History of PME

The International Group for the Psychology of Mathematics Education came into existence at the Third International Congress on Mathematical Education (ICME-3) in Karlsruhe, Germany in 1976. It is affiliated with the International Commission for Mathematical Instruction.

Goals of PME-NA

The major goals of the North American Chapter of the International Group for the Psychology of Mathematics Education are:

1. To promote international contacts and the exchange of scientific information in the psychology of mathematics education.

2. To promote and stimulate interdisciplinary research in the aforesaid area, with the cooperation of psychologists, mathematicians, and mathematics teachers.

3. To further a deeper and better understanding of the psychological aspects of teaching and learning mathematics and the implications thereof.

Preface

These Proceedings are the product of the 32nd Annual Conference of the North American Chapter of the International Group for the Psychology of Mathematics Education held in Columbus, Ohio, October 28-31, 2010. They are a written record of the research presented at the conference.

The theme of the conference, *Optimizing Student Understanding in Mathematics*, has been at the forefront of the mathematics education as a professional community since its institution in late 1890s in North America. Indeed, it has also been the motive behind a majority of inquiry activities within mathematics education as a research community since its conception in mid 20th century. With introduction of new theories of learning and teaching mathematics, conceptualization of new methodologies for studying the problems of mathematics learning and teaching, development of new curricular materials for advancement of mathematical knowledge of teachers and learners either implicitly or explicitly the agenda of the community has focused on defining ways and constructs that might help attain this long-standing goal and target of our discipline.

This year’s conference brings together the voices of scholars from various genres of research in mathematics education. Different perspectives offered by this diverse group can help build a list of issues that need further contemplation as we, collectively, continue to conceptualize and operationalize how Student Understanding in Mathematics might be initiated, nurtured and monitored.

THE POWER OF NATURAL THINKING: APPLICATIONS OF COGNITIVE PSYCHOLOGY TO MATHEMATICS EDUCATION

Uri Leron
Technion – Israel Institute of Technology
uril@technion.ac.il

The talk begins with an inquiry into the relationship between people’s natural thinking – the suit of skills that is acquired by all people spontaneously and successfully under normal developmental conditions – and mathematical thinking. More specifically, when do these two thinking modes go together and when do they clash? The influential dual-process theory from cognitive psychology is applied to shed some light on this issue. A remarkable conclusion is that many of the recurring errors we make come from the strength of our mind rather than its weakness. The talk then proceeds to address a crucial design issue: In cases where natural and mathematical thinking clash, what can we as math educators do to help students create peaceful coexistence between the two? The extensively-researched medical diagnosis problem will be used to demonstrate how theory, design and experiment collaborate in the pursuit of this goal.

Introduction

In the background of this talk lurks the momentous rationality debate: Are humans rational beings or not? Or, better, how rational are human beings? Or, still better, what kind of rationality (or irrationality) is invoked under what conditions? This question had been endlessly debated by the great philosophers through the millennia, but has become an empirical issue for cognitive psychologists in the second half of the 20th century, culminating with the 2002 Nobel Prize in economy to Daniel Kahneman for his work with Tversky on “intuitive judgment and choice” (Kahneman, 2002).

In this talk I will focus on a narrower (and more immediately relevant) facet of the rationality debate: What is the relation between people’s natural thinking – the suit of skills that is acquired by all people spontaneously and successfully under normal developmental conditions – and mathematical thinking. More specifically, when do these two modes of thinking go together and when do they clash? Or, even more specifically, when can we as math educators build on the strength of students’ natural thinking, and when do we need to devise ways to overcome it (For a comprehensive discussion of the rationality debate see Gigerenzer, 2005; Samuels et al., 2004; Saunders and Over, 2009; Stanovich and West, 2000; Stanovich, 2004; Stein, 1996).

To begin our one-thousand-mile journey with a small step, consider the following puzzle:

A baseball bat and ball cost together one dollar and 10 cents. The bat costs one dollar more than the ball. How much does the ball cost?

This simple arithmetical puzzle would be totally devoid of interest, if it were not for the fact that it poses what I will call a cognitive challenge, best summarized in Kahneman’s (2002) Nobel Prize lecture:

Almost everyone reports an initial tendency to answer ‘10 cents’ because the sum $1.10 separates naturally into $1 and 10 cents, and 10 cents is about the right magnitude. Frederick found that many intelligent people yield to this immediate
impulse: 50% (47/93) of Princeton students, and 56% (164/293) of students at the University of Michigan gave the wrong answer (p. 451).

The trivial arithmetical challenge has thus turned into a non-trivial challenge for cognitive psychologists: What is it about the workings of our mind that causes so many intelligent people to err on such a simple problem, when they surely possess the necessary mathematical knowledge to solve it correctly?

Complicating this cognitive challenge even further, research in cognitive psychology has revealed that harder versions of the task may result in better performance by the subjects. For example, we can enhance the subjects’ performance by making the numbers more messy (let the bat and ball cost together $1.12 and the bat cost 94 cents more than the ball), or by displaying the puzzle via hard-to-read font on a computer screen (Song & Schwarz, 2008).

This challenge, and many others like it, have led to one of the most influential theories in current cognitive psychology, Dual Process Theory (DPT), roughly positing the existence of “two minds in one brain”. These two thinking modes – intuitive and analytic – mostly work together to yield useful and adaptive behavior, yet, as the long list of cognitive challenges demonstrate, they can also fail in their respective roles, yielding non-normative answers to mathematical, logical or statistical tasks. A corollary of particular interest for mathematics education is that many recurring and prevalent mathematical errors originate from general mechanisms of our mind and not from faulty mathematical knowledge. Significantly, such errors often result from the strengths of our mind rather than its weaknesses (hence the power of natural thinking in the title). This paper is organized in two main parts. In the first part (based on Leron & Hazzan 2006, 2009), I introduce the dual process theory and demonstrate its explanatory power in math education research. In the second part, which is based on work in progress with Abraham Arcavi and with Lisser Rye Ejersbo, I address the educational challenge of bridging the gap between intuitive and analytical thinking. This is treated as a design issue. That is, given a problem with counter-intuitive solution (in our case, the famous and extensively-researched medical diagnosis problem), design a variation of the problem that brings the solution closer to intuition (or, alternatively, stretches the intuition towards the solution).

I hope that by focusing on the power of students’ natural thinking, this talk might contribute to the goal of this conference: Optimizing student understanding in mathematics!

“Doin’ what comes natur’lly”: Dual-process theory (DPT)

Annie Oakley’s phrase “doin’ what comes natur’lly”, from Irving Berlin’s musical Annie get your Gun, touches charmingly on the ancient distinction between intuitive and analytical modes of thinking. This distinction has achieved a new level of specificity and rigor in what cognitive psychologists call dual-process theory (DPT). In fact, there are several such theories, but since the differences are not significant for the present discussion, we will ignore the nuances and will adopt the generic framework presented in Stanovich and West (2000), Kahneman and Frederick (2005) and Kahneinan (2002). For state of the art thinking on DPT – history, empirical support, applications, criticism, adaptations, new developments – see Evans and Frankish (2009). The present concise – and much oversimplified – introduction to DPT and its applications in mathematics education is based on Leron and Hazzan (2006, 2009).

According to dual-process theory, our cognition and behavior operate in parallel in two quite different modes, called System 1 (S1) and System 2 (S2), roughly corresponding to our common sense notions of intuitive and analytical thinking. These modes operate in different ways, are

activated by different parts of the brain, and have different evolutionary origins (S2 being evolutionarily more recent and, in fact, largely reflecting cultural evolution). The distinction between perception and cognition is ancient and well known, but the introduction of S1, which sits midway between perception and (analytical) cognition is relatively new, and has important consequences for how empirical findings in cognitive psychology are interpreted, including applications to the rationality debate and to mathematics education research.

Like perceptions, S1 processes are characterized as being fast, automatic, effortless, non-conscious and inflexible (hard to change or overcome); unlike perceptions, S1 processes can be language-mediated and relate to events not in the here-and-now. S2 processes are slow, conscious, effortful, computationally expensive (drawing heavily on working memory resources), and relatively flexible. In most situations, S1 and S2 work in concert to produce adaptive responses, but in some cases (such as the ones concocted in the heuristics-and-biases and in the reasoning research), S1 may generate quick automatic non-normative responses, while S2 may or may not intervene in its role as monitor and critic to correct or override S1’s response. The relation of this framework to the concepts of intuition, cognition and meta-cognition as used in the mathematics education research literature (e.g., Fischbein, 1987; Stavy & Tirosh, 2000; Vinner, 1997) is elaborated in Leron and Hazzan (2006).

Many of the non-normative answers people give in psychological experiments – and to mathematics education tasks, for that matter – can be explained by the quick and automatic responses of S1, and the frequent failure of S2 to intervene in its role as critic of S1. Significantly, according to this framework, some of the ubiquitous mathematical misconceptions may have their origins in general mechanisms of the human mind, and not in faulty mathematical knowledge.

The bat-and-ball task is a typical example for the tendency of the insuppressible and fast-reacting S1 to “hijack” the subject’s attention and lead to a non-normative answer. Specifically, the salient features of the problem cause S1 to jump automatically and immediately with the answer of 10 cents, since the numbers one dollar and 10 cents are salient, and since the orders of magnitude are roughly appropriate. For many people, the effortless and slow moving S2 is not alerted, and they accept S1’s output uncritically, thus in a sense “behave irrationally” (Stanovich, 2004). For others, S1 also immediately had jumped with this answer, but in the next stage, their S2 interfered critically and made the necessary adjustments to give the correct answer (5 cents). Evolutionary psychologists, who study the ancient evolutionary origins of universal human nature, stress that the way S1 worked here, namely coming up with a very quick decision based on salient features of the problem and of rough sense of what’s appropriate in the given situation, would be adaptive behaviour under the natural conditions of our ancestors, such as searching for food or avoiding predators (Buss, 2005; Cosmides & Tooby, 1997; Tooby & Cosmides, 2005). Gigerenzer (2005; Gigerenzer et al., 1999) claims that this is a case of ecological rationality being fooled by a tricky task, rather than a case of irrationality.

Evans (2009) offers a slightly different view – called default-interventionist approach – of the relations between the two systems. According to this approach, applied to the bat-and-ball data, only S1 has access to all the incoming data, and its role is to filter it and submit its "suggestions" for S2's scrutiny, analysis and final decision. This is a particularly efficient way to operate in view of the huge amount of incoming information the brain constantly needs to process, because it saves the scarce working memory resources that S2 depends on. On the other hand, it is error-prone, because the features that S1 selects are the most accessible but not always the most essential. In the bat-and-ball phenomenon, according to this model, the features that S1
has selected and submitted to S2 were the salient numbers 10 cents and 1 dollar, but the condition about the difference has remained below consciousness level. Even though S2 has the authority to override S1's decision, it may not do it due to lack of access to all the pertinent data.

The seemingly paradoxical phenomena that more difficult task formulations actually enhance performance is also well explained by DPT. Making the task more difficult in the above-mentioned sense, has the effect of suppressing the automatic response of S1, thus forcing S2 to participate. Since the subjects’ S2 does possess the necessary mathematical knowledge, all that is required to solve the problem correctly is suppressing S1 and activating S2, which is exactly the effect of these added complications.

It is important to note that skills can migrate between the two systems. When a person becomes an expert in some skill, perhaps after a prolonged training, this skill may become S1 for this person. For example, driving is an effortful S2 behavior for beginners, requiring deep concentration and full engagement of working memory processing. For experienced drivers, in contrast, driving becomes an S1 skill which they can perform automatically while their working memory is engaged in other tasks, such as a deep intellectual or emotional conversation. Conversely, many S1 skills (such as walking straight or talking in a familiar but non-native language), deteriorate with advancing age, or when just being tired or drunk, all of a sudden requiring conscious effort to perform successfully (behaving in effect like S2).

We have now moved well along our one-thousand-mile journey, contemplating the power of natural thinking (roughly the psychologists’ S1), and its uneasy relation with analytical thinking (S2). The psychological research literature on dual-process theory is immense, and we could barely touch the surface here. Many interesting and important questions remain open, such as what are the mechanisms that cause (or fail to cause) S2 to intervene and override S1’s output. Much more is known to psychologists about such questions, but equally much still remains unanswered (see Evans and Frankish, 2009). In the rest of this paper we will delve more deeply into the educational relevance of the foregoing theoretical framework.

Bridging intuitive and analytical thinking: A design approach

Our second one-thousand-mile journey begins again with a small step – this time the famous string-around-the-earth puzzle (dating back to 1702).

Imagine you have a string tightly encircling the equator of a basketball. How much extra string would you need for it to be moved one foot from the surface at all points? Hold that thought, and now think about a string tightly encircling the Earth – making it around 25,000 miles long. Same question: how much extra string would you need for it to be one foot from the surface at all points?

Everybody seems to feel strongly that the Earth would need a lot more extra string than the basketball. The surprising answer is that they both need the same amount: $2\pi$, or approximately 6.28 feet (If R is the radius of any of them, then the extra string is calculated by the formula $2\pi(R+1) - 2\pi R = 2\pi$).

As with the bat-and-ball puzzle, this surprise is what we are after, for it tells us something important about how the mind works, which is why cognitive psychologists are so interested in such puzzles. This time, however, alongside with the cognitive challenge, there is also an important educational challenge, to which we now turn. Suppose you present this puzzle to your math class. Being a seasoned math teacher, you first let them be surprised; that is, you first let
them do some guessing, bringing out the strong intuitive feeling that the required additional string is small for the basketball but huge for the earth. Then you have them carry out the easy calculation (as above) showing that – contrary to their intuition – the additional string is actually quite small, and is in fact independent of the size of the ball.

