of communicating about mathematics and mathematics research more publicly, bringing mathematics to the world beyond the classroom and mathematics education research beyond the scholarly community. This paralleling of methods of doing and researching mathematics will also serve to build a performance community of students, teachers and researchers. In this sense, the researchers are immersing themselves and their methods in the performance tools and methods of the subjects of their study.

## Findings and Discussion

The study is currently in progress and some of the classroom activities are underway. However, we do not have sufficient data on which to report at this stage. The project will be completed by June 2009 and we will be able to provide details of the findings at the 2009 PMENA Conference.

# COMMON PLANNING IN THE MIDDLE SCHOOL: WHAT DO 7TH GRADE MATHEMATICS TEACHERS DO?

Eileen Murray
University of Georgia

Dorothy Y. White
University of Georgia
dywhite@uga.edu

Victor L. Brunaud-Vega
University of Georgia
lbrunaud@uga.edu

*This paper describes preliminary analysis from data obtained during the common planning time for a team of 7th grade mathematics teachers. The focus of the planning time was primarily about what the teachers were going to teach that day or in the near future. Later in the semester we began to see changes in this focus towards discussions about tasks, students, and activities that would best suit the needs of various groups of students.*

Curriculum standards are sweeping across the education landscape (Sandholtz, Ogawa, & Scribner, 2004). In the last two decades, state level interventions have encouraged the adoption of standards (Marzano & Kendall, 1997; Ravitch, 1996; Tucker & Codding, 2001), due to federal mandates such as *No Child Left Behind* (2001). Most states have launched some form of standards-based instruction with the expectation that the reform would improve student achievement and equality of educational opportunity (Berger, 2000; Buttram & Waters, 1997; Sirotnik & Kimball, 1999; Sutton & Krueger, 1997). According to Pappano (2007) teachers need collaboration to help them implement standards-based instruction.

Teacher collaboration is a primary factor in teachers' ability to implement change in their instruction towards more effective pedagogical strategies (Briscoe & Peters, 1997; Gajda & Koliba, 2008). Collaboration serves as a catalyst to teachers' abilities to reflect on their practice, is vital to continuous teacher learning (Riley, 2001), helps teachers find the courage to take risks in their practice through developing and providing new learning experiences for their students, and fosters growth in teachers' pedagogical and content knowledge (Briscoe & Peters, 1997). These differences caused by increased collaboration aid teachers in working towards more inquiry-based, or standards-based, instruction.

It is important for researchers to understand that collaboration is necessary but it alone is not sufficient for teacher change and learning (Briscoe & Peters, 1997). Collaboration can certainly help facilitate teacher change, but to create an environment that is conducive to change, teachers' individual commitment to change is equally important (Briscoe & Peters, 1997). Teacher collaboration should include active learning in which teachers engage in activities such as observing other classes, collaborative planning, and reviewing student work together (Garet, Porter, Desimone, Birman, & Yoon, 2001). These characteristics have a positive relationship "to changes in teachers' knowledge and skills and changes in practice" (Graham, 2007, p. 6).

Principals and other school administrators have tried to promote collaboration by giving teachers additional time to plan together during school hours (DuFour, 2004). However, most of the research on common planning time has focused on elementary, special education, language arts, and science teachers. However, mathematics teachers are also increasing their use of common planning. This paper describes preliminary analysis of a research study that answers the question: What do 7th grade mathematics teachers focus on when they plan collaboratively?

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

## Relevant Literature

Several researchers have examined the effectiveness of collaboration, including common planning (Briscoe & Peters, 1997; Graham, 2007; Shachar & Shmuelevitz, 1997; Tonso, Jung, & Colombo, 2006). This planning should have a focus on students and student learning in order to be successful (Tonso, Jung, & Colombo, 2006). One way to make sure that planning is focused on student learning is to use specific techniques to engage teachers in reflection of their practice. Smith (2001) uses a reflective teaching cycle in her professional development with teachers. This cycle includes building teacher knowledge, planning a lesson, observing implementation, and reflecting on the lesson. Briscoe and Peters (1997) describe collaboration that shapes teacher change using three assertions that resemble Smith's approach. The first assertion, similar to building knowledge and planning a lesson, is brainstorming. This is an important process that assists teachers to learn content and pedagogical knowledge from one another. Assertion two, like observing, provides teachers with the knowledge that a colleague would be there to try similar activities and discuss successes and failures provided teachers with courage to take risks they would not otherwise have taken. Finally, the third assertion, like reflection, is that teachers should participate in meetings that provide a valuable opportunity to consider what worked and what did not. These experiences rejuvenated teachers and encouraged them to continue to use problem-centered activities (Briscoe & Peters, 1997).

Shachar and Shmuelevitz (1997) also use a method of collaboration similar to the reflective teaching cycle. In their research, teachers engaged "in cooperative planning of lessons, implementation of plans by one teacher in the group while the others made systematic observations, followed by a feedback session based on the observations made during the lesson" (Shachar & Shmuelevitz, 1997, p. 58). The researchers found that the teachers who reported effective collaboration had a higher level of self-efficacy and efficacy in their ability to promote students' social relations in the classroom.

## Conceptual Framework

Brown, Arbaugh, Allen, and Koe (2000) identified three ways teachers address issues related to mathematics content during common planning time: (1) Scope and Sequence; (2) Talk about Tasks; and (3) Working through Tasks. *Scope and Sequence* is the time teachers spend discussing mathematics topics taught and the order in which they are taught. *Talking about Tasks* refers to the time teachers spend discussing specific tasks or activities that were or would be used in instruction. Finally, *Working through Tasks* is the time teachers spend actually working through a task as a student would. The study reported that teachers spent the majority of their time taking about tasks, describing and reflecting upon ones they had already used including a focus on student difficulties with the tasks. The teachers spent a moderate amount of time discussing past and future issues of scope and sequence and a minimal amount of time working through tasks. When the teachers did focus on working through tasks, a mathematics educator initiated and led the conversation.

## Methodology

The research is being conducted in the context of Project ISMAC (Improving Students' Mathematical Achievement through a Professional Learning Community), a school-based professional development project designed to increase teachers' mathematical content and pedagogical knowledge, while building a mathematics education community among the entire mathematics department at College Middle School, one mathematics educator, and two graduate students. The project includes professional development workshops, the facilitation of weekly grade-level planning meetings, demonstration lessons, and classroom observations. This paper focuses on work with a team of 7th grade mathematics teachers during their weekly grade-level planning meetings.

College Middle School is a small urban school enrolling approximately 640 students. In 7$^{th}$ grade, there are two math teachers, Ms. Bell and Mr. Williams, and one special education teacher, Mr. Sanders. The special education teacher supports a classroom teacher during two periods and independently teaches one mathematics class with six students. The classroom teachers instruct five mathematics classes of 20 – 25 students and are provided with one period for planning. Common planning of mathematics occurs on Wednesday.

During the 2008-2009 school year, we facilitated 14 planning and collaborative meetings. During the meetings we wrote field notes and audio-recorded the conversations. A common set of field notes constituted the data for this report. We used the categories established by Brown et. al. (2000) to initially organize the data.

## Findings

There are many topics this team of 7$^{th}$ grade mathematics teachers talked about during collaborative planning. They talked about non-planning as well as planning topics. Non-planning topics include professional growth or concerns, expectations for students, and classroom management and students issues. What follows are the planning topics they discussed using Brown et. al. (2000) three categories: (1) scope and sequence, (2) talking about tasks, and (3) working through tasks.

*Scope and Sequence*

The scope and sequence discussions were typically teacher initiated and dominated the focus of most meetings. Teachers focused attention on two main topics: pacing and presentation of the lesson. The teachers would concentrate their efforts on unit pacing and what they would be teaching that day. These discussions were based on the state unit previews and curriculum maps, what topics would be on the next district assessment, and what was in their instructional materials, i.e. book, unit, and page number. On at least two occasions, one of the teachers expressed anxiety over thinking too far into the future because she may forget what we discussed.

The teachers were concerned about how to preview lessons, use mathematical reflections, modify tasks, and talk about vocabulary. They concentrated on gaps in student knowledge, questioning, and what mathematical procedures and methods would be the most effective. However, these comments were rarely supported by rigorous observations of student thinking. Instead, the teachers defended their ideas by expressing opinions about how the students were feeling or why they were not succeeding on the tasks and assessments.

*Talking about Tasks*

Mathematical tasks are defined as mathematics problems or activities that students will engage in during a lesson. When the teachers focused on mathematical tasks or activities, it was generally to talk about what they would be using for their lessons that day or week. They would only discuss how to use tasks after we prompted them. In only one case did a teacher talk about a task he completed with his class.

In the beginning of the fall semester, the teachers would show what they had found from instructional resources or had been given from other teachers. They also relied on the researchers as additional sources for classroom activities. Their discussions did not include questions about the mathematical goals of the tasks, how the students would approach the task, what the students would have problems with, or what questions the teachers could use to support student learning. In the beginning of the semester, the only time the teachers spoke about these things was when one of the researchers introduced them into the dialogue. As time progressed, the teachers began to take on more responsibility for these types of discussions.

The two classroom teachers, Ms. Bell and Mr. Williams each started approaching the mathematical tasks in different ways. In September, Ms. Bell talked about her warm up problems by saying what they were and what she would tell the students. By November, she spoke about what her warm up problems by not only showing what they were, but how she expected her students to use different models to solve the problems. In the beginning, Mr. Williams was using tasks from other teachers or getting suggestions and lesson plans from the researchers. By mid-October, Mr. Williams was bringing his own ideas to the meetings. He had begun to read his instructional materials and think about what activities would be most appropriate for his students. However, the researchers still worked to press Mr. Williams on the mathematical goals of the tasks to help clarify the content, and to think about appropriate questioning and student thinking.