Now, given the classroom situation just described, here is the educational challenge: \textit{As teachers and math educators, what do we do next?} I haven’t conducted a survey, but my guess is that most teachers would leave it at that, or at best discuss with the students the clash they have just experienced between the intuitive and analytical solutions. But is this the best we can do?

Taking my clue from Seymour Papert (of Logo fame), I claim that in fact we can do better. We want to avoid the “default” conclusion that students should not trust their intuition, and should abandon it in the face of conflicting analytical solution. We also want to help students deal with the uncomfortable situation, whereby their mind harbours two conflicting solutions, one intuitive but now declared illegitimate, the other correct but counter-intuitive.

Papert’s (1993/1980, 146-150) response to this educational challenge is simple but ingenious: Just imagine a cubic earth instead of a spherical one! Now follow in your mind’s eye the huge square equator with two strings, one snug around its perimeter and the other running in parallel 1 foot away (Fig. 1). Then you can actually \textit{see} that the two strings have the same length along the sides of the square (the size doesn’t matter!), and that the only additional length is at the corners. In addition, you can now \textit{see} why the extra string should be $2\pi$: It is equal to the perimeter of the small circle (of radius 1 foot) that we get by joining together the 4 circular sectors at the corners.

The final step in Papert’s ingenious construction is to bridge the gap between the square and the circle with a chain of perfect polygons, doubling the number of sides at each step. The next polygon in the chain after the square would be an octagon (Fig. 1, right). Here we have 8 circular sections at the corners, each half the size of those in the square case, so that they again can be joined to form a circle of exactly the same size as before. This demonstrates that doubling the number of sides (and getting closer to a circle) leaves us with the same length of extra string.

Can this beautiful example be generalized? When intuitive and analytical thinking clash, can we always design such “bridging tasks” that will help draw them closer? How should theory, design and experiment be put together in this search? We go more deeply into these questions in the next section.

\textbf{Theory, design, experiment: The medical diagnosis problem (MDP)}

Drawing inspiration from Papert’s approach, and prompted by the questions closing up the last section, Lisser Rye Ejersbo and I set ourselves the challenge of designing an analogous...
treatment for the more advanced, relevant, and extensively-researched task from cognitive psychology: the medical diagnosis problem (MDP).

**MDP background.** Here is a standard formulation of the MDP task and data, taken from Samuels et al. (2004):

Before leaving the topic of base-rate neglect, we want to offer one further example illustrating the way in which the phenomenon might well have serious practical consequences. Here is a problem that Casscells et. al. (1978) presented to a group of faculty, staff and fourth-year students at the Harvard Medical School.

[MDP:] If a test to detect a disease whose prevalence is 1/1000 has a false positive rate of 5%, what is the chance that a person found to have a positive result actually has the disease, assuming that you know nothing about the person's symptoms or signs? ___%

Under the most plausible interpretation of the problem, the correct Bayesian answer is 2%. But only eighteen percent of the Harvard audience gave an answer close to 2%. Forty-five percent of this distinguished group completely ignored the base-rate information and said that the answer was 95% (p.136).

This task is intended to test what is usually called Bayesian thinking: how people update their initial statistical estimates (the base rate) in the face of new evidence (the diagnostic information). In this case, the base rate is 1/1000, the diagnostic information is that the patient has tested positive, and the task is intended to discover how the subjects will update their estimate of the chance that the patient actually has the disease. The meaning of “5% false positive rate” is that 5% of the healthy people taking the test would test positive. Base-rate neglect reflects the widespread tendency among subjects to ignore the base rate, instead simply subtracting the false positive rate of 5% from 100%. Indeed, it is not at all intuitively clear why the base rate should matter, and how it could be taken into the calculation.

A formal solution to the task is based on Bayes' theorem, but there are many complications and controversies involving mathematics, psychology and philosophy, concerning the interpretation of that theorem. Indeed, this debate, “Are humans good intuitive statisticians after all?” (Cosmides & Tooby, 1996) is a central issue in the great rationality debate. See Barbey and Sloman (2007) for a comprehensive discussion, and a glimpse of the controversy.

![Diagram of the medical diagnosis problem](image)

Fig. 2: Nested subsets in the medical diagnosis problem (for 1000 people)

---

Here is a simple intuitive solution for the MDP, bypassing Bayes' theorem. Assume that the population consists of 1,000 people and that all have taken the test (see Fig. 2). We know that one person will have the disease (because of the base rate) and will test positive (because no false negative rate is indicated). In addition, 5% of the remaining 999 healthy people (approximately 50) will test false-positive – a total of 51 positive results. Thus, the probability that a person who tests positive actually has the disease is 1/51, which is about 2%.

Researchers with evolutionary and ecological orientation (Cosmides & Tooby, 1996; Gigerenzer et al., 1999) claim that people are "good statisticians after all" if only the input and output is given in "natural frequencies" (integers instead of fractions or percentages):

*In this article, we will explore what we will call the "frequentist hypothesis" – the hypothesis that some of our inductive reasoning mechanisms do embody aspects of a calculus of probability, but they are designed to take frequency information as input and produce frequencies as output* (Cosmides & Tooby, 1996, p. 3).

Evolutionary psychologists theorize that the brains of our hunter-gatherer ancestors developed such a module because it was vital for survival and reproduction, and because this is the statistical format that people would naturally encounter under those conditions. The statistical formats of today, in contrast, are the result of the huge amount of information that is collected, processed and shared by modern societies with modern technologies and mass media. Indeed, Cosmides and Tooby (1996) have replicated the Casscells et al. (1978) experiment, but with natural frequencies replacing the original fractional formats, and the base-rate neglect has all but disappeared:

*Although the original, non-frequentist version of Casscells et al.'s medical diagnosis problem elicited the correct bayesian answer of "2%" from only 12% of subjects tested, pure frequentist versions of the same problem elicited very high levels of bayesian performance: an average of 76% correct for purely verbal frequentist problems and 92% correct for a problem that requires subjects to construct a concrete, visual frequentist representation* (Cosmides & Tooby, 1996, p. 58).

These results, and the evolutionary claims accompanying them, have been consequently challenged by other researchers (Evans, 2006; Barbie & Sloman, 2007). In particular, Evans (2006) claims that what makes the subjects in these experiments achieve such a high success rate is not the frequency format per se, but rather a problem structure that cues explicit mental models of nested-set relationships (see below). However, the fresh perspective offered by evolutionary psychology has been seminal in re-invigorating the discussion of statistical thinking in particular, and of cognitive biases in general. The very idea of the frequentist hypothesis, and the exciting and fertile experiments that it has engendered by supporters and opponents alike, would not have been possible without the novel evolutionary framework. Here is how Samuels et al. (1999) summarize the debate:

*But despite the polemical fireworks, there is actually a fair amount of agreement between the evolutionary psychologists and their critics. Both sides agree that people do have mental mechanisms which can do a good job at bayesian*
reasoning, and that presenting problems in a way that makes frequency information salient can play an important role in activating these mechanisms (p. 101).

The educational challenge as design issue

The extensive data on base rate neglect in the MDP (leading to the 95% answer) demonstrates the counter-intuitive nature of the analytical solution, as in the case of the string around the earth. As math educators, we are interested in helping students build bridges between the intuitive and analytical perspectives, hopefully establishing peaceful co-existence between these two modes of thought. As we have seen in Papert’s example, achieving such reconciliation involves a design issue: Design a new bridging task, which is logically equivalent to, but psychologically much easier than the given task. (Compare Clements’ (1993) “bridging analogies” and “anchoring intuitions” in physics education.)

From the extensive experimental and theoretical research in psychology on the MDP, we were especially influenced in our design efforts by the nested subsets hypothesis (Fig. 2):

All this research suggests that what makes Bayesian inference easy are problems that provide direct cues to the nested set relationships involved [...]
It appears that heuristic [S1] processes cannot lead to correct integration of diagnostic and base rate information, and so Bayesian problems can only be solved analytically [i.e., by S2]. This being the case, problem formats that cue construction of a single mental model that integrates the information in the form of nested sets appears to be critical (Evans, 2006, p. 391).

Indeed, it is not easy to form a mental representation of the subsets of sick and healthy people, and even less so for the results of the medical test. Mental images of people all look basically the same, whether they are sick or healthy or tested positive or negative. The task of finding a more intuitive version of the MDP has thus been operationalized to finding a task which will “cue construction of a single mental model that integrates the information in the form of nested sets” (ibid).

Based on this theoretical background, we formulated three design criteria for the new task (which would also serve as testable predictions):

1. Intuitively accessible: The bridging task we will design will be easier (“more intuitive”) than the original MDP (i.e., significantly more people – the term is used here in a qualitative sense – will succeed in solving it correctly).
2. Bridging function: Significantly more people will solve the MDP correctly, without any instruction, after having solved the new task.
3. Nested subsets hypothesis: Base rate neglect will be significantly reduced.

Note that the first two design criteria pull the new task in opposite directions. Criterion 1 (turning the hard task into an easy one) requires a task that is sufficiently different from the original one, while criterion 2 (the bridging function) requires a task that is sufficiently similar to the original one. The new task, then, should be an equilibrium point in the “design space” – sufficiently different from the original task but not too different.

Armed with these criteria, we set out on the search for the new bridging task. After a long process of trial and error, intermediate versions, partial successes and failures, we have finally come up with the Robot-and-Marbles Problem (RMP), which we felt had a good chance of satisfying the design criteria and withstanding the empirical test. The RMP is based on the idea of replacing sick and healthy people in the population by red and green marbles in a box. The medical test is then replaced by a colour-detecting robot, which can distinguish between red and green marbles via a colour sensor. The sensor is not perfect, however, and 5% of the green marbles are falsely identified as red, corresponding to the 5% healthy people in the MDP who are falsely diagnosed as sick. We also decided to make the action of the robot on the marbles more vividly imaginable by actually describing the process, not just the result. A final step in the design of the new problem was to slightly change the numbers from the original MDP, in order to make the connection less obvious. According to the bridging criterion, our subjects who solved the RMP first, should then solve more successfully the MDP. For this to happen, they would first need to recognize the similarity between the two problems, and we didn’t want to make this too obvious by using the same numbers. (For a more detailed and nuanced description of the design process, as well as the experiments that followed, see Ejersbo and Leron, submitted).

Here then is the final product of our design process, the version that would actually be put to the empirical test to see whether the design criteria have been satisfied.

**RMP:** In a box of red and green marbles, 2/1000 of the marbles are red. A robot equipped with green-marble detector with a 10% error rate (10% green marbles are identified as red), throws out all the marbles which it identifies as green, and then you are to pick a marble at random from the box. What is the probability that the marble you have picked would be red?

*The experiment*

The participants in the experiment were 128 students studying towards M.A degree in Educational Psychology at a Danish university, with no special background in mathematics or statistics. All the participants were assigned the two tasks – the medical diagnosis problem (MDP) and the robot-and-marbles problem (RMP) – and were given 5 minutes to complete each task. (In a pilot experiment we found that 5 minutes were enough both for those who could solve the problem and those who couldn’t.) The subjects were assigned randomly into two groups of 64 students each. The order of the tasks was MDP first and RMP second for one group (called here the MR group), and the reverse order for the second group (the RM group). The results of the RM group were clearly our main interest, the MR group serving mainly as control.

Table 1: Numbers of responses in the various categories

The results are summarized in Table 1 above, and it can be seen that the design criteria have been validated and the predictions confirmed. A brief summary of the results for the RM group (with comparative notes in parentheses) follows.

- The RMP succeeded in its role as bridge between intuitive and analytical thinking: 48% (31/64) of the subjects in the RM group solved it correctly. (compared to 18% success on the MDP in the original Harvard experiment and 12% (8/64) in our MR group.)
- The RMP succeeded in its role as stepping stone for the MDP: More than 25% (17/64) solved the MDP, without any instruction, when it followed the RMP. (Again compared to 18% in the original Harvard experiment and 12% in our MR group.)
- The notorious base-rate neglect has all but disappeared in the RMP: it was exhibited by only 1 student out of 64 in the RM group and 4 out of 64 in the MR group. (Compared to 45% on the MDP in the original Harvard group and 34% on the MDP in our MR group.)
- Remarkably, the MDP, when given first, does not at all help in solving the RMP that follows. Worse, the MDP gets in the way: The table shows 48% success on the RMP alone, vs. 31% success on the RMP when given after the MDP.
- Even though the performance on the RMP and the MDP has greatly improved in the RM group, still the largest number of participants appear in the “incorrect other” category. This category consists of diverse errors which do not directly relate to the MDP, including (somewhat surprisingly for this population) many errors concerning misuse of percentages.

**Conclusion**

In this article I illustrated how the dual-process theory from cognitive psychology highlights and helps explain the power of natural thinking. I used the medical diagnosis problem to discuss the gap between intuition (S1) and analytical thinking (S2), and to develop design principles for bridging this gap. It is my belief that bridging the gap between intuition and analytical thinking (in research, curriculum planning, learning environments, teaching methods, work with teachers and students) is a major step towards “optimizing student understanding in mathematics”.

Based on the above examples and analysis, and indulge in a bit of over-optimism, here are some of the developments in the educational system I’d like to see happen in the future. I make no claim of originality of these suggestions since many related ideas have previously appeared in the math education literature in various forms.

- Map out the high school curriculum (and beyond) for components that could build on natural thinking and parts that would need to overcome it. For example, which aspects of functions (or fractions, or proofs) are consonant or dissonant with natural thinking?
- Design curricula, learning environments, teaching methods, that build from the power of natural thinking.
- Build a stock of puzzles and problems which challenge the intuition, and develop ways to work profitably with teachers and students on these challenges.

I wish to conclude with an even bigger educational challenge. If you ask mathematicians for examples of beautiful theorems, you will discover that many of them are *counter-intuitive*; indeed, that they are beautiful *because* they are counter-intuitive, *because* they challenge our
natural thinking. Like a good joke, the beauty is in the surprise, the unexpected, the unbelievable. Like a world-class performance in classical ballet, sports, or a soprano coloratura, the beauty is (partly) in overcoming the limitations of human nature. Examples abound in the history of mathematics: The infinity of primes, the irrationality of $\sqrt{2}$, the equi-numerousity of even and natural numbers, the impossibility theorems (trisecting angles by ruler and compass, solving 5th-degree equations by radicals, enumerating the real numbers, Gödel’s theorems). Recall, too, the joy of discovering that – contrary to your intuition – the extra length in the string-around-the-earth puzzle is quite small, and the beauty of Papert’s cubic earth thought experiment.

Here, then, is the challenge: By all means, let us build on the power of natural thinking, but let us also look for ways to help our students feel the joy and see the beauty of going beyond it, or even against it. We thus arrive at the closing slogan – a variation on the title of the talk:

The power of natural thinking, the challenge of stretching it, the beauty of overcoming it.

Acknowledgement

The application of dual process theory in mathematics education is based on joint work with Orit Hazzan (Leron & Hazzan 2006, 2009). The discussion of cognitive challenges and educational challenges is based on work in progress with Abraham Arcavi. The discussion of the medical diagnosis problem and its cognitive and educational challenges is based on work in progress with Lisser Rye Ejersbo. I am also grateful to each of these colleagues for essential help during the preparation of this manuscript.

A Critique and Reaction to

THE POWER OF NATURAL THINKING: APPLICATIONS OF COGNITIVE
PSYCHOLOGY TO MATHEMATICS EDUCATION

HOW MAY CONCEPTUAL LEARNING IN MATHEMATICS BENEFIT FROM DUAL
PROCESSING THEORIES OF THINKING?

Ron Tzur
University of Colorado Denver
ron.tzur@ucdenver.edu

Concurring with Uri Leron’s cross-disciplinary approach to distinct modes of mathematical thinking, intuitive and analytic, I discuss his elaboration and adaptation to our field of the cognitive psychology dual-processing theory (DPT). I reflect on (a) the problem significance, (b) aspects of the theory he adapts, and (c) elegance of presentation. Then, I further discuss DPT in light of a constructivist stance on the inseparability of thinking and learning. I link DPT to accounts of (i) brain-based conceptual learning and (ii) how mathematics teaching may promote such learning—and discuss advantages of those accounts.

Introduction

I thank the PME-NA organizers for a learning opportunity they created for me in discussing Uri Leron’s plenary address. It re-acquainted me with the inspiring work that he and his colleagues were conducting in the two decades since I last studied with him. It also provided me with a window into literature outside mathematics education that I found thought provoking and relevant to our field. Finally, via his paper(s) I realized how naturally his approach linked with my recent efforts to relate math education with brain studies. I concur with him that “bridging the gap between intuition and analytical thinking … is a major step towards ‘optimizing student understanding in mathematics’,” and am delighted to provide my reflections on this endeavor.

In itself, the thesis that human thinking and rationality consist of two distinct modes is not new to math education. Skemp (1979) articulated and linked both, termed intuitive and reflective intelligences. As far as I know, his constructivist theory evolved independently of the ‘heuristic and bias’ approach (Kahneman, Slovic, & Tversky, 1982; Kahneman & Tversky, 1973; Tversky & Kahneman, 1973). Moreover, in our field it distinction can be traced back to Dewey’s (1933) notion of reflective thought (contrasted with unconscious mental processes), and to Vygotsky’s (1986) notion of ZPD and his related distinction between spontaneous and scientific concepts.

However, two novelties in Uri’s contribution seem useful for math education. First, his review of cognitive psychology literature reveals studies in which a dual view of thinking has been elaborated on (Evans, 2006; Kahneman & Frederick, 2002; Stanovich, 2008) and ‘mapped’ onto corresponding brain regions (Lieberman, 2003). Thus, a timely direction, of linking math education with brain studies, is supported by relevant findings from cognitive psychology.

Second, he reports on studies (Leron & Hazzan, 2006, 2009) informed by DPT that demonstrated applicability to our field, including articulation of instructional goals and design criteria.

Significant Problem/Questions, Useful Theory, Elegant Exposition

Significance

Like many math teachers, Uri and his colleagues noticed what seemed to puzzle researchers in other fields. Often, observers of people’s task solutions framed them as recurring faulty judgments. Examples abound in the above papers; I shall add 3 of my own. Studies of such examples fueled a debate on human rationality that conjoined epistemology and psychology (Nisbett & Ross, 1994; Quine, 1994). For example, alluding to computational complexity, Cherniak (1994) saw ‘ideal’ (normative) rationality as intractable. He proposed ‘minimal’ rationality, in which using ‘quick and dirty’ heuristics that evade mental paralysis.

Addressing this puzzling and significant problem in math education is more pressing and weighty than in other fields, in which solidly explaining why/how the human mind produces erroneous judgments will suffice. Uri’s work indicates that for us this is but a start, while making two key contributions: (a) clarifying a goal for student and teacher learning—closing the gap between intuitive and analytic reasoning, and (b) explicating our duty to find ways of designing and implementing teaching that fosters student development of and disposition toward analytic reasoning. To these ends, Uri identifies four vital questions for mathematics educators:

i) What differentiates among those who solve problems correctly and incorrectly, that is, why do the latter fail to use analytic reasoning whereas the former successfully do so?

ii) How do problem formats cue for correctly solving a problem, and what does it entail for task design?

iii) When using puzzling problems in our teaching (e.g., string-around-earth), what follow-up strategies can be used to effectively capitalize on students’ “Aha” moments regarding those puzzlements?

iv) How can teaching promote (a) students’ awareness of improper intuitions and (b) disposition toward activating analytic reasoning to override the faulty intuitions (i.e., resist + critique)?

Useful Theory?

I use 4 examples to present key features of and articulate purposes DPT can serve in math education (to be brief, language does not precisely replicate the problems).

A. Adults with college education are asked: Two items cost $1.10; the difference in price is $1. How much does each cost? (Over 50% submit to impulse and respond: $1 & $0.10)

B. In the elevator, the 9th floor button is already lit. A person (you?) who also wants that floor gets on the elevator and, though seeing the lit button, presses it again.

C. Third graders were asked what to bet on next (Head/Tail), after 4 ‘Heads’ were flipped in a row. About 50% said ‘Head’, because it’s always been so; the rest said ‘Tail’, because it cannot always be ‘Head’. No one said 50-50 and that previous results are irrelevant.

D. A Sudoku expert solves a ‘black-belt’ puzzle and makes two careless errors (Fig. 1a-1b).

The key insight and tenet of DPT is that responses to diverse problems, faulty or correct, all share a common root: two different modes of brain processing are at work (Evans, 2006; Stanovich, 2008; Stanovich & West, 2000). One mode, intuitive reasoning (or heuristic), is evolutionary more ancient, shared with animals, automatic (reflexive, sub-conscious), rapid, and parallel in nature, with only its final product available to consciousness. The other, analytic, is
evolutionary recent, unique to humans, intentional (reflective, conscious), relatively slow, and sequential in nature. The second mode monitors, critics, and corrects judgments of the first. It suppresses (inhibits) default responses, serving as a failure prevention+correction mental device. As Uri points out, some DPT proponents refer to these modes as System-1 (S1) and System-2 (S2) respectively, stating that often both work mostly in tandem (i.e., S1 judgment agreed by S2).

Figure 1a. Processing error almost committed—placing ‘4’ in mid-lower left cell (transposed row, ignored vertical)

Figure 1b. Same error repeated & committed; ‘9’ in left-lower cell (checked for vertical only)

A second tenet of DPT is that faulty responses reflect failure of analytic processes to prevent-and-correct intuitive outputs. A key corresponding assumption, indicated by the notion of rational judgment, is that at any given problem (e.g., economic benefit, academic success) a person intends for a correct solution that serves one’s purposes. In the examples above, a person tries solving the problems correctly but, as DPT explains, the “tendency of the insuppressible and fast-reacting S1 to “hijack” the subject’s attention [leads] to a non-normative answer” (Leron, this volume). In Example A, S1 ‘falls prey’ to one item’s cost ($1) being equal to the difference; in Example B, S1 activates a planned action (enter elevator, identify + press 9th floor) before S2 re-evaluates circumstantial necessity; In Example D (Figure 1b), S1 directed my actions to place digits with only partial checking before S2 detected that partiality. (Note: it occurred soon after I actually thought of placing the ‘4’ where it’s shown in Figure 1a, but then avoided this error.) Example C highlights a few hurdles with DPT, particularly the effect of solvers’ cognitive abilities (Stanovich & West, 2000). What an observer considers non-normative responses seemed a proper response to children—a case of S1 and S2 working in tandem for the reasoner.

A few points before turning to hindrances I find in DPT. First, Evans (2006) distinguished between dual processes and dual systems. This is important for us particularly because, as he asserted, dual system views are too broad. He suggested specifying dual-reasoning accounts at an intermediate level that explain solutions to particular tasks. To me, his goal (particular task) seems primary whereas the means (dual accounts, or singular, or triple) seems secondary.

This leads to my second point—the need to pay attention to solution processes and kinds of tasks—in which the analytic successfully monitored and corrected the intuitive before the latter reached its judgment. For example, upon reading Example A in Uri’s paper, I immediately identified the task as ‘inviting’ a faulty conclusion, as well as my conscious, proactive ‘flagging’ of this tendency. Consequently, I used a reflective process. This mental adjustment happened before I calculated the faulty difference (90 cents), precisely the desired state of affairs indicated in Uri’s question #4 above. This shows the need to precisely analyze how intuitive and analytic processes interact. Initial DPT assumed sequential operation—outcomes of intuitive processes

(or S1) served as input for and triggered the analytic only if S2 identified S1 output as faulty. Recently, parallel processing of both modes was postulated, including possibly competing for the immediate/final judgment to a given task (Evans, 2006). To further theorize S1-S2 interaction, he suggested 3 principles: (a) singularity—epistemic mental models are generated and judged one-at-a-time, (b) relevance—the intuitive contextualizes problems to exploit relevance to a person’s goals, and (c) satisficing—the analytic accepts intuitive judgments unless there is a good reason to override them. These crucial principles fall short of accounting for how I solved Example A.

My last point refers to factors that make a difference in ways people solve particular problems (see Stanovich, 2008; Stanovich & West, 2000 for review). Here, I refer to a key factor for math education highlighted in Uri’s address—the impact of problem format (‘packaging’) on suppression of intuitive judgments. A substantial part of Uri’s work, and a major contribution to our field, focused on the design of bridging tasks for triggering solvers’ analytic processes and enabling solution of congruent tasks that seemed ‘unpackable’ without bridging. This indirect allusion to assimilatory conceptions of those for whom bridging is required points to a hindrance.

As theoretical and practical hindrance I find in DPT is the unproblematic application of an observer’s frame of reference (‘normative’) to the evaluation of people’s responses (‘rational’ or not). If people of varied cognitive abilities solve the same task differently, and if many who failed on a congruent task solved a bridging task, then the mental toolbox solvers and observers bring to the task must be distinguished. Simply put, the use of two cognitive frames of reference is glossed over by DPT’s equating of the normative with rational (see Nisbett & Ross, 1994). Theoretically, and crucial for math education, this lack of distinction fails to acknowledge different interpretation(s) of a task and different mental activities available to the observed for solving it. That is, it overlooks assimilation (Piaget, 1985; von Glasersfeld, 1995). Recent cognitive psychology studies pointed out to solvers’ different interpretations (Stanovich & West, 2000). But the implication of addressing two frames of reference at once did not seem to follow. In my view, distinguishing the observer and using assimilation as a starting point are necessary in our field to move beyond cognitive psychology’s focus on thinking to accounts of learning as a conceptual advance in someone else’s mind (Steffe, 1995). As Skemp (1979) and Thompson (2010) asserted, at the core of a math education theory of teaching one must articulate learning as a process of cognitive transformation in what the learner already knows toward intended math.

Practically, overlooking learners’ extant conceptions when analyzing their solutions, correct or faulty, hinders the design of bridging tasks shown by Uri. Indirectly, specific features of those tasks (e.g., cueing for a nested sub-set or for the invariant length of string when shapes increase) and the rationale/criteria he provided for using those features (e.g., make the task accessible to the solver’s intuition), draw on conjectured inferences about how a person may interpret and/or solve the alternative tasks. This nicely leads to the discussion of Uri’s elegant and effective exposition, which I shall follow by elaborating on DPT’s core hindrance (Section 3).

**Elegant, Effective Exposition**

I found Uri’s presentation of DPT’s contribution to math education to be elegant and effective. Due to space limitations, I focus on two main features: (a) examples used to portray DPT and (b) applying DPT in his empirical studies. To write this paper, I read a few articles about DPT. My non-exhaustive sample revealed a complex set of constructs, as well as subtle distinctions and heavy debates. Yet, via strategically chosen and lucid examples Uri’s paper successfully conveyed the essence of DPT. Those examples depicted for me, as naïve reader, (a) the problems addressed by DPT, (b) key assumptions and explanations of phenomena studied,
and (c) possible ways in which DPT can promote solution of these problems in math education. Those of us whose interest is sparked by his exposition may inquire further (a great sign of reach!); as is, it clearly portrays DPT and the potential contributions to math education. Further, his examples draw on studies he conducted with colleagues to test how useful DPT can be. The examples from those studies accomplish two key purposes of scholarly exchange of ideas. They demonstrate a commitment for learning through authentic experimentation—walking the walk and talking the talk. They also provide a critical look into adaptations needed for DPT to become useful. In this sense, his elaboration of (bridging) tasks was powerful as it enabled many students to ‘see’ a solution for problems they couldn’t unpack otherwise, while indicating general criteria for designing such instructional tools. As one who’s struggling with writing scholarly papers, especially with drawing on examples, I marvel at Uri’s writing.