*Working through Tasks*

There was only one instance of the teachers working through tasks. This was prompted by the district secondary math coach as she previewed an upcoming unit on Geometric constructions. The mathematics coach wanted the teachers to explore the constructions as a student would. Unfortunately, Mr. Williams and Mr. Sanders were more concerned with finding the answer using procedures and having the necessary tools to teach the lesson. In contrast, Ms. Bell tried to work through the investigation, but we ran out of time. It was unclear if this session was really about working through the task as a student would, but it was the closest we could find in this category.

## Discussion

The research on teacher collaboration suggests that when teachers are provided with opportunities to plan and review student work together they are more likely to deepen their content knowledge and change pedagogical practices. In our study, the teachers used their common planning time to foster collaboration and learning. Although we used the categories developed by Brown and her colleagues (2000), our findings differed in several ways.

We found that teachers spent most of their planning time talking about scope and sequence in general, and what they were going to teach in particular. The teachers were very concerned about the pacing, the sequence of contents, and less interested in choosing inquiry-based activities. This concern may be due to pressures from the state and district for the school to make Adequate Yearly Progress (NCLB, 2001) – something the school has not met in the last six years. As the district continues to push the use of a mandatory pacing guide, teachers are less inclined to consider student thinking and using inquiry-based activities because these decisions may not align with mandated materials.

Whereas Brown et al (2000) reported teachers focusing on the past, present, and future, our data shows the common planning focus very much in the present. The teachers did not spend time reflecting on past lessons or tasks to assess their students' understanding of the material or to think about possible changes that would make the activities more successful in the future. Research says that effective collaboration should focus on student thinking and learning

(Pappano, 2007; Tonso, Jung, & Colombo, 2006). Ms. Bell and Mr. Williams chose mathematical topics and tasks based on state and district resources. They did not work through the tasks to determine the level of difficulty, the appropriateness, or the potential problems the activities could cause for their students. Similar to Brown et al's (2000) observations, the only time the teachers talked about how the tasks would be used and how their students would react was when a researcher asked them. Otherwise, the teachers were trying to figure out what they considered to be the best way to present the material instead of starting from student thinking to figure out how to build on their students' knowledge and experience to facilitate learning.

We are starting to see changes in the teachers' focus during common planning time. This was accomplished in part through our facilitation of deeper discussions as we asked teachers to predict what their students would struggle with and why. They are realizing that by focusing more on student thinking, they can stay true to the district guides and textbook. They are also working to modify mathematical tasks to best suit their classes' needs, but these observations remain largely about groups of students instead of individuals. Thus, teachers can make more progress towards improving instruction by considering particular student's thinking when planning.

Teachers may need support in learning how to effectively use common planning time, and one way to do this is to have a facilitator present who can ask questions, probe the teachers thinking, and lead them into talking about tasks and doing tasks. We will conduct further research to understand our role in this process and how we may best support the teachers in focusing their common planning time on matters that will more directly impact their students' learning. Further research also needs to be done to understand the depth of teacher change and their movement towards discussions about tasks and working through tasks.

# TYPES OF REPRESENTATIONS VALUED IN A HONG KONG EIGHTH-GRADE MATHEMATICS CLASSROOM

Soo Yeon Shin
Purdue University
shin10@purdue.edu

## Background

The significance of linking and translating among multiple representations (e.g symbolic, graphical, numerical, and matrix) has been paid a great deal of attention over the past few decades because this mathematical practice enables students to look at different facets of intricate mathematical concepts in depth (Arcavi, 1995; Keller & Hirsch, 1998; Knuth, 2000).

In this study, data for one Hong Kong classroom, which is a subset of data collected as part of the Learner's Perspective Study (LPS) (Clarke, Keitel, & Shimizu, 2006), will be analyzed to examine how different types of representations can be practiced in the classroom. Specifically, I will analyze the data to address the following questions: 1) how does the teacher employ different types of representations related to systems of linear equations when problem solving within different contexts; and 2) what affect does teacher-preference for one type of representation have on students' choices to make use of different representations in problem solving?

## Methodology

A comparative case study will be employed during the Spring of 2009 to explore how a teacher utilizes different types of representations in varying problem contexts and how this practice influences students' choice of representations in solving systems of linear equations. Eleven consecutive lesson transcripts will be examined and a coding scheme will be developed to specifically identify instances of the following: (a) different type of representations being used, (b) evidence of students and/or the teacher connecting and translating among multiple representations, and (c) different problem contexts involved in the classroom. In addition, five different student post-lesson interviews and three interviews with the teacher will be analyzed in terms of which types of representations are viewed as important for understanding concepts.

## Analysis and Findings

Analysis will provide information about the impact of a teacher's portrait of representation on students' understanding of mathematical concepts. This study will provide useful implications for teachers and researchers because, although Hong Kong classroom culture may differ from that in the U.S., the practices can be employed as catalysts for discussion and reflection on the practices of the U.S. classrooms and the values that underlie them (c.f., Clarke et al., 2006).

# STUDENTS' INTERPRETATIONS OF PROBABILITY DISTRIBUTIONS IN A SIMULATION ENVIRONMENT

Hollylynne Stohl Lee
North Carolina State University
Hollylynne@ncsu.edu

J. Todd Lee
Elon University
tlee@elon.edu

*In this paper we present findings across multiple data sources of how young learners (ages 8-12) often interpret probability distributions within the context of a probability microworld environment. We provide a brief description of the software, followed by details about several research observations made in multiple investigations of student explorations with this probability simulation package. The paper concludes with a discussion of a next generation innovation for representing a theoretical probability distribution in the software.*

Introductory probability lessons typically attempt to build from at least one of two primary student intuitions: 1) the concept of equiprobable outcomes, 2) and the law of large numbers (Batanero, Henry, & Parzysz, 2005). Breaking sample spaces into equiprobable outcomes and viewing the probability of an event as a part-to-whole proportion is the primary paradigm known as the classical approach. This approach does not apply well to inherently non-uniform or continuous situations, and the combinatorial techniques can sometimes be difficult for young learners (see Jones, Langrall, & Mooney, 2007 for synthesis of research on student's understanding of sample spaces via combinatorial reasoning). In contrast, the frequentist approach appeals to the law of large numbers by describing the probability of an event as being a limiting proportion of a large number of quasi-identical trials. With access to more advanced technologies, teachers are encouraged to use an empirical or frequentist introduction to probability through computer simulations (e.g., Batanero, Henry, & Parzysz, 2005; Jones et al, 2007). This approach gives little guidance for neither interpreting probability for a single or small numbers of trials, nor few guarantees for relative frequencies in the long run.

The pseudorandom number generators in technology tools use a function dependent on a defined distribution as the basis for its input to generate subsequent "random" outputs. Thus, in a technology environment, students can model probabilistic situations based on assumptions about a theoretical distribution, simulate an experiment to generate a large amount of data, and manipulate and represent the data in various ways that would be nearly impossible to do within the time constraints of school curriculum and instruction. Thus, technology offers a rich medium for designing tools and studying students' reasoning about theoretical probability distributions as well as empirical distributions from simulated data, and many researchers have designed various software environments and studied students' learning of probability. Several of these researchers have documented how students are able to make connections between distributions of data from a simulation and the theoretical distribution described in the model with particular attention to the effect of the number of trials (e.g., Abrahamson & Wilensky, 2007; Konold, Harradine, & Kazak, 2007; Pratt 2000; Stohl & Tarr, 2002).

In this paper, we are focusing on the specific designs used in *Probability Explorer* and, in accord with suggestions from Clements (2007) concerning iterative curricula and tool design research, we are taking a retrospective examination across several studies. We are specifically interested in how students' have interpreted theoretical probability distributions within simulation environments. Others have used computer tools to examine students’ thinking about probability distributions in two-stage experiments or compound events that relied on combinatorial reasoning (e.g., Kazak, 2006; Abrahamson & Wilensky, 2007; Konold et al, 2007). Our focus is thus on students’ thinking about a probability distribution with one-stage experiments or simple events. In such contexts, how do students interpret probability distributions when using *Probability Explorer*?

### Modeling a Theoretical Probability Distribution in *Probability Explorer*

The current version of *Probability Explorer* (*PE*, Stohl, 2002, v.2.01) was a result of prior iterative research and design studies (Drier, 2000a, 2000b, 2001; Stohl & Tarr, 2002). *PE* is designed to allow students to explore the numerical representations of an underlying probability distribution as well as the numerical and graphical representations of the distribution of results from repeated trials (Drier, 2000a, 2001). A probability distribution is currently represented in *PE* with a finite set of outcomes, each of which has an integer “weight”. Various numerical representations of this distribution can be accessed through a “Weight Tool” that allows students to examine and create distributions that build from part-to-part and part-to-whole reasoning (see Figure 1). Traditional scenarios of fair coins, dice, and bag of marbles are easily represented; bias coins and dice and several real world scenarios (such as the weather) can also be represented. To conduct a simulation, students decide the possible outcomes for a simple experiment, how many of these to combine into a compound experiment (1, 2, or 3), the number of trials to conduct, how to arrange data, and which graphical or numerical representations to view for analysis (Figure 1). In addition, all data representations update dynamically *after each trial* to facilitate students analyzing data during a simulation, rather than only viewing representations of data in an aggregate static form (Drier, 2000a).

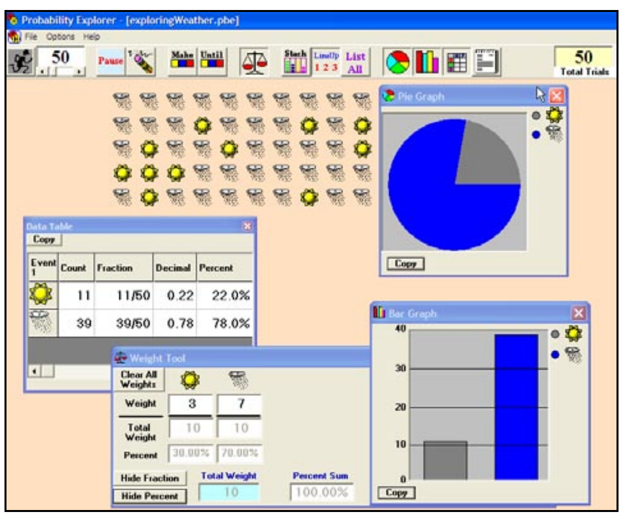

*Figure 1*. Screenshot of probability distribution in Weight Tool and empirical distribution from sample of 50 trials.

As an experiment is being defined, the probability distribution is stored, and can be altered, through a Weight Tool (Figure 1). The metaphor of “weight” was used to help students understand the process of assigning probabilities to an outcome. “Heavier” outcomes are more likely to occur, while “lighter” outcomes are less likely to occur. Weight is measured in units of whole numbers. To facilitate the instantiation of the “weighting” process, students can click on an object in the Weight Tool to increase its weight. Each click corresponds to an increase of one in the weight. By default, students view the distribution of weights as a count. This view of the distribution will allow them to think about the part-to-part relationship between the outcomes. This level of thinking is also aligned with children’s early fractional thinking when they only consider the “parts” of a fraction (numerator) rather than the “part” in relationship to its “whole” (denominator). A part-to-part display is also similar to the concept of odds and can be useful for distinguishing between the odds and probability of an event. Because theoretical probabilities rely on both “part” and “whole,” the weights can be displayed with fractions and percents.

## Exploring Probability Distributions

In several prior and on-going studies with students ages 8-14 (e.g., Drier, 2000a, 2000b; Stohl & Tarr 2002; Tarr, Lee, & Rider, 2006; Weber et al, 2008) it has been observed that many students use similar approaches to interpret the probability distribution. In each of these studies, students were working in small groups (2-3 students per computer) with *Probability Explorer*. Students’ interactions with the software and each other in the primary studies were videotaped and analyzed for critical events (Powell, Francisco, & Maher, 2003). A constant comparative method (Strauss & Corbin, 1990) was then utilized to look for patterns in critical events within the individual studies, followed by an interpretation cycle across the different studies (Lesh & Lehrer, 2000). Each example presented represents similar activities observed across studies.

*What is the Role of a Probability Distribution?*

In the current design of *PE*, most tasks in which students initially design an experiment involve an equiprobable distribution (e.g., fair coin, fair die, choosing up to 8 possible outcomes), in which the Weight Tool defaults to assigning Weights of 1 to each outcome. The most common ways that students interpret an equiprobable distribution is to state that the chances are “50-50”, even when there are more than two equiprobable outcomes. When pressed on this interpretation, many students use language such as “no difference”, or “equally likely” or “all fair” or “anything can happen”. These vague expressions seem to indicate their awareness of equal probabilities but give no real indication of how they perceive the role of a distribution in a simulation. Thus, it is important to consider ways in which students interpret distributions in the context of a simulation of equiprobable as well as nonequiprobable distributions. Two common interpretations have been found to be prevalent:

1) Students often imagine a hypothetical experiment where the sample size is equal to the total weight and they explain that the empirical distribution should be equal, or almost equal, to the assigned weights. For example, Carmella (age 9) designed an experiment with two equiprobable outcomes, the sun and the rain.

| | |
|---|---|
| Carmella: | It means that if you were to press this [points to the “run” button] twice, then one of them would be the sun and one of them would be the rain, most likely. |
| Teacher: | Most likely. Okay and why is that most likely? |
| Carmella: | Because the weight is one and one. And then the total weight would be two. And one is divided, and two is divided into one. And that's most likely because there is no guarantee. |

2) Students often describe the weights in terms of an imaginary box or bucket filled with the number of each items equal to each assigned weight. For example, when Jasmine (age 9) designed a weather situation where it would be twice as likely to be sunny than to rain, after a lot of struggles, she assigned 24 to "lightening" and 48 to "sun."

Teacher: 48 and 24. So what do these numbers mean here? 48 over 72?

Jasmine: Forty-eight over 72 …Oh, there are 72 suns and lightening bolts put in the box. Forty-eight of them are suns. Twenty-four of them are lightening bolts. And children put in that many because they think out of 72 days … there are going to be 48 sunny days and 24 thundering days.

Of course Jasmine also used the first strategy to apply the distribution to an imagined empirical situation. Neither of these strategies is surprising, as it is common for students to describe the probability of an event in both ways, the first representing a typical empirical probability interpretation, and the second a classical counting approach to computing probability.

In many studies, when conducting a simulation where a total weight is known from the Weight Tool or suggested from the task context (e.g. knowing there are n marbles in a bag but not the exact distribution of colors of marbles), students gravitate towards using the total weight (or $n$) for an initial sample size. Then, when these same students are conducting simulations with a hidden Weight Tool and the experiment suggests no integer weights or a total weight (e.g., many fish in a pond), students often are faced with a dilemma and do not know what sample size to choose for their experimentation. At this point a teacher or peer typically has to tell them they need to choose a sample size, or one is suggested.

Students readily accept a strong tie between the Weight Tool and trial results. This is a strong start in forming intuitions about the connections between the theoretical distribution and empirical data. Students are not surprised by some variation between samples and their expectations based on the Weight Tool. However, a big question is what tolerance do they have for this variation? How do they form intuitions about this variability? In fact, in many studies, observing surprising variations provoked students' playful exploration (see Lee, 2005).

A key lesson learned is that the integer values in the Weight Tool are highly suggestive to students, both in interpretation and sample size choice for running a simulation. And it may be these interpretations that drive student expectations for a rather close match between the empirical data and the distribution of weights.

*Modeling Situations with the Weight Tool*

When modeling a situation, it is not uncommon to observe students using an additive approach to create an equivalence relation of different sets of weights for a situation. For example, if given a real bag of marbles with 4 red and 6 green, students would initially believe that weights of 1 and 3 could be used in *PE* to model this situation since 6-4 = 3-1. As students gain more experience or are old enough to readily apply multiplicative reasoning, they will correctly use weights proportional to the context or to a different set of weights. In addition, when asked to create an equivalent experiment including setting a new Weight Tool distribution using weights different from a previous experiment, students will often alter the order in which possible outcomes are entered in the Weight Tool but correctly maintain the proportionality.

Of real interest is that regardless of a students' maturity in weight equivalence reasoning, they appear to expect that equivalent distributions should give similar empirical results. Students often realize after collecting empirical data that their "equivalent" weights designed with additive reasoning do not correctly model the context. For example, Brandon and Manuel (age 11) used the Weight Tool to create a model (Pink: 4, Yellow: 2, Blue: 4) for a spinner with pink and blue sectors each 40% and the yellow sector of 20%. They subsequently ran several trials to collect data from their spinner experiment, used the pie graph, decimals and percentsto analyze data and test the “goodness” of their model. They most often ran multiple sets of 100 trials and occasionally a larger number of trials. After Brandon and Manuel were convinced that their 4:2:4 model was accurate, a teacher challenged them to design a model of the spinner using a total weight of 50. Manuel typed in 20:10:20 in the Weight Tool. Brandon claimed, “that’s not right” and Manuel said, “I bet you a billion dollars it is.” The teacher–researcher asked Manuel to convince Brandon that 20:10:20 could be used to model the spinner. Manuel struggled to explain how the weight model was in proportion to the original weights of 4:2:4 or the spinner regions. Brandon decided to run simulations in *PE* to “see if it still comes close, as long as we have the same percentages.” He first ran 100 trials with the pie graph and data table open and after 60 trials said, “That looks pretty right.” When the 100 trials were complete [showing a 34:23:43 distribution] he said, “Okay, that’s right.” Brandon continued to run sets of 50 and 100 trials and compare percentages of the theoretical distribution in the Weight Tool with the empirical data shown in the pie graph and data table. Brandon ran several sets of 50 and 100 trials before he was convinced that the empirical data supported the weights of 20:10:20 to model the spinner.

A key lesson learned is that students seek relatively stable and similar repeated empirical results, in graphical and numerical form, as a means of comparing the goodness of a model of a probability distribution and for comparing the equivalence of models.

*What Does a Weight of Zero Do?*

Since the Weight Tool uses whole numbers to model a distribution, students are often faced with situations when zero is used. Some students seem to be able to connect this with empirical results where that outcome does not, or could not occur. For example, Jasmine had designed an experiment with four different icons (tails, circle, hexagon, volleyball) with weights of 1. When asked if they each had the same chance, she used the Weight Tool to illustrate her thinking.

Jasmine: They each have one. But they wouldn’t have the same chance if someone did [she changed the 1 under the tails to a 0] that. Then there would never be any of those [tails]. Or how about this? [she changed the zero under tails to be a two] now it’s more likely to get the tails because there are two out of five. But there’s only one circle, one hexagon, one volleyball out of five.