A Constructivist Lens on DPT: ‘Brainy’ Mathematics Learning and Teaching

Taking Issue with DPT

I adhere to a core premise common to Piaget’s (1970), Dewey’s (1902), and Vygotsky’s (1978) grand theories: knowing (thinking) cannot be understood apart from how one’s knowing evolved. This premise entails my twofold thesis about hurdles in adapting DPT to math education. First, contrasting normative and faulty ‘snapshot’ reasoning in math (or cognitive psychology) falls short of accounts needed to intentionally foster optimal student understandings. Second, although DPT can inform our work, math education already has models that interweave accounts of knowing, coming to know (learning), and teaching. As I shall discuss below, one such model seems to (a) singularly resolve issues of faulty/normative reasoning and of conceptual learning (with or without teaching) and (b) explain different modes of thinking without alluding to 2 systems (or distinct processes). Moreover, this model is supported by and gives support to cognitive neuroscience models of the brain. Due to space limitations, the brief exposition below makes wide use of references to comprehensive versions.

Uri’s work, and accounts of DPT I read, raised 7 critical questions for math education:

1. Why/how does the mental system of some people make an error (e.g., selects $1 and 10 cents in Example A) whereas other people focus also on the difference? Unless one also considers a problem solver’s assimilatory conceptions, this question (and #2, #3, & #4 below) cannot be resolved by DPT assumptions that S2 has no direct access to the perceived information, or that it selects accessible instead of relevant information.
2. When a response is not normative, is it due to (a) having the required conceptions but failing to trigger them (e.g., Sudoku and elevator examples), (b) having a rudimentary form of those conceptions that require some prompting (e.g., nested subset in Uri’s bridging task, pointing out the difference feature in Example A and/or making the numbers more ‘difficult”), or (c) lacking a conception for S2 to monitor S1 (e.g., next coin-flip and DMP base-rate examples)? And how can we distinguish among these three cases?
3. How does S2, which failed to monitor S1 in a specific task, become capable of doing so? Is the process of learning, and required teaching, different for each of the three cases above?
4. How do new monitoring capacities learned by S2 ‘migrate’ to S1 (become automatic)?
5. What is the source of learners’ surprise (e.g., string-around-earth example), how may it be linked to learning, and how might teaching capitalize on this (one of Uri’s key pleas)?
6. What role do specifically designed examples/illustrations play in learning (by S2 and/or S1)?

7. Can we explain why particular bridging tasks promote some students’ learning but not others’, and provide explicit ideas for changing them in the latter case?

A Brain-Based Model of Knowing and Learning

In recent years, a few interdisciplinary meetings of cognitive neuroscientists with math educators took place. One of those (Vanderbilt, 2006) dealt with the design of tasks that (a) reveal difficult milestones and (b) can be examined at the brain level. Using the reflection on activity-effect relationship (Ref*AER) account of knowing and learning (Simon & Tzur, 2004; Simon, Tzur, Heinz, & Kinzel, 2004; Tzur, 2007; Tzur & Simon, 2004), I presented fraction tasks. This presentation, and the fertile dialogue with brain researchers that ensued, led to an elaborated, brain-based Ref*AER account (Tzur, accepted for publication), found highly consistent with DPT studies of the brain (Lieberman, 2003).

Briefly, knowing (having a conception) is explained as anticipating and justifying an invariant relationship between a goal-directed activity-sequence the mental system executes at any given moment (Evans’ Singularity principle), potentially or actually, and the effect it must bring forth. Learning is explained as transformation in such anticipation via two basic types of reflection. Type-I consists of continual, automatic comparison the mental system executes between the goal it sets for the activity-sequence and subsequent effects produced. As Piaget (1985) asserted, the internal global goal (anticipated effect) regulates the execution and detects interim effects and the final one (Relevance principle) (see also Stich, 1994). The effects either match the anticipation or not (Satisficing principle). By default, the mental system runs the activity-sequence to its completion as determined by the goal (e.g., elevator example). Yet, the execution may stop earlier if the goal detects unanticipated sub-effects (e.g., Sudoku–1a) or if a different goal became the regulator, including a sub-goal of the activity-sequence overriding the global goal. Type-II consists of comparison across records of experiences, each containing a linked, represented ‘run’ of the activity and its effect, sorted as match/no-match. Type-II is not automatic—it may or may not be executed. Recurring, invariant AER across those experiences are linked with the situation(s) in which they were found anticipatory of the proper goal and are registered as a new conception. Constructing a new conception proceeds through 2 stages. The first, participatory stage requires reflection Type-I and is marked by anticipation that a solver can access only if somehow prompted for the novel, provisional AER (In a forthcoming paper with Lambert I linked this stage with ZPD). The second, anticipatory stage requires reflection Type-II and is characterized by spontaneously activating and justifying the novel anticipation. It should be noted that this model, although developed independently, is consistent with Skemp’s (1979) foundational theory; the reflection types and stage distinctions extend his work.

To link Ref*AER to the brain, I separated and ‘distributed’ von Glasersfeld’s (1995) tripartite notion of scheme—situation, activity, and result—across 3 major neuronal systems in which they are postulated to be processed. The assumption about both knowing and learning is that the basic unit of analysis in the brain is not one synaptic connection or a neuron (Hebb, 1949, cited in Baars & Gage, 2007; Fuster, 1997). Rather, and to stress neuronal ‘firing’ in the brain and growth/change/decay of neuronal networks, I introduced the term Synapse inhibition-Excitation Constellation (SIEC)—any-size aggregate of synapses of connected neurons that, once ‘firing’ and updating, forms a pattern of activity. The roles and functions of SIECs are described below in terms of three neuronal networks in which they may be activated (Baars & Gage, 2007): a ‘Recognition System’ (RecSys) with the sensory input/buffer and long-term memories, a
‘Strategic System’ (StrSys) with the Central Executive, and an ‘Engagement-Emotive System’ (EngSys). Within these, solving a problem is postulated as follows (indices match Figure 2):

1. Solving a problem begins with assimilating it via one’s sensory modalities into the **Situation** part of an extant scheme in the RecSys. This **SIEC** is firing and updating until reaching its activity pattern (recognizing state), and activates firing and updating of a Goal **SIEC** in the StrSys.

2. A Goal **SIEC** is set in the StrSys, setting a desired inhibition-excitation state that will regulate the execution and termination of an activity sequence. The goal **SIEC** also triggers:
   a. Corresponding **SIECs** in the EngSys, which set the desirability of the experience and the sense of control the learner has over the activity (McGaugh, 2002; Tzur, 1996; Zull, 2002); This emotional component was linked to activity in the anterior cingulate cortex (Bush, Luu, & Posner, 2000; Lieberman, 2003).
   b. A temporary auxiliary **SIEC** checks if an activity has already been partly executed and can thus be resumed. If its output is ‘Yes’, it re-triggers the **AER**’s execution in the StrSys from the stopping point (go to #4); if ‘No,’ it triggers the Goal **SIEC** to trigger #3 below.

3. A **SIEC** responsible for searching/selecting an available **AER** is triggered by the Goal **SIEC**. The search operates on three different long-term memory ‘storages’ of **SIECs**. Using a metaphor of ‘road-map’, Skemp (1979) explained that, within every universe of discourse (e.g., math, economy), the ‘path’ from a present state to a goal state may consist of multiple activity-sequences from which the one eventually executed is selected (see also multiple-trace theory in Nadel, Samsonovich, Ryan, & Moscovitch, 2000). The 3 **SIECs** are:
   a. Anticipatory **AER** of the mental process to be carried out;
   b. Participatory **AER** that a learner is currently forming and can be called up only if prompted (dotted arrow);
   c. Mathematical ‘objects,’ which are essentially anticipatory **AER** established and encapsulated previously (e.g., ‘number’ is an encapsulated, anticipated effect of a counting operation).

4. Once an operation and ‘object’ **AER** were selected, the brain executes them while monitoring progress to the goal via a meta-cognitive **SIEC** in the StrSys responsible for Type-I reflections. Skemp’s (1979, see ch. 11) model articulates this component in great details, including how it can be carried out automatically (intuitive) and/or reflectively (analytic). This component seems compatible with Norman and Shallice’s (2000) model of schema activation and Corbetta and Shulman’s (2002) notion of ‘circuit breaker’.

5. The execution of the selected **AER** is constantly monitored by **Type-I reflection** to determine 3 features:
   a. Was the learner’s goal, as set in **SIEC** 2a, met?
   b. Is the **AER** execution moving toward or away from the goal (see McGovern, 2007, for relevant emotions)?
   c. Is the final effect of the executed portion of the **AER** different from the anticipated, set goal. Goldberg and Bougakov (2007) suggested that this is mainly a prefrontal cortex (PFC) function.

Each feature (5a, 5b, 5c) can stop the executed **AER**. If the output of 5c is ‘No’, that ‘run’ of the **AER** is registered as another record of experience of the existing scheme (see Zull, 2002). Symbolically, such no-novelty can be written: Situation$_0$-Goal$_0$-$\text{AER}_0$. If the output is ‘Yes’, symbolized as Situation$_0$-Goal$_0$-$\text{AER}_1$, a new conceptualization may commence (see next).
This perturbing state of the mental system (von Glasersfeld, 1995), has recently been linked to anticorrelations of brain networks (Fox, et al., 2005).

6. **Type-II** reflective comparisons may then operate on the output records of Type-I reflection. Whenever the output of Type-I question 5c is ‘Yes,’ the brain updates a new SIEC for that recently run AER and stores it in a temporary auxiliary SIEC in the RecSys (symbolized A0-E1, or AER1). Each repetition of the solution process for which the output of 5c is ‘Yes’ adds another such record to the temporary auxiliary.

7. The accruing records of temporary AER1 (novel) compounds are continually monitored by the Type-II reflective comparison SIEC in terms of two features:
   a. Is the effect of the new AER (E1) closer to or further away from the Goal?
   b. How is the new AER1 similar to or different from the extant anticipatory and/or participatory AER in the RecSys? This aspect of Type-II reflection is consistent with Moscovitch et al.’s (2007) articulation of the constant interchanges between the Medial Temporal Lobe (MTL) and PFC.

The output of recurring Type-II reflections is a new SIEC (AER1). As the anticipatory-participatory stage distinction implies, initially the Search/Select SIEC (#3) may only access a new SIEC if the learner is prompted for the activity (A0), which generates the effect (E1) and thus ‘opens’ a neuronal path to using AER1 in response to the triggering situation (Situation0). In time, Type-II comparisons of the repeated use of AER1 for Situation0 produces a new neuronal pathway from the Situation0 SIEC to the newly formed AER1, that is, to the construction of a directly retrievable, anticipatory SIEC (new scheme symbolized as Situation1-Goal1-AER1).

**Comparing DPT with Brain-Based Ref*AER.**

I contend that Ref*AER, with its brain-based elaboration, simultaneously resolves not only the reasoning puzzlement addressed by DPT, but also central problems of math learning and teaching. Concerning normative solutions, Ref*AER explains and predicts their production as the outcome of either an anticipatory conception, which can run automatically and/or reflectively, or a compatible participatory conception that was accessed via a prompt—self/internal (e.g., Soduku-1a) or external (e.g., Uri’s bridging task, apple falling on Newton’s head). Accordingly, faulty solutions are the outcome of (a) partial/inefficient/flawed execution of a suitable anticipatory conception (e.g., Soduku-1b, elevator), (b) prompt-dependent inability to access a proper participatory conception (e.g., incorrectly solving the $1.10 when difference=$1 but correctly with other amounts), and, often, (c) lack of suitable conception for correctly solving the given task (e.g., 3rd graders facing the next coin flip problem; students in Uri’s study who could not solve the bridging task).

I further contend that, for cognitive psychology and math education purposes, Ref*AER resolves DPT problems better. Instead of postulating two systems (or processes), it explains how the brain gives rise to a multi-part single thought process by which a problem solver may get at a normative or a faulty answer. Furthermore, it stresses that a ‘solution’ must encompass not only the answer, but also the (inferred) solver’s reasoning processes used for producing it. Ref*AER makes such inferences via analyzing the solver’s: (i) goal and sub-goals (see Stanovich & West, 2000, for differing researcher/subject goals), (ii) entire or partial activity-sequence selected and executed (see Kahneman & Frederick, 2002, for Attribute Substitution), (iii) suitability of objects operated on (see Uri’s explication of objects, such as length gap in string-around-earth and nested sub-set in his RMP bridging task), (iv) sub- and final effects noticed and
successful/failed reflections (both Types). Last but not least, Ref*AER analyses distinguish between two frames of reference in the evaluation of solvers’ judgments—observer’s advanced/justified frames and observeds’ evolving and sensible relative to her or his extant conceptions.