However, many students do *not* initially interpret a weight of zero as meaning the associated outcome is absolutely impossible, just highly unlikely. These students willingly run relatively large samples in search of this outcome occurring and are surprised when it does not happen. For example, Dean and Lydia (8 years old) were modeling a situation where they were choosing whether to play soccer or baseball. When asked to design the chances so they were *certain* to play soccer no matter how many times they ran the experiment, they gave the soccer ball a weight of 12 and the baseball a weight of 0. Looking over at their screen, Jon turned to his computer and used weights of 19 and 0. When asked if the different computers would give different results since they used different weights, Jon thought his weight of 19 made him “more certain” to get a soccer ball than the other computer. Dean promptly said “it doesn’t matter since we both gave baseball 0.” After 100 trials and all soccer balls, Lydia was surprised and then, after a pause, noted “it doesn’t matter what number you use as long as you give it all to the soccer ball.” Similarly, Amanda thought if she used one and zero as the weights for heads and tails in a coin toss, there would be more heads, but that a “few tails” could occur. She ran a simulation with these weights and after about 400 trials decided tails would not occur because "it's like there are none in the bucket."

Some of the students' initial interpretations of a weight of 0 demonstrate that the number zero itself may be too abstract to interpret in a meaningful way. One possible interpretation is that students think that the mere listing of the outcome in the Weight Tool asserts its possibility. But how is this possibility coordinated with a weight of zero? What if students are envisioning the weights as the "usual" distribution of outcomes in a sample of size equal to the total weight, but being random means, to them, that there is some variation in these sets. It is in these variations where any outcome listed in the Weight Tool can occur. So a zero weight may be interpreted as the outcome not occurring in the "usual" sample, but the mere listing of the outcome makes it a candidate for appearance in the random "errors". Note that this would mean a subtle but real separation of probability and variation.

It is also worth noting that when building the distribution in the Weight Tool via placing marbles in a bag, students have never been observed in believing, say, a yellow marble will possibly occur if they do not place a yellow marble in the bag, even though a yellow marble is listed with a zero probability in the Weight Tool after construction. So whatever students are thinking, it seems to change if they construct weights via a more physical representation.

A key lesson learned is that a weight of zero is not directly interpreted as an impossible outcome, although a physical representation (bag of marbles) seems to eliminate this difficulty. In addition, the expectation that an outcome with zero as a weight can occur with a small chance may be related to students' imagination, and expectation, of a hypothetical experiment with results similar, but not exactly, like a probability distribution.

## Reflections on Design Improvements for Modeling a Probability Distribution

The results from the various studies using *PE* can inform the next iterative cycle of design. Specifically, what Weight Tool redesigns may better help students coordinate representations of the probability distribution with those of the empirical results? The first response may be to keep the Weight Tool essentially the same, but to add on the ability to view the distribution in the same bar or pie chart as is available for the empirical results. Being able to watch a static pie chart of the theoretical distribution beside the wiggly, slowly stabilizing pie chart of results from a running simulation would probably prove to be quite useful to a student in solidifying connections between the two via some governing law of large numbers. However, students' interpretations may be artifacts of the design of the Weight Tool using whole number weights.

Since the bag of marbles has shown promise in being a powerful metaphor, we would like to draw from the strengths of that, but we want students to move beyond (or avoid altogether) a total weight approach to their experimentation. Thus, we would need so many marbles that counting the total would be impossible, even as we maintain the appropriate ratios of subset cardinalities. Not only would this approach hopefully discourage the thought that a particular sample size is optimal, but it may even suggest the desirability of a large sample size.

The current Weight Tool was designed based on research of students' tendency to relate probability in terms of part-to-part relationships rather than part-to-whole. Thus, an initial conjecture for the design was to have weights displayed and entered in part-to-part format. While that early design was built to help students where they may be starting, we also need to consider a design for the Weight Tool that is robust enough to lead the students where they are going—inferential statistics. An issue of particular importance to statistics is developing a successful transition from different representations (relative frequency tables, etc.) of discrete sample spaces to those (density functions, etc.) of continuous spaces (Lee, 1999).

## Granular Approach to Probability Distributions

In upgrading *Probability Explorer*, we propose a *granular density* paradigm to replace the integer Weight Tool. A unit amount of "sand" will contain grains, each grain being equally likely to be selected in a trial. Thus, the primary concepts of equiprobable and large numbers are integrated in all scenarios. As a student decides on the *n* possible outcomes for the sample space, the Distribution Tool will default to *n* bins of equal width. The content of each bin represents the probability for that outcome. A unit volume of sand will be in a large container with the goal of redistributing it to the bins below to assign a probability to each outcome. The user has the option of auto-distributing the sand equally to all bins or manually "pouring" an amount of sand into each bin (Figure 2), either through typing in numerical values or manually operating the spigot. When the Run button is pressed to execute a number of trials, for each trial, a grain of sand will be randomly picked and illuminated.

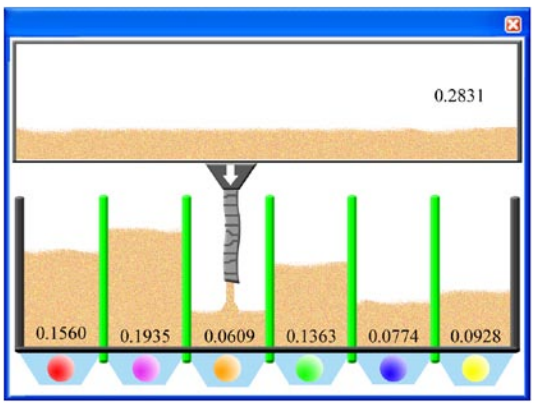

*Figure 2.* Redistributing sand into bins.

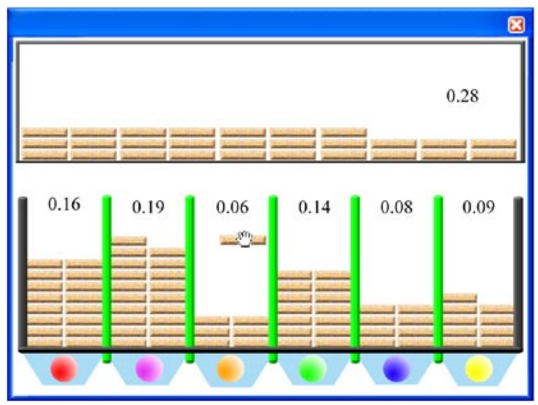

*Figure 3.* Redistributing sand as bricks.

To build off the powerful metaphor of "marbles in a bag", the unit of sand can also be discretized into "bricks" that can be distributed to the bins by either dragging a brick, clicking on the outcome icon to auto-move a brick, or typing in a numerical value to indicate the quantity of bricks to place in an outcome bin (Figure 3). In order to stay true to our desires to give students access to the ability to model a probability distribution in a part-to-part manner, the bricks allow a user to conceive of the total sand as divisible into a small number of equal parts. Distributing bricks of sand then becomes a partitioning task of sharing *r* bricks among *n* outcomes. Of course, we recognize the potential for *n* bricks to also promote a total weight approach to experiments. However, the bricks can be "broken" back into sand grains. Thus, whether the sand is contained in "bricks" or not, the entire probability distribution is made up of a very large number of tiny grains of sand. We believe this large number will reduce the total weight approach in students' data collection and may be suggestive of collecting large sample sizes.

As students become more sophisticated in their use of the sand bins, they will be able to drag the bin dividers to adjust the width of a bin. This can be done prior to redistributing sand from the unit container or after sand has been poured. In the later case, students should notice that the amount of sand in each bin is invariant. We conjecture that having the bins being adjustable in width can strengthen the notion of probability being stored in area with height being a byproduct of density. This step from the discrete to the continuous, with this move from storing distributions as a finite set of numbers to storing them in density functions, is quite weak in most curricula. The granular density paradigm may provide a nice tool for this transition. Further design and research will help us know.

# WHAT DOES IT MEAN TO UNDERSTAND STATISTICS MEANINGFULLY?

Richard Lesh
Indiana University
ralesh@indiana.edu

Andy Hurford
University of Utah
andy.hurford@utah.edu

*This paper reports results of a study in which models and modeling perspectives were used to investigate what it means for university students—graduate students in education—to develop meaningful understandings of foundation-level statistics concepts and skills. Our research findings indicate that while graduate students in education can be very capable of earning excellent grades in introductory statistics courses, their actual understandings of the course materials tend to be quite shallow. Results indicate that most of the students participating in the study were essentially unable to use statistics to evaluate, describe, or otherwise make sense of data or the relationships between them.*

## Why Focus on Data Modeling?

Most future-oriented statements of mathematics curriculum goals identify data modeling as a topic that should be receiving priority attention. At the same time, for a wide range of students from elementary school through graduate school modern data modeling concepts and tools are becoming both accessible and empowering. One reason that data modeling is so accessible is that many of these concepts, skills, and abilities involve straightforward extensions of basic ideas in elementary mathematics. The second is that new technologies for model conceptualization, design, representation, and communication have strongly impacted both the capabilities and accessibility of data-driven models as "reflection tools" (Hamilton, Lesh, Lester, & Yoon, 2007) for supporting the development of mathematical knowledge.

As we enter the 21st century, these same types of next-generation technologies are also changing the nature of work in many industries at ever-increasing rates. These two developments (in tools for schools and tools for work) have caused us to adapt the designs of our statistics courses in the following ways:

- We mean to introduce the kind of problem solving situations in which some beyond-school type of "mathematical thinking" is needed for success (Lesh, Caylor, & Gupta, in press).
- We encourage deep and reflective thinking about the levels and types of "mathematical thinking" that are needed in those kinds of problems (Lesh, Hamilton, & Kaput, 2007).
- We want to extend the ways that these concepts and abilities can be thought about, learned, documented, and assessed (Lesh & Lamon, 1994).