Thus, consistent with Stich’s (1994) assertion that cognitive systems serve an organism’s goals and not absolute truths, Ref*AER evades the pitfalls of equating normative with rational. Instead, it clarifies that upon a solver’s assimilation of a task and setting her/his goal(s), one path is selected among multiple, extant activity-sequences (spontaneous or prompted), executed, and being monitored by the solver’s goal. By default, the brain runs the sequence to its completion, which is signaled via Type-I comparison (goal SIEC), and may thus be portrayed by an observer as intuitive/automatic. However, at any given moment during the execution or after completion, the system’s regulator (goal SIEC) may notice effects that require interruption and/or correction to the run and/or even to the goal (portrayed as analytic/reflective). Instead of “I think, therefore I err,” (Gigerenzer, 2005), we say: “I (learn to) think, therefore I adjust erroneous anticipations.”

Most importantly, I contend that Ref*AER also contributes to resolving two problems that, while not addressed by DPT, are vital for a foundation of math education (Thompson, 2010), namely, explaining (a) how learning to reason—intuitively and analytically—may occur and (b) how can teaching capitalize on it and foster (optimize) students’ maths. The former has been articulated above; the latter exceeds the scope of this discussion and was articulated elsewhere (Tzur, 2008, 2010) as a 7-step cycle that proceeds from analysis of students’ extant conceptions.

To briefly convey the potential of this teaching cycle, I return to Uri’s RMP bridging task. In that task, a 2-phase activity-sequence of considering base-rate (1/1000) and diagnostic info (5% false positive) was made explicit as linked sub-goals. What’s more, ‘objects’ on which this alternative sequence would operate were replaced, from multiplicatively related quantities...
(fractions, percents) to whole number frequencies considered additively until the final
multiplicative calculation (51/1000). In terms of Ref*AER, these alterations shed light on why
some of those who incorrectly solved the DMP problem could correctly solve the RMP problem.
The alteration was more likely to orient a solver to (a) clearly coordinate sub-goals (specifying
each of the nested sub-sets) of the task’s global goal and (b) select and operate on accessible quantities—anticipatory AER (‘objects’)—in place of quantities that are notoriously prompt-
dependent (or lacking) in youngsters and adults and, not surprisingly, were ‘neglected’.
These insightful alterations also explain the educative power of the RMP task as a ‘bridge’. It
brought forth an anticipatory AER that, I infer, could serve as an internal prompt for correctly
selecting/executing the entire activity-sequence when, later, operating similarly on the more
difficult-to-grasp multiplicative quantities/relationships. A novel dissertation study of my PhD
student, Xianyan Jin, provides a penetrating examination of how Bridging (xianjie) tasks are
uniformly fitted within a 4-component lesson structure in Chinese mathematics teaching. Her
work includes ‘mapping’ the 7-step cycle onto the fourfold lesson structure, emphasizing the role
that bridging tasks, like those designed by Uri et al., can play in activating students’ extant assimilatory conceptions. Alluding to Uri’s closing slogan, while not positing thinking dualities,
I believe that such brain-based, Ref*AER-informed teaching can nurture “the power of natural
thinking,” address “the challenge of stretching it,” and inform “the beauty of overcoming it.”

PROMOTING STUDENT UNDERSTANDING THROUGH COMPLEX LEARNING

Lyn D. English
Queensland University of Technology
l.english@qut.edu.au

The world’s increasing complexity, competitiveness, interconnectivity, and dependence on technology generate new challenges for nations and individuals that cannot be met by “continuing education as usual” (The National Academies, 2009). With the proliferation of complex systems have come new technologies for communication, collaboration, and conceptualization. These technologies have led to significant changes in the forms of mathematical thinking that are required beyond the classroom. This paper argues for the need to incorporate future-oriented understandings and competencies within the mathematics curriculum, through intellectually stimulating activities that draw upon multidisciplinary content and contexts. The paper also argues for greater recognition of children’s learning potential, as increasingly complex learners capable of dealing with cognitively demanding tasks.

Although reformers have disagreed on many issues, there is a widely shared concern for enhancing opportunities for students to learn mathematics with understanding and thus a strong interest in promoting teaching mathematics for understanding (Silver, Mesa, Morris, Star, & Benken, 2009, p.503).

Introduction

In recent decades our global community has rapidly become a knowledge driven society, one that is increasingly dependent on the distribution and exchange of services and commodities (van Oers, 2009), and one that has become highly inventive where creativity, imagination, and innovation are key players. At the same time, the world has become governed by complex systems—financial corporations, the World Wide Web, education and health systems, traffic jams, and classrooms are just some of the complex systems we deal with on a regular basis. For all citizens, an appreciation and understanding of the world as interlocked complex systems is critical for making effective decisions about one’s life as both an individual and as a community member (Bar-Yam, 2004; Jacobson & Wilensky, 2006; Lesh, 2006).

Complexity—the study of systems of interconnected components whose behavior cannot be explained solely by the properties of their parts but from the behavior that arises from their interconnectedness—is a field that has led to significant scientific methodological advances. With the proliferation of complex systems have come new technologies for communication, collaboration, and conceptualization. These technologies have led to significant changes in the forms of mathematical thinking that are needed beyond the classroom. For example, technology can ease the thinking needed in information storage, retrieval, representation, and transformation, but places increased demands on the complex thinking required for the interpretation of data and communication of results. Computational skills alone are inadequate here—the ability to interpret, describe, and explain data and communicate results of data analyses is essential (Hamilton, 2007; Lesh, 2007a; Lesh, Middleton, Caylor & Gupta, 2008).

The rapid increase in complex systems cannot be ignored in mathematics education. Indeed, educational leaders from different walks of life are emphasizing the importance of developing students’ abilities to deal with complex systems for success beyond school. Such abilities include:
constructing, describing, explaining, manipulating, and predicting complex systems; working on multi-phase and multi-component component projects in which planning, monitoring, and communicating are critical for success; and adapting rapidly to ever-evolving conceptual tools (or complex artifacts) and resources (Gainsburg, 2006; Lesh & Doerr, 2003; Lesh & Zawojewski, 2007).

In this paper I first consider future-oriented learning and then address some of the understandings and competencies needed for success beyond the classroom, which I argue need to be incorporated within the mathematics curriculum. A discussion on complex learners and complex learning, with mathematical modeling as an example, is presented in the remaining section.

**Future-oriented learning**

*Every advanced industrial country knows that falling behind in science and mathematics means falling behind in commerce and property* (Brown, 2006).

Many nations are highlighting the need for a renaissance in the mathematical sciences as essential to the well-being of all citizens (e.g., Australian Academy of Science, 2006; The National Academies, 2009). Indeed, the first recommendation of The National Academies’ *Rising above the Gathering Storm* (2007) was to vastly improve K-12 science and mathematics education. Likewise the Australian Academy of Science has indicated the need to address the “critical nature” of the mathematical sciences in schools and universities, especially given the unprecedented, worldwide demand for new mathematical solutions to complex problems. In addressing such demands, the Australian Academy emphasizes the importance of interdisciplinary research, given that the mathematical sciences underpin many areas of society including financial services, the arts, humanities, and social sciences.

The interdisciplinary nature of the mathematical sciences is further evident in the rapid changes in the nature of the problem solving and reasoning needed beyond the school years (Lesh, 2007b). Indeed, numerous researchers and employer groups have expressed concerns that schools are not giving adequate attention to the understandings and abilities that are needed for success beyond school. For example, potential employees most in demand in the mathematical sciences are those that can (a) interpret and work effectively with complex systems, (b) function efficiently and communicate meaningfully within diverse teams of specialists, (c) plan, monitor, and assess progress within complex, multi-stage projects, and (d) adapt quickly to continually developing technologies (Lesh, 2008). Research indicates that such employees draw effectively on interdisciplinary knowledge in solving problems and communicating their findings. Furthermore, although such employees draw upon their school learning, they do so in a flexible and creative manner, often generating or reconstructing mathematical knowledge to suit the problem situation (unlike the way in which they experienced mathematics in school; Gainsburg 2006; Hamilton 2007; Zawojewski, Hjalmarson, Bowman, & Lesh, 2008). Indeed, such employees might not even recognize the relationship between their school mathematics and the mathematics they apply in solving problems in their daily work activities. We thus need to rethink the nature of the mathematical learning experiences we provide students, especially those experiences we classify as “problem solving;” we also need to recognize the increased capabilities of students in today’s era.

In his preface to the book, *Foundations for the Future in Mathematics Education*, Lesh (2007b) pointed out that the kinds of mathematical understandings and competencies that are
targeted in textbooks and tests tend to “represent only a shallow, narrow, and often non-central subset of those that are needed for success when the relevant ideas should be useful in ‘real life’ situations” (p. viii). Lesh’s argument raises a number of issues, including:

What kinds of understandings and competencies should be emphasized to reduce the gap between the mathematics addressed in the classroom (and in standardized testing), and the mathematics needed for success beyond the classroom?

How might we address the increasing complexity of learning and learners to advance their mathematical understanding within and beyond the classroom?

Understandings and competencies for success beyond the classroom

The advent of digital technologies changes the world of work for our students. As Clayton (1999) and others (e.g., Jenkins, Clinton, Purushotma, Robinson & Weigel, 2006; Lombardi & Lombardi, 2007; Roschelle, Kaput, & Stroup, 2000) have stressed, the availability of increasingly sophisticated technology has led to changes in the way mathematics is being used in work place settings; these technological changes have led to both the addition of new mathematical competencies and the elimination of existing mathematical skills that were once part of the worker's toolkit.

Studies of the nature and role of mathematics used in the workplace and other everyday settings (e.g., nursing, engineering, grocery shopping, dieting, architecture, fish hatcheries) are important in helping us identify some of the key understandings and competencies for the 21st century (e.g., de Abreu, 2008; Gainsburg, 2006; Roth, 2005). A major finding of the 2002 report on workplace mathematics by Hoyles, Wolf, Molyneux-Hodgson and Kent was that basic numeracy is being displaced as the minimum required mathematical competence by an ability to apply a much wider range of mathematical concepts in using technological tools as part of working practice. Although we cannot simply list a number of mathematical competencies and assume these can be automatically applied to the workplace setting, there are several that employers generally consider to be essential to productive outcomes (e.g., Doerr & English, 2003; English, 2008; Gainsburg, 2006; Lesh & Zawojewski, 2007). In particular, the following are some of the core competencies that have been identified as key elements of productive and innovative work place practices (English, Jones, Bartolini Bussi, Lesh, Tirosh, & Sriraman, 2008). I believe these competencies need to be embedded within our mathematics curricula: Problem solving, including working collaboratively on complex problems where planning, overseeing, moderating, and communicating are essential elements for success;

• Applying numerical and algebraic reasoning in an efficient, flexible, and creative manner;
• Generating, analyzing, operating on, and transforming complex data sets;
• Applying an understanding of core ideas from ratio and proportion, probability, rate, change, accumulation, continuity, and limit;
• Constructing, describing, explaining, manipulating, and predicting complex systems;
• Thinking critically and being able to make sound judgments, including being able to distinguish reliable from unreliable information sources;
• Synthesizing, where an extended argument is followed across multiple modalities;
• Engaging in research activity involving the investigation, discovery, and dissemination of pertinent information in a credible manner;
• Flexibility in working across disciplines to generate innovative and effective solutions.
Although a good deal of research has been conducted on the relationship between the learning and application of mathematics in and out of the classroom (e.g., de Abreu 2008; Nunes & Bryant 1996; Saxe 1991), we still know comparatively little about students’ mathematical capabilities, especially problem solving, beyond the classroom. We need further knowledge on why students have difficulties in applying the mathematical concepts and abilities (that they presumably have learned in school) outside of school—or in classes in other disciplines.

A prevailing explanation for these difficulties is the context-specific nature of learning and problem solving, that is, competencies that are learned in one situation take on features of that situation; transferring them to a new problem situation in a new context poses challenges (Lobato 2003). This suggests we need to reassess the nature of the typical mathematical problem-solving experiences we give our students, with respect to the nature of the content and how it is presented, the problem contexts and the extent of their real-world links, the reasoning processes likely to be fostered, and the problem-solving tools that are available to the learner (English & Sriraman, 2010). This reassessment is especially needed, given that “problems themselves change as rapidly as the professions and social structures in which they are embedded change” (Hamilton, 2007, p. 2). The nature of learners and learning changes likewise. With the increasing availability of technology and exposure to a range of complex systems, children are different types of learners today, with a potential for learning that cannot be underestimated.

**Complex learners, complex learning**

Winn (2006) warned of the “dangers of simplification” when researching the complexity of learning, noting that learning is naturally confronted by three forms of complexity—the complexity of the learner, the complexity of the learning material, and the complexity of the learning environment (p. 237). We cannot underestimate these complexities. In particular, we need to give greater recognition to the complex learning that children are capable of—they have greater learning potential than they are often given credit for by their teachers and families (English, 2004; Lee & Ginsburg, 2007; Perry & Dockett, 2008; *Curious Minds*, 2008). They have access to a range of powerful ideas and processes and can use these effectively to solve many of the mathematical problems they meet in daily life. Yet their mathematical curiosity and talent appear to wane as they progress through school, with current educational practice missing the goal of cultivating students’ capacities (National Research Council, 2005; *Curious Minds*, 2008). The words of Johan van Benthem and Robert Dijkgraaf, the initiators of *Curious Minds* (2008), are worth quoting here:

> What people say about children is: “They can’t do this yet.”
> We turn it around and say: “Look, they can already do this.”
> And maybe it should be: “They can still do this now.”

As Perry and Dockett (2008) noted, one of our main challenges here is to find ways to utilize the powerful mathematical competencies developed in the early years as a springboard for further mathematical power as students progress through the grade levels. I offer three interrelated suggestions for addressing this challenge:

1. Recognize that learning is based within contexts and environments that we, as educators shape, rather than within children’s maturation (Lehrer & Schauble, 2007).
2. Promote active processing rather than just static knowledge (Curious Minds, 2008).
3. Create learning activities that are of a high cognitive demand (Silver et al., 2009).

In the remainder of this paper I give brief consideration to these suggestions. In doing so, I argue for fostering complex learning through activities that encourage knowledge generation and active processing. While complex learning can take many forms and involve numerous factors, there are four features that I consider especially important in advancing students’ mathematical learning. These appear in Figure 1.

![Figure 1. Key Features of Complex Learning](image)

Research in the elementary and middle school indicates that, with carefully designed and implemented learning experiences, we can capitalize on children’s conceptual resources and bootstrap them towards advanced forms of reasoning not typically observed in the regular classroom (e.g., English & Watters, 2005; Ginsburg, Cannon, Eisenband, & Pappas, 2006; Lehrer & Schauble, 2007). Most research on young students’ mathematical learning has been restricted to an analysis of their actual developmental level, which has failed to illuminate their potential for learning under stimulating conditions that challenge their thinking—“Research on children’s current knowledge is not sufficient” (Ginsburg et al., 2006, p.224). We need to redress this situation by exploring effective ways of fashioning learning environments and experiences that challenge and advance students’ mathematical reasoning and optimize their mathematical understanding.

Recent research has argued for students to be exposed to learning situations in which they are not given all of the required mathematical tools, but rather, are required to create their own versions of the tools as they determine what is needed (e.g., English & Sriraman, 2010; Hamilton, 2007; Lesh, Hamilton, & Kaput, 2007). For example, long-standing perspectives on classroom

problem solving have treated it as an isolated topic, with problem-solving abilities assumed to develop through the initial learning of basic concepts and procedures that are then practised in solving word (“story”) problems. In solving such word problems, students generally engage in a one- or two-step process of mapping problem information onto arithmetic quantities and operations. These traditional word problems restrict problem-solving contexts to those that often artificially house and highlight the relevant concept (Hamilton, 2007). These problems thus preclude students from creating their own mathematical constructs. More opportunities are needed for students to generate important concepts and processes in their own mathematical learning as they solve thought-provoking, authentic problems. Unfortunately, such opportunities appear scarce in many classrooms, despite repeated calls over the years for engaging students in tasks that promote high-level mathematical thinking and reasoning (e.g., Henningsen & Stein, 1997; Silver et al., 2009; Stein & Lane, 1996).

Silver et al.’s recent research (2009) analyzing portfolios of “showcase” mathematics lessons submitted by teachers seeking certification of highly accomplished teaching, showed that activities were not consistently intellectually challenging across topics. About half of the teachers in the sample (N=32) failed to include a single activity that was cognitively demanding, such as those that call for reasoning about ideas, linking ideas, solving complex problems, and explaining and justifying solutions. Furthermore, the teachers were more likely to use cognitively demanding tasks for assessment purposes than for teaching to develop student understanding. While Silver et al.’s research revealed positive features of the teachers’ lessons, it also indicated that the use of cognitively demanding tasks in promoting mathematical understanding needs systematic attention.

Modeling Activities

One approach to promoting complex learning through intellectually challenging tasks is mathematical modeling. Mathematical models and modeling have been interpreted variously in the literature (e.g., Romberg, Carpenter, & Kwako, 2005; Gravemeijer, Cobb, Bowers, & Whitenack, 2000; English & Sriraman, 2010; Greer, 1997; Lesh & Doerr, 2003). It is beyond the scope of this paper to address these various interpretations, however, but the perspective of Lesh and Doerr (e.g., Doerr & English, 2003; Lesh & Doerr, 2003) is frequently adopted, that is, models are “systems of elements, operations, relationships, and rules that can be used to describe, explain, or predict the behavior of some other familiar system” (Doerr & English, 2003, p.112). From this perspective, modeling problems are realistically complex situations where the problem solver engages in mathematical thinking beyond the usual school experience and where the products to be generated often include complex artifacts or conceptual tools that are needed for some purpose, or to accomplish some goal (Lesh & Zawojewski, 2007).

In one such activity, the Water Shortage Problem, two classes of 11-year-old students in Cyprus were presented with an interdisciplinary modeling activity that was set within an engineering context (English & Mousoulides, in press). In the Water Shortage Problem, constructed according to a number of design principles, students are given background information on the water shortage in Cyprus and are sent a letter from a client, the Ministry of Transportation, who needs a means of (model for) selecting a country that can supply Cyprus with water during the coming summer period. The letter asks students to develop such a model using the data given, as well as the Web. The quantitative and qualitative data provided for each country include water supply per week, water price, tanker capacity, and ports’ facilities. Students can also obtain data from the Web about distance between countries, major ports in
each country, and tanker oil consumption. After students have developed their model, they write a letter to the client detailing how their model selects the best country for supplying water. An extension of this problem gives students the opportunity to review their model and apply it to an expanded set of data. That is, students receive a second letter from the client including data for two more countries and are asked to test their model on the expanded data and improve their model, if needed.

Modeling problems of this nature provide students with opportunities to repeatedly express, test, and refine or revise their current ways of thinking as they endeavor to create a structurally significant product—structural in the sense of generating powerful mathematical (and scientific) constructs. The problems are designed so that multiple solutions of varying mathematical and scientific sophistication are possible and students with a range of personal experiences and knowledge can participate. The products students create are documented, shareable, reusable, and modifiable models that provide teachers with a window into their students’ conceptual understanding. Furthermore, these modeling problems build communication (oral and written) and teamwork skills, both of which are essential to success beyond the classroom.

Concluding Points

The world’s increasing complexity, competitiveness, interconnectivity, and dependence on technology generate new challenges for nations and individuals that cannot be met by “continuing education as usual” (The National Academies, 2009). In this paper I have emphasized the need to incorporate future-oriented understandings and competencies within the mathematics curriculum, through intellectually stimulating activities that draw upon multidisciplinary content and contexts. I have also argued for greater recognition of children’s learning capabilities, as increasingly complex learners able to deal with cognitively demanding tasks.

The need for more intellectually stimulating and challenging activities within the mathematics curriculum has also been highlighted. It is worth citing the words of Greer and Mukhopadhyay (2003) here, who commented that “the most salient features of most documents that lay out a K-12 program for mathematics education is that they make an intellectually exciting program boring,” a feature they refer to as “intellectual child abuse” (p. 4). Clearly, we need to make the mathematical experiences we include for our students more challenging, authentic, and meaningful. Developing students’ abilities to work creatively with and generate mathematical knowledge, as distinct from working creatively on tasks that provide the required knowledge (Bereiter & Scardamalia, 2006) is especially important in preparing our students for success in a knowledge-based economy. Furthermore, establishing collaborative, knowledge-building communities in the mathematics classroom is a significant and challenging goal for the advancement of students’ mathematical learning (Scardamalia, 2002).

A Critique and Reaction to
PROMOTING STUDENT UNDERSTANDING THROUGH COMPLEX LEARNING

Bharath Sriraman
The University of Montana
sriramanb@mso.umt.edu

The plenary by Lyn English addresses “the world’s increasing complexity, competitiveness, interconnectivity, and dependence on technology” which education and changes hitherto to education fails to meet. In her talk, future oriented competencies and multidisciplinary activities are proposed as ways in which complex learning as opposed to simplistic (rote) learning can be promoted. In this critique I weigh the strengths and weaknesses of her proposals in light of existing research.

The times we live in have often been characterized as the nexus of the information age and globalization in which society is increasingly driven by industry, economies, innovation, research and development that need not occur at a local level. Numerous mathematics and science educators as well as position documents from the national academy of science have called for promoting a better understanding of the world in which students are situated by making use of complex adaptive systems in the curriculum and in day to day lessons (The National Academies, 2007, 2009). The plenary paper by English focuses on three main areas, namely:

1. What is future oriented learning and why it is relevant?
2. What are the competencies necessary for success beyond the classroom, and
3. What are complex systems and examples of complex learning activities?

By surveying the recommendations of existing research within models and modeling, complex adaptive learning, and different types of workplace situated learning, English asks us to recognize that contextual and complex learning within an idea rich environment should be strived for in the classroom. Examples of learning activities are then given which place high cognitive demands on students (Silver et al., 2009) as well as active knowledge processing (Curious Minds, 2008).

Future oriented learning is described as learning that takes into account that disciplinary boundaries of science today are not as rigid as they were, say even a decade ago, and promotes competencies which takes this into account. Indeed new fields of study such as mathematical biology, neuroeconomics, bioinformatics, ethnobotany, and other professions that have emerged are often both interdisciplinary and transdisciplinary, and call for competencies related to understanding complex real world phenomena, team work, communication and technological skills.

Numerous definitions of complex systems are found in the literature. One commonly used definition by different non-linear dynamic groups is as follows:

---

Complex systems are spatially and/or temporally extended nonlinear systems characterized by collective properties associated with the system as a whole—and that are different from the characteristic behaviors of the constituent parts.

Viewing learning in a classroom as a complex adaptive system is a non-trivial enterprise. The examples of research which (attempt to) “operationalize” complexity theory and examine learning as a complex adaptive system in students occur in lessons involving simulations of a real world phenomena which a classroom as a whole or in groups can simultaneously observe and manipulate (Wilensky & Stroup, 1999, 2000), and those involved in models and modeling research which make use of model eliciting activities (Lesh et al., 2007; Lesh & Sriraman, 2010). In learning situations which make use of model eliciting activities, complex systems are understood as: (a) “real life” systems that occur (or are created) in everyday situations, (b) conceptual systems that humans develop in order to design, model, or make sense of the preceding “real life” systems, and (c) models that researchers develop to describe and explain students’ modeling abilities. Models for designing or making sense of such complex systems are, in themselves, important “pieces of knowledge” that should be emphasized in teaching and learning—especially for students preparing for success in future-oriented fields that are heavy users of mathematics, science, and technology (English & Sriraman, 2010; Lesh, 2006; Lesh et al., 2007; Lesh & Sriraman, 2005).

Having summarized some of the major themes in the plenary paper by Lyn English, I now turn my attention to the problem of researching learning in complex adaptive situations. The assumptions in such research are that individual learners, groups and classrooms are complex adaptive systems (Hurford, 2010), and that learners adapt to the classroom situation involving a model eliciting activity, or a simulation involving a CAS. With these assumptions in mind, the goal of researchers is to identify the constituent components of learning without losing sight of the big picture. In other words, if an individual learner is considered to be a meta-agent whose activity is the observable pattern emerging from other interacting agents (Lesh & Yoon, 2004, Hurford, 2010), then how are the internal conceptual models that learners are dynamically forming reflected in the rules, actions and artifacts in external artifacts and representations. The question I am posing is whether there is a match in the internal and external representations produced by such learning activities, and if so, what implication does this have for a coherent theory of learning that goes beyond the traditional neo-Piagetian/Vygotskian dichotomy or other situated/socio cultural accounts of learning? Can cultural-historical activity theory provide an adequate theoretical framework to clearly document and explain how these moments of complex learning are reflected in the actions of lower and higher order agents, and in the continually evolving artifacts produced by learners?

While I agree that “establishing collaborative, knowledge-building communities in the mathematics classroom is a significant and challenging goal for the advancement of students’ mathematical learning (Scardamalia, 2002)”, I remain pragmatic about the adequacy of existing theoretical frameworks to capture the learning that takes place in such environments. The question of how this burgeoning area of research can have a systemic impact on school, curricula, textbooks and teacher education is even more complex (pun intended).

PRACTICAL RATIONALITY AND THE JUSTIFICATION FOR ACTIONS IN MATHEMATICS TEACHING

Patricio Herbst
University of Michigan
pgherbst@umich.edu

The action happens in a high school geometry course in late November. The class has spent some time learning to use triangle congruence to prove statements and has begun the study of quadrilaterals. Mr. Jones starts the day congratulating students for their progress learning to do proofs. He then draws Figure 1 on the board and asks the class to prove a statement about the relationship between the sides of the rectangle \(ABCD\). There is some hesitation. Somebody is heard to ask whether they could prove that \(AB\) is longer than \(BC\) while another kid asks what they have to go on; the teacher ignores them. A student asks whether triangles \(ADE\) and \(BCE\) are congruent. Mr. Jones writes down this question on the board and draws two arrows from it. One arrow points toward a question he writes, “how would it help to know that those triangles are congruent?;” the other arrow points toward another question he also writes, “what would you need to assume to be able to say that those triangles are congruent?” You can hear somebody say that it’s obvious they are congruent while another says that they could then say the triangles are isosceles. Another student says “you’d need to know that \(AEB\) is a right angle;” Mr. Jones writes this on the board and asks the class what they have to say about that. Some students claim to not really know what the teacher means with that question but others raise their hands. One of these students says that she thinks it would be useful if the angle were right because then the angles at the top would be congruent with the small angles at \(E\). Some kids perk up and one kid says, “and you could then say that \(AB\) is twice \(BC\).” The teacher asks them to take a few minutes and see if they can prove that the ratio between the sides is 2 assuming as little as possible. You see a kid write, “Prove: The ratio is 2 ” while others have written “Given:” and are pensive.

---

Figure 1. Mr. Jones diagram

I want to use that episode to raise a few questions around mathematics instruction in school classrooms. Some of these questions concern the substance of the episode—in particular, what is the nature of students’ engagement in proving and of the teacher’s work managing that activity? Other questions are about theory: What kind of considerations about classroom instruction could help us describe and explain how teacher and students ordinarily transact mathematical ideas, in such a way that we could also account for possible avenues for change and foresee their consequences? Finally, other questions are about methodology: What kind of data can help us

ground those theoretical considerations? How to obtain it? These questions, though large, serve to introduce a program of research that falls under the name of practical rationality of mathematics teaching (Herbst & Chazan, 2003; Herbst, Nachlieli, & Chazan, in review).