Tools on the drawing boards now may be expected to deliver unforeseeable potentials and innovations with unique and new requirements for modeling expertise. At a time when we should be striving to help our students to prepare for a dynamic and technologically demanding future, many of our best graduate students in education (as well as students in the other sciences) emerge with only the most superficial "cook book" conceptions of relevant statistics concepts and procedures.

## What Theoretical Framework Supports Our Research?

As many readers will recognize, the theoretical framework for our work is known as a models and modeling perspective on mathematical problem solving, learning, and teaching (MMP). Details about MMP have been described in a variety of recent publications (e.g. Lesh & Doerr, 2003). In the context of the research reported here, one of the most important characteristics of MMP is its emphasis on the fact that, in virtually every area of learning or problem solving where researchers have investigated differences between effective and ineffective learners or problem solvers, the results typically indicate that the more effective people not only do things differently, but they also see (or interpret) things differently. For example, expert teachers not only do things right, but they also *do the right things—at the right time, for the right reasons, and with the right people.*

Consequently, because judgments about when, where, why, and how to do things depend on how experiences are interpreted, and because mathematical and scientific interpretations tend to be referred to as models, MMP treats the development of powerful interpretation systems as one of the most important characteristics of what it means to develop expertise in many fields– including teaching and researching mathematics and science education for all citizens. The primary goal of our MMP research is to develop models of teachers' and students' modeling abilities because these models are expected to be embodied in useful tools. As those tools are subsequently shared, tested, revised or rejected, then so will the underlying models, resulting in fundamental changes in our understandings of learning and teaching in the mathematical sciences.

## What Students were Involved in the Project?

The project involved 108 graduate students at two large research universities in the midwestern United States. Students participating in the study had just completed their first course in "quantitative methods" for their doctoral degrees in education and the information we report includes only results from students who had earned A's or B's in the course. In order to focus on students who were users of (not specialists in) quantitative research methodologies, we also eliminated from the study any students whose primary studies were mathematics education, science education, or research design.

The course that the students had just completed was a traditionally taught course that covered statistics concepts corresponding to the left hand column of Table 1. The course covered topics ranging from means and standard deviations up through correlation, regression, hypothesis testing, and analysis of variance. The right hand side of Table 1 corresponds to topics and coverage in an introductory statistics course that we are developing. In order to gather base-line data relative to traditionally taught students' understandings, skills, and fluency in using statistics to understand data we introduced these students to the types of modeling and analysis tasks that we use in our experimental classrooms.

Table 1. *A Comparison of Topics Emphasized in Traditional Statistics Textbooks and the "Big Ideas" Currently Emphasized in Data Modeling Approaches to Statistics*

| Traditional Approaches | Topics Emphasized in Data Modeling Approaches |
|---|---|
| • Variables and graphs<br>• Frequency distributions<br>• Measures of central tendency: mean, median, mode<br>• Measures of dispersion: standard deviations and variance<br>• Probability theory<br>• Binomial, normal, Poisson distributions<br>• Sampling theory<br>• Estimation theory<br>• Hypothesis testing<br>• Chi-squared test<br>• Curve fitting<br>• Correlation theory<br>• Analysis of variance | • Measuring the expected occurrence of uncertain events (probability)<br>• Quantifying qualitative information (or in other ways organizing, systematizing, or mathematizing information)<br>• Transforming data (making comparisons or combinations)<br>• Operationally defining quantities or characteristics that cannot be measured directly<br>• Aggregating qualitatively different types of information<br>• Operationally defining "centers" and central tendencies for collections of data<br>• Operationally defining "spread" for data collections<br>• Developing complex rules from simple rules<br>• Developing rules to describe patterns or trends (e.g., to make predictions)<br>• Measuring unaccounted variation (error)<br>• Measuring relationships between two data sets (correlation)<br>• Developing rules to describe how well data fit known distributions<br>• Sorting out sources of variation (analysis of variance)<br>• Comparing collections of data (testing hypotheses) |

## Which Research Methodologies Were Used?

The type of whole-class teaching interviews that we used were developed and refined in a series of NSF-supported projects that have come to be known collectively as The Rational Number Project (e.g., Post, Lesh, Cramer, Behr, & Harel, 1993). Whole-class teaching interviews are specialized versions of the kind of teaching experiment methodologies that mathematics educators pioneered during the 1970s (Kelly & Lesh, 2000). They were intended to focus in on many of the kinds of understandings that had emerged in past research when investigators were administering Piaget-style clinical interview—but this interview method was also intended to be scalable for use with larger numbers of students. To accomplish these goals, students were asked to record their answers to our questions as they do on most paper-and-pencil tests; however, the questions were presented to the class-as-a-whole by an experienced interviewer who used brief oral descriptions, concrete materials, computer-generated graphics, and other media designed to support the questions.

Many of the questions in the whole-class teaching interviews were based in contexts that involved model-eliciting activities (MEAs). As the name suggests, MEAs are activities in which learners create products which involve the development of models (or conceptual tools that embody models), rather than producing short mathematical solutions to previously mathematized textbook word problems. In general, MEAs are designed to be simulations of "real life" and authentic (to the students) problem solving situations which usually require sixty to ninety minutes for students to complete. Solution processes generally involve a series of modeling cycles in which current ways of thinking are iteratively expressed, tested, and revised or refined—so that auditable trails of documentation are automatically generated as the process progresses and which reveal important information about the nature of students' evolving ways of thinking.

When MEAs are extended across ninety-minute periods, students have a sufficient amount of time to go through multiple cycles in which they express → test → revise their current ways of thinking. However, when MEAs were used as the contexts for whole-class clinical interviews, students had only a few minutes to respond to each problem or problem situation. So while the students being tested had the typical MEA benefits of being presented with authentic problems rich with data, they did not enjoy the usual concomitant benefits of multiple modeling cycles and peer collaboration.

## Results and Discussion

The whole-class interviews revealed that more than 80% of the students expressed the strong opinion that "The main thing I need to know from my statistics courses is how to calculate correct answers for the kind of problems that are in [my textbook]." Paradoxically, most of these same students also said that they themselves didn't plan to do any such calculations for their own dissertation studies, "I'll get someone else (who is good at statistics, but doesn't need to know details about my study) to tell me which SPSS program to use, how to plug in my numbers, and what the results mean." In other words, most of these students really were not expecting to be anything more than intelligent consumers of statistics routines and results that would be provided and interpreted by others (i.e., quantitative analysis experts) who were not expected to be familiar with details about the relevant studies.

Less than 10% of the students exhibited more than superficial understandings of the fact that all computational formulas presuppose models—models that are based upon assumptions that may or may not be appropriate for a given situation. Nor were those students aware of the fact that small changes in underlying models and assumptions applied to data can often lead to large differences in results and analyses. Due to space limitations, we next turn to one only of the many assessment iterations included in our study and use it to illustrate the following general findings of this research project:

- Few of the students were able to estimate the magnitude of biases introduced by inappropriate coding or aggregating information.
- Few students were able to estimate the consequences of inappropriate thinking about (and measuring) basic constructs such as distances, centers, and spread.
- Few students were able to visualize or describe how different computational formulas are related to one another.
- Few students were able to visualize or describe how different computational formulas may be based in completely different ways of thinking about (and measuring) basic constructs.

- Few students were able to modularize or unpack formulas in order to show how different constructs (such as correlations and regression lines) are related to one another—or how components of these formulas corresponded to basic.
- Most students chose to use procedures that they judged to be (politically?) “correct” rather than choosing procedures whose relationships to the given situations were reasonable.

For the most part the students in this study simply were not aware of implicit assumptions that their choices of procedures presupposed. Virtually all of our results point to the fact that most of these students believed choosing appropriate data acquisition and analysis methods was basically a multiple-choice problem where the possible choices would be listed in their statistics text—rather than collecting data and choosing analytical tools based upon considered and reasonable assumptions (models) of the situation at hand.

We administered an established MEA, the “Test Scores Problem” (c.f., Lesh, 1987, p. 326) to the students in our studies in order to gain a useful window into participants’ understandings of the statistics and statistical tools that they had apparently mastered the semester before. In The Test Scores Problem, students are presented with a table of data that provides a number describing the quantity of work each student-artist has produced as well as a value that describes the quality of the work. In the MEA, the story goes like this

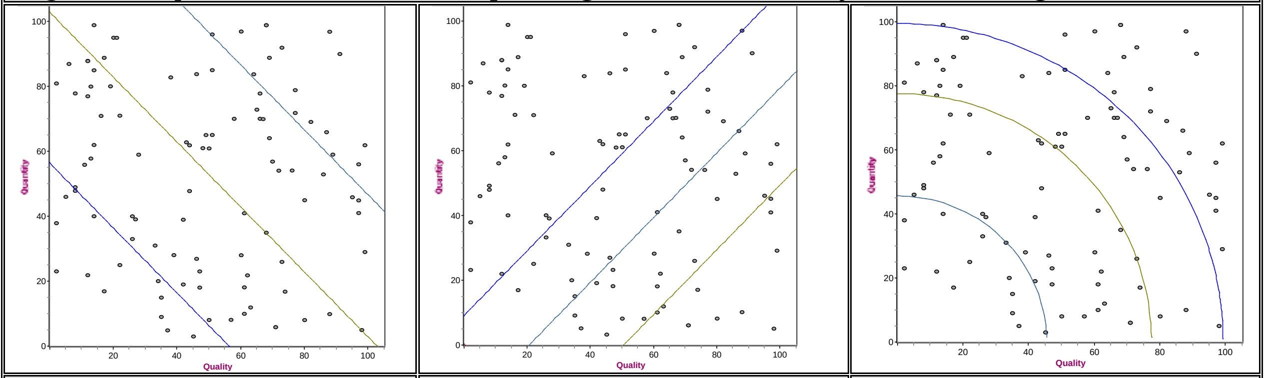
> … the chairman of the art department explains the system ... “The quantity score focuses on "product objectives." We count how many projects each student completes satisfactorily. The quality score focuses on "process objectives." We count how many different tools and techniques each student uses.” (Lesh, 1987, p. 326)

In our tests, the interviewer briefly displayed and described the given information about both quality scores and quantity scores that were earned by students in an art class. Next the interviewer briefly described five suggestions that “students in another class” had made about ways to combine these quality and quantity scores to obtain an overall achievement score for students in the art class. The five suggestions were:

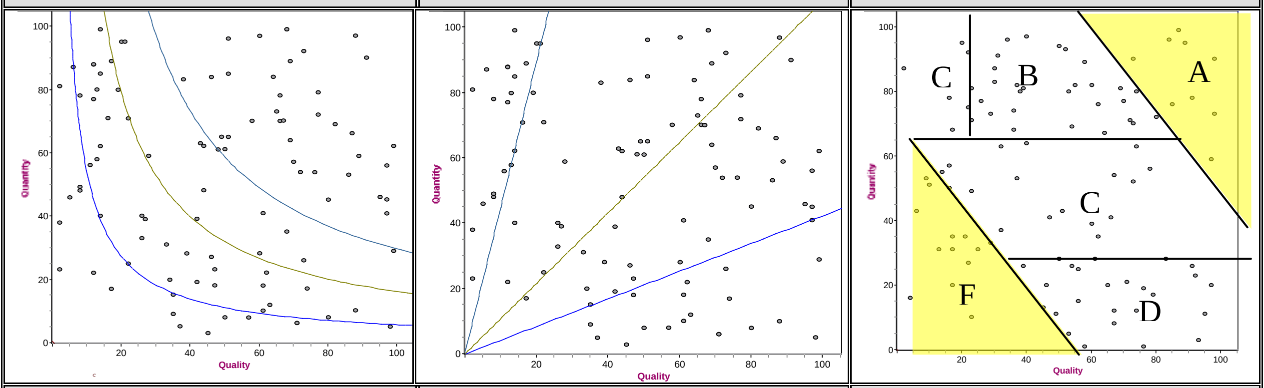
- Combine the scores using Sums: Quality + Quantity
- Combine the scores using Differences: Quality – Quantity
- Combine the scores using Products: Quality x Quantity (i.e., Total Quality)
- Combine the scores using Quotients: Quality ÷ Quantity (i.e., Quality-per-Unit-of-Quantity)
- Combine the scores using Vector Sums: the square root of (Quality$^2$ + Quantity$^2$).

The interviewer then quickly discussed the graphs shown in Figure 1—and pointed out the equivalence classes that are formed when each of the preceding combinations is used to calculate overall achievement scores. Finally, the interviewer showed Figure 1F and asked the students whether they thought that it would be okay to use such a diagram to assign overall scores to the art students—instead of assigning scores using an algebraic or arithmetic formula.

*Figure 1.* Equivalence classes corresponding to six different ways of combining scores



A. Equivalence based on addition | B. Equivalence based on subtraction | C. Equivalence based on vector sums



D. Equivalence based on multiplication | E. Equivalence based on division | F. Equivalence based on locations

More than half of the students thought that Figure 10F was not an appropriate way to solve the problem, and almost all of the students thought that "the more quantitative methods" were going to be "more correct." Even more interestingly, over half of the students expressed the view that, if methods like the one shown in Figure 1 are used, then you are no longer doing quantitative research. Yet, Figures 1A-E clearly showed how qualitative assumptions underlie even the simplest quantitative methods. The students interviewed appeared to be almost completely unaware of the fact that "choosing a computational procedure" involves "describing a situation mathematically"—and that these descriptions are based on relational assumptions that are the most important factors determining the appropriateness of employing the procedures associated with them.

## Conclusions

Even though the 108 students who participated in our studies had earned A's or B's in an introductory statistics course that they had just completed, their performances on the MEA-type questions that we posed demonstrated that their understandings were severely restricted. Their understandings were apparently excellent as long as questions they responded to involved standard word problems in which the relevant data were presented in forms that fit the computational procedures that the students were expected to use—and as long as the choice as to computational procedures only depended on “knowing rules for [course curriculum-based] socially acceptable behavior.”

These A-grade students were not at all adept at developing their own mathematical descriptions of problem situations. They had little awareness of alternative ways to “operationally define” constructs such as centrality, variation, distance, or other relevant metrics that underlie the computational formulas that they appeared to have learned. They were remarkably challenged in describing and visualizing how different computational formulas are related to one another. They were not able to deconstruct formulaic representations or discuss how different constructs (such as correlations and regression lines, or two-sample hypothesis tests and analyses of variation) are related to one another—nor how components of these formulas correspond to basic statistical concerns.

As another telling example, consider that throughout the statistics courses that these students had completed, they had been allowed to develop their own one-page “formula sheets” where they could write notes to themselves about any of the facts or formulas that they thought that they might need to use on tests. We also allowed the students to use their “formula sheets” during our interviews to serve as scaffolds for their reasoning and explanations. After the interviews had been completed, we collected and analyzed these formula sheets and scored them according to how much they emphasized “conceptual simplicity” relative to “procedural simplicity.” The results of this analysis showed that most of the formulas that the majority of students used were focused primarily on *procedural* rather than *conceptual* simplicity. Furthermore, the extent to which students emphasized conceptual simplicity was strongly correlated (.48) with high performance on the MEA interview questions.

In some ways, results of the preceding study seem somewhat paradoxical especially when juxtaposed with results that we have reported in past publications (Lesh & Harel, 2003; Lesh, Yoon & Zawojewski, 2007; Lesh, Caylor & Gupta, in press; Lesh, Middleton, Gupta & Caylor, in press). On the one hand our past research has shown that when classroom learning curricula emphasize model eliciting activities then average-ability students routinely *invent* more powerful ideas, procedures, and explanations than their past performances on tests suggest that they could be *taught*. In a related manner, the results reported here suggest that when model eliciting activities are used as *contexts for assessing* students’ understandings of important data modeling ideas, the meanings that many high-achieving students have developed are often seemed to be remarkably narrow and shallow.

Two primary facts may help explain this apparent discrepancy. First, when students engage in model-eliciting activities, their solutions typically evolve through several modeling cycles. Therefore, the final responses that MEA students produce can be similar to the “$n^{th}$” draft of a paper that an academician might write: while the first draft may be seriously lacking, the processes of product evolution and adaptation can result in an excellent and insightful $n^{th}$ revision. In contrast the evidence generated in typical classroom assessments tends to be students’ 1$^{st}$ and only iteration of problem solution—because traditional word problems seldom if ever provide students with the types of data or the expressed challenge that would cause and assist them in assessing the plausibility and sensibility of alternative ways of thinking about the problem.

Second, the word problems contained in most textbooks and tests mainly require students to know rules about when and how to use a list of routine procedures. As such, students are seldom required to develop their own mathematical descriptions of situations; they are seldom required to access the assumptions that underlie alternative operational assumptions; and they are most often asked to know about which rules are to be used when to demonstrate the algorithmic, rules-based, “correct” solutions. In this way, dogmatic and formula-driven solutions are imposed on situations where they do not fit, and alternative means for describing, analyzing, and assessing problem situations remain uninvestigated.

This important distinction between “choosing a correct computational procedure” and “developing a sensible mathematical description” is probably the most essential difference between the types of data modeling that we emphasize in this paper and introductory statistics as it is taught in traditional courses. In courses that employ MEA-like, open-ended, and “generative” (Stroup, Ares, & Hurford, 2005) learning activities, students tend to develop much deeper understandings of the important mathematical relationships inherent in the system under investigation. Adding to our concerns, this distinction tends to become even more important when technology-based tools are central to statistics instruction. In this case, when modern technological tools become primary instructional foci, then problem-solving goals are even more likely to seem to be about choosing and using correct algorithmic routines, about punching in the right numbers, and about stating results in ways that “just seem to fit” with the status quo.

# EXPLICATING THE MULTIVALENCE OF A PROBABILITY TASK

Egan J Chernoff
University of Saskatchewan
egan.chernoff@usask.ca

*This article demonstrates that a famous task found in probability research is multivalent (i.e., has many interpretations). More specifically, the multivalence of the sequence, likelihood, experiment, and question elements will be the main focus of this investigation. Further, this article demonstrates that certain individuals answer the famous task according to an interpretation not in accord with researchers' intended interpretation of the task. Utilization of a novel theoretical framework, the Task Interpretation Framework (TIF), will aid in investigating unintended interpretations of the task.*

## Introduction

Certain prior research on the comparative likelihood task (Kahneman & Tversky; 1972; Konold, 1989, 1991, 1995; Konold, Pollatsek, Well, Hendrickson & Lipson, 1991; Konold, Pollatsek, Well, Lohmeier & Lipson, 1993; Lecoutre, 1992; Tversky & Kahneman, 1974), hereafter denoted the CLT, consists of interpretations and hypotheses based on multivalent elements of CLT responses. In a general sense, elements of the CLT *response* are interpreted by *researchers*, whereas elements of the *task* are interpreted by *respondents*. However, it is possible for researchers to attempt to interpret responses for evidence of how respondents interpret the task. Motivated by the notion that respondents may have interpreted that task differently than intended and interested in the interpretation of the task by respondents, the author proposes a focal shift in mathematics education research concerning the CLT. Instead of continuing to base research on multivalent elements of CLT responses, the author creates a new theoretical framework, the Task Interpretation Framework (or TIF), with which to analyse CLT responses based on multivalent elements of the CLT. In doing so, it will be demonstrated that certain individuals do not respond to the task they are presented.