What mathematical work are students doing in the episode above? I’d describe it as listing plausible statements about a figure and considering whether they could be connected through logical necessity. The source of some of those statements is perceptual—e.g. the observation that \( \angle AEB \) is right. But regardless of their origin, statements are being connected through deduction in two directions—what statements would enable one to infer the plausible statement made and what inference could be made taking that plausible statement for granted. The assertion about the relative length of the sides of the rectangle eventually derives from the plausible truth of those earlier statements. Students are thus reducing a question of truth (what could be true about an object) to a question of deducibility from possible statements about an object. They are using proof as a method to find things out.

That mathematical work is valuable from a mathematical perspective as well as from a more general epistemological perspective. Such use of proof as method in knowledge inquiry is essential to the discipline of mathematics (Lakatos, 1976). It is also behind the drive to model mathematically other fields of experience: The expectation that in those fields it will also be possible to reduce the problem of truth to the quest for deducibility, which can then warrant new, still unknown, possible truths is important in pure and applied science (Jahnke, 2007). Insofar as that kind of work could empower students with such way of knowing, I’d argue that participating in problem solving of the kind presented in the scenario above is not only authentic mathematical work to do but also a skill that, if learned, would enable students to contribute to society. It is likely the case, however, that few students encounter such opportunities to learn about proof in school mathematics. The work they do during those years rarely includes chances to acquire the skill or the appreciation of the methodological, model-making function of proof or even experiences doing work that could have had that exchange value.

Given: \( ABCD \) rectangle, 
\[ E \text{ midpoint of } CD, \]
\[ \angle AEB \text{ right angle} \]
Prove: \[ \frac{AB}{BC} = 2 \]

**Figure 2. A more likely proof exercise**

It is more likely that the problem above would be presented to high school geometry students as shown in Figure 2. In particular, while students are responsible to prove propositions in high school geometry, it is normative that the teacher (or the book) will state the givens and conclusion of the propositions they prove. I call that statement a norm of “doing proofs” in the sense that an observer describes teachers and students acting as if they expected this would be the case. The sense to which ‘normative’ means ‘usual’ could be corroborated empirically by observing, over large number of high school geometry classrooms, the recurrence of this feature in proof activity. Yet other techniques would be needed to corroborate that the statement is a norm in the sense that participants act as if they expected such behaviors as appropriate or

correct. I return to this below, after more considerations about how the study of instruction and its rationality can help improve opportunity to learn.

Traditionally the question of what opportunities to learn are created in instruction has been thought of as a question of resources. For example, one might think that the limited nature of students’ encounters with proof result from instruction having insufficient or inadequate resources: unsophisticated curricula, teachers that don’t know enough, etc. Traditional theorizing in education has had instruction playing an instrumental role, feeding from resources and producing student learning; improvement has been conceptualized as improving resource quality. But more recently researchers have realized that resource use in instruction is what makes a difference (Cohen, Raudenbush, and Ball, 2003; Stein, Grover, and Henningsen, 1996). A more fundamental inquiry into the nature and function of instruction itself is therefore warranted. Within that inquiry I am interested in what in how instruction regulates itself.

I started my work from pondering whether the kind of mathematical work described above—the use of proof as a tool to know with—could feasibly be deployed in classrooms. Of course that question includes questions of resource development and my instructional experiments have included developing resources (e.g., Herbst, 2003, 2006). But behind that feasibility question is the fundamental hypothesis that classrooms are complex systems where actions are not merely a projection of the will or capacity of the actors or the richness of their resources. Rather, actions of individual actors contribute to the deployment of a joint activity system whose performance also feeds back, and thus gives shape, to the actions that the participants can take in that system. The question then is not simply how to design materials that enable desirable mathematical work or how to create in teachers the desire to promote that work. The questions also are what is the structure and function of the activity system where that work might be deployed and how this system might accommodate or resist attempts to deploy that work. In particular this requires thinking of mathematics instruction in school classrooms as a system of relationships that are deployed under various conditions and constraints. A conceptualization of this system could enable us to think in a more sophisticated and potentially accurate way about what teacher and students do and thus be able to foresee if given improvement efforts have a prospect of success.

An analogy with how mathematics educators have evolved in their thinking about students’ errors can illuminate this conceptualization of instruction as a system. There used to be a time when student errors were seen as indications of misfit, mishaps, or forgetfulness. Things changed when research on students’ mathematical work started to be treated within a cognitive paradigm. For example Resnick and colleagues’ (1989) study on decimal fractions showed that students’ errors had conceptual basis: Their errors could be explained on the existence of tacit controls such as the “fraction rule” or the “natural number rule”. Students that made errors did so not out of the lack knowledge but out of the possession of some knowledge. Our stance toward students’ errors thus changed from a judgment stance early on to an inquiry stance later on: Rather than judging students as irrational when they make errors, we strive to understand what rationality leads them to make those errors.

I want to propose that we think of the actions of teachers (and students) in the classroom in analogy with how we have come to think about error in students’ mathematical work. The analogy I propose is that we could think of “error” in teaching—really teaching that deviates from what we might deem desirable—not as an indication of misfit, ill will, or lack of knowledge, of the practitioner. Rather, we can think of it as an indication of the possible presence of some knowledge, knowledge of what to do, which is subject to a practical rationality that justifies it. This is a rationality that we should try to understand better before judging teachers or legislating.
their practice. Teachers and students act in classrooms in ways that attest to the existence of specialized knowledge of what to do; knowledge that outsiders of those classrooms are less likely to have even if they know the knowledge domain being taught and learnt. For example teachers and students of geometry would likely see it as strange for Mr. Jones to ask the students for the givens of the problem. I want to focus here on the rationality associated with the role of the teacher and how this might warrant or indict actions like that one.

The teacher of a specific course of mathematics studies, such as high school geometry, is an institutional role to play, not just a name to describe an aspect of an individual’s identity (Buchmann, 1986). There is a person who plays the role, for sure, and that person comes to play the role with personal assets that are likely to matter in what he or she chooses to do. These assets are likely to include mathematical knowledge for teaching and skill at doing some tasks of teaching (Ball, Thames, & Phelps, 2008). These assets make a difference; teachers who have these assets may be able to figure out and do things that others may not be able to do. But while teachers’ causes and motives to do things may have personal grounds, it is unlikely that their actions could always be justified on personal grounds. One could imagine that Mr. Jones in the scenario above was bored with the prospect of giving his students another routine proof exercise or wanted to have a fun day teaching geometry. But we could not really expect him to use any of that as the warrant for doing what he did—his job is not to find activities that amuse him, but rather to teach geometry to his students. How could he justify having done that? The notion of practical rationality points to a container of dispositions that could have currency in a collective, for example within the set of colleagues who teach geometry in similar settings. By dispositions we mean what Bourdieu (1998) describes as the categories of perception and appreciation that would compel agents in a practice to act in specific ways. Dispositions tend to be tacit but they can be articulated to others when justifying to one’s peers (or to other stakeholders) why one might or might not do something like what Mr. Jones did with that proof problem. The high school geometry course and the work of doing proofs, in particular, have been particularly fertile grounds for me to develop theory about instruction and the practical rationality of mathematics teaching. I want to use this context to present some of those theoretical ideas.

A basic notion to describe the role the teacher (and the student) play in classrooms is that of didactical contract (Brousseau, 1997): The hypothesis that student and teacher have some basic roles and responsibilities vis-à-vis a body of knowledge at stake. These responsibilities include the expectation for the teacher to give students work to do which is supposed to create opportunities to learn elements of that body of knowledge, and the expectation for the student to engage in the work assigned, producing work that can be assessed as evidence of having acquired that knowledge. I use the word norm to designate each of those statements that an observer makes in an effort to articulate what regulates practice: Actors act as if they held such statement as a norm, though they may be quite unaware of it. From the perspective of the teacher, the didactical contract authorizes a basic exchange economy of knowledge that he or she has to manage: An exchange between work designed for, assigned to, and completed by students and elements of knowledge, prescribed by the contract, at stake in that work, and hopefully embodied in students’ productions. A fundamental role of the teacher is to manage those exchanges. This management includes, first, enabling and supporting mathematical work; and second, interpreting the proceeds of this work, exchanging it for the knowledge at stake, acting on behalf of the discipline as well as of other stakeholders. Evidently, the hypothesis of a didactical contract only says that a contract exists that has those characteristics; the hypothesis means to describe any mathematics teaching inside an educational institution. But it is also obvious that

---

the teacher and student roles and responsibilities are under-described by that hypothesis: There are many ways in which the didactical contract could be enacted to have at least those characteristics; contracts could be quite different from each other not the least because the mathematics at stake could be very different from course to course and thus require very different forms of work to be learned. Even for the same course of studies, say high school geometry, different contracts could further stipulate the roles and responsibilities of teacher and student differently. In classes that work under a contract for teaching through problems (Lampert, 2001), where students’ work on problems enabled them to come across and use the geometric propositions in the curriculum, students might have a responsibility for recognizing new knowledge. It is not expected that they do so in the usual geometry course, where students only use in problems those propositions that have been previously installed in class.

While some research has endeavored to conceptualize, enact, and study the characteristics of alternative contracts (e.g., Chazan, 2000; Yackel & Cobb, 1996), in my work I have been interested in using a variety of approaches to study the usual high school geometry contract and the practical rationality behind the teachers’ work managing the exchanges enabled by that contract. The reason for that has been the thought that durable change in instruction will need not only to provide new and better resources but also to be able to deal with the inertia and possible reactions from established practice. Knowing how instruction usually works and what rationality underpins its usual operations is key for designing reforms that are viable and sustainable. Furthermore, knowledge of how usual instruction works can encourage piecemeal, incremental changes that don’t throw the proverbial baby with the bathwater.

“Doing proofs” has been a useful starting point in that research agenda. With my research group we have studied “doing proofs” in high school geometry using several approaches: looking at intact geometry classrooms (Herbst, 2002a; Herbst et al., 2009), historical textbooks and documents (Herbst, 2002b; González & Herbst, 2006), geometry lessons that accommodate alternative proving work (Herbst, 2003, 2006), students’ responses to different tasks that might involve proving (Herbst & Brach, 2006) and geometry teachers’ responses to problematic scenarios of geometry instruction (Nachlieli & Herbst, 2009; Weiss, Herbst, & Chen, 2009). The historical analysis has showed how the general skill “how to do proofs” became an object of study in and of itself, leaving behind the important role that proofs played in the construction of specific concepts, theorems, and theories that result from mathematizing a field of experience (Boero, 2007). The work that students do has also evolved. When students “do proofs” what matters is not (anymore) what they can prove given what they avail themselves of but just whether and how well they prove whatever they prove. In exchange for a claim on that knowledge students are to show that they can connect a “given” with a “prove” by making a sequence of statements justified on prior knowledge. I argue that this exchange is facilitated by a specialized set of norms that elaborate how the didactical contract applies.

From observing work in geometry classrooms we have noted that implicit expectations of who is to do what and when vary depending on the specifics of the object of study. In relation to diagrams, for example, the extent to which students can draw objects into a diagram or draw observations from a diagram varies according to whether the work is framed as a construction, an exploration, or a proof. While a contract for a course may have some general norms that differentiate it from a different contract, there is also differentiation in the more specific norms within the course, depending again on what is at stake. Much of those rules are cued in classroom interaction through the use of selected words such as prove, construct, or conjecture. These words frame classroom interaction by summoning special, mutual expectations, or norms,
of who can do what and when. I have used the expression *instructional situation* to refer to each of those frames. Instructional situations are specialized, local versions of the didactical contract that frame particular exchanges of work for knowledge, obviating the need to negotiate how the contract applies for a specific chunk of work. “Doing proofs” is an example of an instructional situation in high school geometry; “solving equations” is an example of an instructional situation in algebra I (Chazan & Lueke, 2009). We contend that these frames for classroom interaction, these instructional situations, are defaults for classroom interaction, tacit knowledge of what to do that the classroom as an organization has (Cook & Brown, 1999), perpetuated through socialization (and with the aid of textbooks and colleagues) that, in particular, provide cues for the teacher on what to do and what to expect the student to do. Instructional situations are social units of analysis; they organize joint action with content. Of course explaining causally their empirical realization (and the chances for deliberate alteration through teacher development) requires some use of psychological constructs to understand precisely how individuals come to recognize that they are indeed in an instructional situation or how they come to perceive alternatives for action in an instructional situation. Our work has not progressed that far. Thus far we have created models of those situations that consist of arrays of norms that describe each situation in terms of who has to do what and when. Those models facilitate research on the content of practical rationality.