## Task Interpretation Framework (TIF)

*Multivalent Elements of the CLT*

The CLT is multivalent. However, the degrees of freedom of the CLT dictate the multivalence be examined in terms of different elements of the task. Specific to this research, four elements of the task—sequence, likelihood, experiment, and question—will be investigated, and will be described below in accordance with an example of the CLT seen in Figure 1.

> *Which of the following sequences is the least likely to occur from flipping a fair coin five times. Justify your response.*
> *a) THTTT b) THHTH c) HHHTT d) HTHTH e) equally likely*

*Figure 1.* CLT example for elemental examination.

*Sequence element.* Consider the four sequences presented in the CLT: While each of the sequences can, and is intended to, be seen as a sequence of heads and tails for five flips of a coin

*Swars, S. L., Stinson, D. W., & Lemons-Smith, S. (Eds.). (2009). Proceedings of the 31st annual meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Atlanta, GA: Georgia State University.*

(i.e., THTTT interpreted as: tail on the first flip, then head on the second flip, and then tail on the third, fourth and fifth flips), the four sequences may be interpreted in other ways. For example, THTTT, THHTH, HHHTT, and HTHTH are, concurrently with the first interpretation, sequences with a ratio of four tails to one head, three heads to two tails, three heads to two tails, and three heads to two tails, respectively. From this interpretation, the sequence THTTT has a different ratio of heads to tails (4:1) than the sequences THHTH, HHHTT, and HTHTH (3:2). As such, THTTT is different than the others. The ratio of heads to tails is not the only plausible interpretation of the sequences presented in the CLT. There are other attributes associated with sequences of heads and tails derived from flipping a fair coin that may also be concurrently employed when interpreting sequences.

The number of switches (or alterations), the length of the longest run, and the combination of the two attributes (i.e., switches & longest run) are examined. As such, the sequences of THTTT, THHTH, HHHTT, and HTHTH, which coexist with the ratio of heads to tails interpretation, also coexist as: (1) sequences that have two switches, three switches, one switch, and four switches, respectively; (2) sequences that have a longest run of three, two, three, and one, respectively; and (3) sequences that have two switches and a longest run of three, three switches and longest run of two, one switch and a longest run of three, and four switches with a longest run of one, respectively. As evidenced, there exist a variety of meanings for the sequences of H's and T's that are seen in the sequence element of the CLT. The sequence element of the CLT is multivalent.

*Likelihood element.* Similar to the sequence element of the task, the likelihood element of the task is multivalent. First, there is the colloquial use of the word likelihood. For example, 'in all likelihood Jim has passed his exam.' In this particular use of the word 'in all likelihood' implies that it is probable, or perhaps very probable, that Jim will have passed his exam. That being said, 'very probable' is yet another colloquial usage of the notion of probability, which can be closely connected to 'certainty.' This procedure, of changing from one colloquial word for probability or likelihood to another adds to the multivalence of the task. Further, there is tremendous usage of colloquial terms for probability in the English lexicon, and usage of these words begins at a very young age also adding to the multivalence of the task. As such, the multivalence of the colloquial representations of likelihood may bring high levels of coexistence of interpretations to the likelihood component of the CLT.

The second non-colloquial domain of usage for the word likelihood is in the field of probability, or in a more general sense the field of mathematics. The precise nature of mathematics may, at first, appear to clarify the coexistence of multiple interpretations; however, the usage of likelihood is not as precise as one may expect. Likelihood, within the domain of mathematics is seen more as a synonym for words such as: probability, degree of certainty, or frequency. However, there is a particular distinction when likelihood is used in the formal sense in mathematics. "The concept [likelihood] differs from that of probability in that a probability refers to the occurrence of future events, while a likelihood refers to past events with known outcomes" (Wesstein, 2008). Thus, usage of likelihood and probability as synonyms, formal or informal, will not recognize an inherent temporal distinction, i.e., the coexistence of multiple interpretations. Further compounding the temporal multivalence of the likelihood element, the task employs an informal representation of likelihood, yet expects formal use of likelihood in completing the task.

*Experiment element.* The experiment element for the CLT is the flipping of a fair coin five times, and as will be shown, contains a number of coexisting interpretations. While the experiment may not appear as a source of much confusion, there exist a number of plausible interpretations. More specifically, the derivation of the four particular sequences is one manner in which it can be shown that the experiment element of the CLT is multivalent, because interpretations of how the sequences were derived for the task are not entirely clear. The sequences could have been derived from: flipping one coin twenty times, or twenty coins all at once. There are other plausible combinations of coin flips and coins: five coins flipped at once on four separate occasions, four sets of five different coins flipped all at once, four different coins flipped one at a time for five times simultaneously, four different coins flipped subsequently one at a time for five times, or four sets of five coins flipped simultaneously or subsequently one at a time. Given coin flips are independent events it would not matter how the outcomes were derived; however, it must be recognized that independence is one of the key elements being examined in the implementation of the CLT. As such, it is plausible that an individual answering the task may be influenced by the derivation of sequences.

The temporal notion of the likelihood element also influences the experimental element of the CLT. Individuals' who interpret likelihood in reference to past events will be aligned with an *a-posteriori* (or frequentist) perspective to the experiment, whereas individuals who interpret likelihood as probability will be aligned with an *a priori* (or classical) perspective to the experiment. Thus, the coexistence of the experiment 'having been' conducted and 'to be' conducted also exists in the experimental element of the task.

As shown, the sequence element of the task, the likelihood element of the task, and the experiment element of the task are multivalent. However, the argumentation presented above is all based on the assumption that the question posed in the task is being appropriately interpreted. As such, the question element of the CLT is now investigated.

*Question element.* There are viable, coexisting interpretations of the question posed in the CLT. For example, the question does ask the subject to determine which of the sequences presented is least likely to occur, but sequences presented may be pitted against the other three sequences in the task for likelihood comparison, or may be pitted against all thirty-two possible outcomes for five flips of a fair coin. That said, the coexisting interpretations do not have to be based solely on the question element of the task. The multivalence of the question element of the task can also be derived from the answer, likelihood, and experiment elements of the task, whether treated in some sort of unison or singularly. Alternatively stated, and as an example, an unintended interpretation of the sequence element of the task implies an unintended interpretation of the question element of the task: If a subject interprets the sequences of heads and tails as a ratio interpretation, that individual is answering an unintended interpretation of the question element of the task. As another example, if an individual interprets likelihood in an unintended manner, then they are also not interpreting the question element of the task in an intended manner. The task of achieving the intended interpretation for the question element is based on achieving intended interpretations for the answer, likelihood, experiment, and question elements, treated singularly or in some type of inter-elemental arrangement. Given the argumentation for the multivalence of the elements of the CLT, the author contends that the question element of the CLT is perilously multivalent. Probabilistically stated, the chances of answering the CLT as the researchers intended is unlikely. Alternatively stated, it is likely that a subject answering the CLT is answering an unintended interpretation of the task.

## Research Method

To determine which interpretation has occurred for an individual completing the CLT, inferences can be made by examining responses made by the individuals who have completed the task. Consider an individual who after completing the task comments, 'One of the four sequences had a different number of heads to tails.' The author contends that it is more likely that the individual has interpreted the sequence element of the task in terms of a ratio interpretation. Further, and as another example, the reading of an individual who comments 'the longer the run of tails the less likely the sequence' causes the author to infer that it is more likely the individual interpreted the sequence element of the task in terms of the length of runs.

Examination of CLT responses not only provides insight into the interpretation used in an individual's completion of the task, but also provides the opportunity to determine whether or not an individual's interpretation matches the intended interpretation of the researcher implementing the task. The researcher, knowing the intended interpretation of the task, is able to determine—by the reading of responses made by subjects who have completed the task—whether or not the subject's interpretation aligns with the intended interpretation of the researcher.

## Participants

Participants in this study were 56 prospective elementary teachers enrolled in a methods for teaching elementary mathematics course, which is a course in the teacher certification program. The 56 participants consist of members from two different classes who were taught by two different instructors. In both classes the variation of the CLT was presented prior to the introduction of probability content in the course.

## Task

Participants were presented with the following iteration of the CLT seen in Figure 2.

> *Which of the following sequences is the least likely to occur from flipping a fair coin five times: a) HHTTH b) HHHHT c) THHHT d) HTHTH e) THHTH f) all five sequences are equally likely to occur*

*Figure 2.* CLT utilized.

## Results

While there were six choices available to the participants, responses fell into only four of the six categories. 27 of the 56 participants (approximately 48%) "correctly" chose that all sequences were equally likely to occur, and 29 of the 56 participants (approximately 52%) "incorrectly" chose that HHHHT was the least likely sequence to occur. Further, nine of the participants "incorrectly" chose the sequence HTHTH least likely to occur, and one individual "incorrectly" chose the sequence THHHT as least likely to occur. No participants chose sequences HHTTH or THHTH.

## Analysis of Results

*Likelihood Element Multivalence*

*Sample response justifications for multivalence of the likelihood element.*

> *Barney:* All five sequences are equally likely to occur because when you flip a coin it is random so you cannot predict whether it will turn heads or tails so all these sequences

have an equal chance of occurring.

*Catie:* F) because it is RANDOM!!!!!

Analysing Catie and Barney's responses via the TIF demonstrates an interesting relationship between randomness and likelihood: their responses evidence the likelihood element of the CLT is multivalent. As found in Lecoutre's (1992) research random events are considered equiprobable, yet here it is demonstrated that sequences are equiprobable because the process is random. As such, claims made regarding probability could be substituted for randomness and, similarly, claims for randomness could be substituted for probability without contestation. As a result, there exists a concurrency of interpretations with the term likelihood, thus the likelihood element.

*Question Element Multivalence*

Not necessarily evident from an examination of purely numerical results, the multivalence of the question element appears in many of the sample responses justifications presented. Further, different responses are aligned with different multivalent elements of the CLT, as earlier hypothesized. In fact, and according to the inter-elemental argument posed in the TIF presentation, each of the responses evidencing multivalence in the experiment, likelihood, and sequence elements are also evidencing the multivalence of the question element. Nevertheless, examples of the multivalence of the question element were evidenced.

*Sample response justification for multivalence of the question element.*

*Tawnie:* Letter T is the least likely to occur for A, B, C, and D. If you count them, T is the least. Because in A there's 5 letters, but T only has two or one so it is the least likely to occur.

Tawnie's response shows that the intended interpretation of the CLT was not achieved and, thus, it can be argued that the intended question was not answered. That said, the intended interpretation of the CLT was not achieved in other responses, yet the evidence of such is more nuanced because it plays on the other multivalent elements of the task, not the question element as seen with Tawnie's response. Nevertheless, Tawnie's response that the letter T is least likely to occur evidences the question element of the task is multivalent.

*Experiment Element Multivalence*

*Sample response justification for multivalence of the experiment element.*

*Monah:* …it all depends on the coin thrower. Coin throwing is really random

*Oliver:* You have to think of all the possible things that could happen like the wind could change how much it flips. How it lands also depends on it if it bounces.

*Ronald:* I think it really depends on how you flip the coin, or where it lands

*Nina:* because coins rarely flip h, then t, then h repeatedly

*Paloma:* I was flipping a coin earlier, and it always landed on tails

*Quentin:* I flipped a coin lots of times and I never got 4 heads in a row.

Monah, Oliver, and Ronald all allude to the experiment element of the CLT. The coin thrower, how the coin is flipped, and certain physical factors such as wind and where the coin lands, are taken into consideration in their answering the CLT. Given the classical interpretation is *a priori* probability, the intended interpretation of the task does not mean for any of the physical characteristics of the experiment to be take into consideration. As such, it can be argued that they too are not answering the intended interpretation of the task. In fact, given the intended interpretation of the CLT uses the classical interpretation of probability, the responses of Nina, which is indicative of a propensity interpretation of probability (i.e, probability is a physical propensity), does not meet the intended interpretation; and, as such, it can be argued that the subjects are not answering the intended question. Similarly, Paloma and Quentin adopt a different theoretical interpretation of probability—the frequentist perspective—than the intended classical interpretation; and, as such, are also not answering the intended interpretation of the task. The unintended interpretations presented all indicate that the experiment element of the TIF is multivalent.

*Sequence Element Multivalence*

From the analysis of results the majority of 'incorrect' responses were based on the multivalence of the sequence element. However, two particular interpretations (seen in prior research, e.g., Kahneman and Tversky, 1972) of the sequence element—the ratio of heads to tails and the perceived randomness determined by pattern or lack thereof—dominated the response justifications. As such, the response verifications for multivalence of the sequence element are further categorized into (1) the ratio interpretation, and (2) the perceived randomness interpretation.

*Sequence Element Multivalence: Ratio interpretation*

*Sample response justification for multivalence of the sequence element: Ratio.*

*Francine:* It's most unlikely to have four heads and one tail because there is a 50% chance.

*Gerard:* It has the "most uneven" amount of heads and tails.

*Hannah:* B, it's the only one with one T and four Hs, the rest have 3 Hs and 2 Ts.

Approximately 52% of the participants incorrectly answered that the sequence HHHHT was least likely to occur. That said, reasons for why HHHHT was considered least likely fell into two distinct subcategories. The responses of Francine, Gerard, and Hannah (and others) exemplify the ratio of heads to tails being used as a clue (e.g., B, it's the only one with one T and four Hs, the rest have 3 Hs and 2 Ts.), which has been seen in prior research (e.g., Kahneman & Tversky, 1974).

Batanero and Serrano's (1999) found "that students had a greater difficulty in recognizing run properties than frequency properties [which] indicates that the similarity between the observed and expected frequencies may be more important than the run lengths in students' deciding whether a sequence is random" (p. 562). As such, a second subcategory of reasons for HHHHT being the least likely sequence to occur used the population ratio, but, arguably, in a more subtle manner because runs involve ratio implicitly.

*Sample response justifications for multivalence of the sequence element: Runs.*

*Dianne:* the chances of getting the same one four times is least likely.

*Evan:* because it is hard to get one consecutive side to be flipped repeatedly.

*Uri:* B —because it is unlikely that you will flip heads 4 times and then one tails. But you could also say F because anything is possible. But my final answer is B

Dianne mentioned, "the chances of getting the same one four times is least likely." In this instance there is recognition of the ratio of head to tails, but ratio is not, necessarily, at the crux of the explanation. Dianne's comments are related to the length of the run of heads seen in the HHHHT sequence, four heads in a row. While the response is normatively incorrect, it can be inferred from Dianne and Evan's explanations that the interpretation of the sequence element of the task being used to answer the question posed are not the intended interpretation because the sequence is being interpreted in terms of runs. The interpretation of the sequence via runs and not the ratio of heads to tails demonstrates alternative unintended interpretations, and bolsters

Cox and Mouw's (1992) findings that disruption of one aspect of the representativeness heuristic, such as the population ratio, did not exclude the other, i.e., the appearance of randomness, being used as a clue, and, further, demonstrates the multivalence of the sequence element.

*Sequence Element Multivalence: Perceived Randomness Interpretation*

The use of length of run based on the ratio of heads to tails found in the responses of Dianne and Evan is connected to the perceived randomness of the sequence. Also, from the responses of Dianne and Evan (and others) it is inferred that interpreting the sequence element of the task by the appearance of randomness is also connected to likelihood element. More specifically, sequences that appear more random (i.e., had less of a pattern) are considered to be more likely to occur, and sequences that are considered less random (i.e., were more patterned) were considered less likely to occur, represented in prior research as not being equally representative yet equally likely (e.g., Tversky & Kahneman, 1974). While this connection between the appearance of randomness (via runs) and likelihood is seen in responses for HHHHT as least likely, the connection between randomness and likelihood is also seen in the responses for the sequence HTHTH being least likely to occur, as shown next.

*Sample response justifications for HTHTH.*

*Igor:* Usually, when you flip a coin, the answer won't usually be in a pattern. It would most likely be random.

*Justine:* Because its kind of odd for it to land in a pattern like that. Usually, it's a totally random sequence of heads or tails.

*Ken:* D because when something is random it doesn't usually go in a pattern.

Research has shown (e.g., Falk, 1981) that randomness was perceived through frequent switches and short runs. It appears from the justifications of Igor, Justine, and Ken, that a perfect alteration of heads and tails—the highest possible number of switches and the smallest possible runs—does not appear random. The sequence HTHTH did not appear random because it is patterned. The appearance of pattern implies a lack of randomness, and the lack of randomness implies that it is less likely to occur. As such, a perfect alteration of heads to tails demotes the likelihood of the pattern causing it to be the least likely to occur.

## Conclusion

In a general sense, the results evidence the multivalence of the CLT. More specifically, the results evidence the multivalence of the likelihood, experiment, question, and sequence elements of the CLT. Further, and also evidenced in the results, there is reason to suspect that certain individuals responses may be answering a question other than the one they were originally posed; and, thus, it becomes understandable that an individual may answer that one of the sequences presented in the CLT is least (or most) likely to occur.

# MIDDLE AND HIGH SCHOOL STUDENTS' THINKING ABOUT EFFECTS OF SAMPLE SIZE: AN IN AND OUT OF SCHOOL PERSPECTIVE

Laurie H. Rubel
Brooklyn College of the City University of New York
LRubel@brooklyn.cuny.edu

*This article examines middle and high school student thinking about an effect of sample size task related to coin tosses. The analysis identifies common justification categories for incorrect responses as well as correct responses. These results are then discussed using a lens of in and out of school mathematical thinking.*

## Objectives

This article presents empirical findings about student thinking about a mathematical task related to the concept of effects of sample size. I present results about student thinking and then discuss these results in terms of the relationship between in- and out- of school mathematical thinking.

## Perspectives

Over the last three decades, a variety of researchers have examined the ways that children solve problems differently in school or out of school contexts. The comparison has been framed as a contrast between formal and informal (Scribner & Cole, 1973), written or oral (Carraher, Carraher, & Schliemann, 1987), school and street (Nunes, Carraher, & Schliemann, 1993), or school and everyday (Brenner & Moschkovich, 2002; Saxe, 1988). The central tenet of these contrasts is that "school represents a specialized set of educational experiences which are discontinuous from those encountered in everyday life and…requires and promotes ways of learning and thinking which often run counter to those nurtured in practical daily activities" (Scribner & Cole, 1973, p553). For instance, Boaler (1999) describes how students used a high degree of precision in completing a classroom task about carpeting a space, alongside an admission that they would have done it differently in the "real world."