Practical rationality is a container whose content includes the categories of perception and appreciation that are viable within the profession of mathematics teaching to warrant (or indict) courses of action. The notion of an instructional situation is the point of departure to study this rationality empirically. We build on the ethnomethodological notions of *breaching experiment* and *repair strategy* (Mehan & Wood, 1975) to propose, as a methodological hypothesis, that if participants of an instructional situation are immersed in an instance of a situation where one of its norms has been breached, they will engage in repair strategies that not only confirm the existence of the norm but also elaborate on the role that the norm plays in the situation. Our technique of data collection relies on representations of breached instances of instructional situations—representations in video or comic strips, using real teachers and students or using cartoon characters. We confront usual participants of such instructional situation with one such breached representation. For example the classroom scenario narrated above is quite close in content to an animated classroom story, “A proof about rectangles,” that we produced in order to study with it the rationality behind the tacit norm that the teacher is in charge of spelling out the givens and the prove. To find out about that rationality we attend to participants’ reactions to the representation: Do they perceive the breach of the norm? Do they accept the situation in spite of the breach? What do they identify as being at risk because of the breach? What opportunities, if any, do they see being created or lost because of the breach? Our aim is not so much to understand the participants themselves as it is to use the participants’ experience with the situation to understand the situation better. In particular we want to understand what elements of the practical rationality of mathematics teaching teachers can see as viable justifications of breaches of situations that would arguably be desirable, say because they might create a more authentic kind of mathematical work. In the case of the story narrated above our question concretely would be on what account could a teacher justify (or indict) an action like the one Mr. Jones took. Clearly, researchers might have some good reasons why what Mr. Jones did is justifiable and I have tried to articulate that from a mathematical perspective above; but in spite of the fact that some of us have had experience teaching we don’t know teaching now in the way

---

practitioners do. By virtue of the role that they play they have to respond to specific obligations that shape their decisions. This leads me to introduce the last element of the theory.

When teachers respond to a breach in an instructional situation, they may reject the situation. For example teachers might say that Mr. Jones is leading students in an exploration rather than a proof. But participants might also accept the situation as “doing proofs” and engage in repairs that rehearse grounds for justifying the breach Mr. Jones made. One set of justifications of it might address the nature of proof in mathematical practice. Participants might also repair by rehearsing grounds for indicting the breach. For example they might note how the time taken in having students state the givens precluded them from doing other proofs that day. In general, we propose that four professional obligations can organize the justifications (or indictments) that participants might give to actions that depart from a situational (or contractual) norm. We call these obligations disciplinary, individual, interpersonal, and institutional (Herbst & Balacheff, 2009; see also Ball, 1993). The disciplinary obligation says that the mathematics teacher is obligated to steward a valid representations of the discipline of mathematics. The individual obligation says that a teacher is obligated to attend to the well being of the individual student. The interpersonal obligation says to all members of the class that they are obligated to share and steward their (physical, discursive) medium of interaction. And the institutional (schooling) obligation says that the teacher is obligated to observe various aspects of the schooling regime including policies, schedules, and such. We contend that those obligations can be present in participants’ justifications or indictments of breaches of norms and that combined with the norms of contracts and situations they span the practical rationality of mathematics teaching. Within that rationality one can see specific contracts (high school geometry, algebra I) and their instructional situations (doing proofs, solving equations) as sociohistorical constructions dependent on elements of practical rationality; more importantly, one can see possibilities for improved practices as subject to similar grounds for justification. Practices that are close to existing instructional situations (as gauged by how many norms of a situation a practice breaches) may be easier to justify than others. The theory also provides the means for the researcher to anticipate how instruction may respond to new practices: A novel task such as “what is something interesting that could be proved about the object in Figure 1” conjures up by resemblance one or more instructional situations (e.g., “doing proofs” and “exploration”) as possible frames for the work to be done. Models of those situations provide the researcher with a baseline of norms that could be breached as the work proceeds. Researchers can then use the obligations to anticipate what kinds of reactions the teacher may perceive in and from practice that feedback and thus shape how they manage the work. This can be useful in examining the potential derailments in the implementation of new practices in classrooms as well as the examination of teachers’ responses to assessment or development interventions. Thus the theory provides not only the basis for the design of probes for the rationality of teaching (Herbst & Miyakawa, 2008) but also a framework for an analysis of the reactions of participants. Combined with finer tools from discourse analysis (e.g., Halliday & Matthiessen, 2004) teachers’ responses to representations of breaching (but arguably valuable) instances of an instructional situation can help us understand not only what justifies teaching as it exists today but also how new practices could be justified in ways that practitioners find compelling. The psychology of mathematics teachers may still be useful to inform what enables and motivates individual teachers to do things, but the logic of action in mathematics teaching addressed by practical rationality may help us understand why some of those actions can be viable and sustainable.

Endnotes

A Critique and Reaction to

PRACTICAL RATIONALITY AS A FRAMEWORK
FOR MATHEMATICS TEACHING

Deborah Moore-Russo
University at Buffalo, State University of New York
dam29@buffalo.edu

Grossman and McDonald (2008) recently argued that the research community needs to move its “attention beyond the cognitive demands of teaching … to an expanded view of teaching that focuses on teaching as a practice (p. 185).” Building on the work of Bourdieu (Bourdieu & Wacquant, 1992; Bourdieu, 1985, 1998), Pat Herbst and colleagues (Herbst & Chazan, 2003, 2006) have written about mathematics teaching as a practice, just as law and medicine are considered practices, in an attempt to better understand the rationality that produces, regulates, and sustains mathematics instruction. This practical rationality is the commonly held system of dispositions or the “feel for the game” (Bourdieu, 1998, p. 25) that influences practitioners as to those actions that are appropriate in the classroom. It is practical rationality that:

...not only enables practices to reproduce themselves over time as the people who are the practitioners change, but also regulates how instances of the practice are produced and what makes them count as instances (Herbst & Chazan, 2003, p. 2).

To better understand the practice of mathematics teaching, whether to communicate or improve it, one must understand the practical rationality that guides it. However, practical rationality often “erases its own tracks” (Herbst & Chazan, 2003, p. 2) so that its practitioners come to view these practices as being natural. Because this rationality provides the regulatory framework that socializes its current and future practitioners into ways of thinking and acting that conform to expectations, it is important to bring to the forefront a deliberate, conscious understanding of the rationality that drives the practice of mathematics teaching.

While practical rationality allows for a certain amount of diversity in its similarity, it is driven by norms. These norms provide the persistent continuity of the practice. Before future teachers ever enroll in education courses, they have ideas about schools in general and mathematics instruction in particular (Ball, 1988). Through an apprenticeship of observation, they develop deep-seated ideas about mathematics and its teaching and learning (Lortie, 1975). These ideas often form the foundation on which they will eventually build their own practice of mathematics teaching (Millsaps, 2000; Skott, 2001).

Herbst has suggested four obligations of teachers that frame instruction and that have the potential to organize a departure from normative practice: disciplinary, individual, interpersonal, and institutional obligations. Of the four, I would like to focus on the disciplinary obligation. What is taken as:

Mathematically normative in a classroom is constrained by the current goals, beliefs, suppositions, and assumptions of the classroom participants. At the same time these goals and largely implicit understandings are themselves influenced by what is legitimized as acceptable mathematical activity (Yackel & Cobb, 1996, p. 460).

This raised an initial series of questions in my mind. First, what is “acceptable mathematical activity” in the words of Yackel and Cobb? Is it the same as “authentic mathematical work” using the words of Herbst? Next, what role does authentic mathematics work\(^1\) play in the practice of mathematics teaching as well as in the practice of mathematics teacher education?

Herbst’s plenary paper encouraged me to ponder if the rationality that often drives the teaching of mathematics (or more specifically the teaching of geometry) overlaps with the rationality associated with doing mathematics. While I confess to having studied neither systematically, the following assumptions and questions are based on my experiences\(^2\) and seem to be supported by the work of Michael Weiss (2009), one of Herbst’s students\(^3\).

Mathematicians, those whose goals are to generate new and refine existing mathematical ideas and methods (Weiss, 2009), are more than just proficient at mathematics. While they demonstrate exactly those qualities and competencies that have been identified by the National Research Council (2001) as goals of mathematics learning (namely conceptual understanding, procedural fluency, strategic competence, adaptive reasoning, and productive disposition), mathematicians also demonstrate a certain mathematical wonder and an appreciation of mathematics that extends past their professional careers into their personal lives. They often tweak problems; at times this is done out of curiosity, other times to make the problem more accessible. To what extent do the activities commonly seen in classrooms nurture authentic mathematical work? Do current norms in mathematics instruction promote either mathematical proficiency or curiosity? Does the rationality that drives mathematics teaching help encourage an appreciation of mathematics?

Herbst has drawn our attention to the practice of geometry instruction. He has provided a scenario and suggestions that should provoke thought as to the norms surrounding the teaching of proof, but what about other key components of geometry courses? For example, definitions play a critical role in geometry. What norms exist for the teaching of definitions in geometry? Are students presented with finalized definitions or are they given opportunities to create, reflect on, and compare definitions (de Villiers, 1998)?

What rationality underpins other aspects of geometry instruction? What is normative in regards to the introduction and use of the diagrammatic register often seen only in geometry classes? What rationality guides teachers’ and students’ expectations in regard to the role of perception in the reading of geometric diagrams? What norms influence the teaching of subtle, yet key, concepts of geometry like existence and uniqueness? Are students given impossible problems\(^4\) as a means to discover existence? Are students allowed to explore situations that demonstrate uniqueness?\(^5\)

While the above questions are particular to geometry, others apply to the many branches of mathematics. Is it normative to encourage students to tweak existing problems or to introduce their own assumptions when solving problems? How often are students encouraged to pose their own problems? Are they taught strategies like Brown and Walters’ (2004) “what-if-not” strategy as a relatively simple means to generate new problems?\(^6\)

Unfortunately, a large number of teachers view mathematics “as a discipline with a priori rules and procedures that … students have to learn by rote” (Handal, 2003, p. 54). For many teachers in the U.S. “knowing” mathematics is taken to mean being efficient and skillful in performing rule-bound procedures and manipulating symbols (Thompson, 1992). As a consequence, mathematics students are “not expected to develop mathematical meanings and they are not expected to use meanings in their thinking” (Thompson, 2008, p. 45).

---

\(^1\) Herbst's plenary paper encouraged me to ponder if the rationality that often drives the teaching of mathematics (or more specifically the teaching of geometry) overlaps with the rationality associated with doing mathematics. While I confess to having studied neither systematically, the following assumptions and questions are based on my experiences and seem to be supported by the work of Michael Weiss (2009), one of Herbst’s students.

\(^2\) Mathematicians, those whose goals are to generate new and refine existing mathematical ideas and methods (Weiss, 2009), are more than just proficient at mathematics. While they demonstrate exactly those qualities and competencies that have been identified by the National Research Council (2001) as goals of mathematics learning (namely conceptual understanding, procedural fluency, strategic competence, adaptive reasoning, and productive disposition), mathematicians also demonstrate a certain mathematical wonder and an appreciation of mathematics that extends past their professional careers into their personal lives. They often tweak problems; at times this is done out of curiosity, other times to make the problem more accessible. To what extent do the activities commonly seen in classrooms nurture authentic mathematical work? Do current norms in mathematics instruction promote either mathematical proficiency or curiosity? Does the rationality that drives mathematics teaching help encourage an appreciation of mathematics?

\(^3\) Herbst has drawn our attention to the practice of geometry instruction. He has provided a scenario and suggestions that should provoke thought as to the norms surrounding the teaching of proof, but what about other key components of geometry courses? For example, definitions play a critical role in geometry. What norms exist for the teaching of definitions in geometry? Are students presented with finalized definitions or are they given opportunities to create, reflect on, and compare definitions (de Villiers, 1998)?

\(^4\) What rationality underpins other aspects of geometry instruction? What is normative in regards to the introduction and use of the diagrammatic register often seen only in geometry classes? What rationality guides teachers’ and students’ expectations in regard to the role of perception in the reading of geometric diagrams? What norms influence the teaching of subtle, yet key, concepts of geometry like existence and uniqueness? Are students given impossible problems as a means to discover existence? Are students allowed to explore situations that demonstrate uniqueness?

\(^5\) While the above questions are particular to geometry, others apply to the many branches of mathematics. Is it normative to encourage students to tweak existing problems or to introduce their own assumptions when solving problems? How often are students encouraged to pose their own problems? Are they taught strategies like Brown and Walters’ (2004) “what-if-not” strategy as a relatively simple means to generate new problems?

\(^6\) Unfortunately, a large number of teachers view mathematics “as a discipline with a priori rules and procedures that … students have to learn by rote” (Handal, 2003, p. 54). For many teachers in the U.S. “knowing” mathematics is taken to mean being efficient and skillful in performing rule-bound procedures and manipulating symbols (Thompson, 1992). As a consequence, mathematics students are “not expected to develop mathematical meanings and they are not expected to use meanings in their thinking” (Thompson, 2008, p. 45).
Herbst has suggested that it is crucial to recognize how instruction typically works, understanding the practical rationality that underpins teaching, if we are to design reforms that are viable and sustainable. He has claimed that through incremental changes that recognize current practice permanent transformation is most likely to occur, but how might incremental changes be introduced? What form might such changes take?

One method that has been shown to have a profound, transformative effect on future teachers’ beliefs about the nature of mathematics and its teaching and learning is through experiences with mathematical discovery (Liljedahl, 2005). Through engagement in authentic mathematical activities, teachers might come to view mathematics differently. If they come to view mathematics differently, the disciplinary obligation that frames their instruction could lead to changes in what they deem valid representations of mathematics.

Undergraduate mathematics courses should not be the only opportunities for future teachers to experience mathematics. Mathematics teacher educators need to realize that they “have the dual responsibility of preparing teachers, both mathematically and pedagogically (Liljedahl, Chernoff, & Zazkis, 2007, p. 239).” Besides providing future and current teachers opportunities to engage in authentic mathematical activities during their mathematics education courses, teacher educators should also provide opportunities for teachers to witness authentic mathematical work in secondary classrooms through episodes of instruction such as written and video cases (much like the scenario of Mr. Jones’ class that Herbst presented). Such experiences would provide teacher educators a first-hand experience of teachers’ reactions to breaches in normative practice. Moreover, such experiences might even transform teachers’ views of the nature of mathematics and its teaching and learning, possibly influencing the rationality that underpins their instruction.

While Herbst made a strong case for the use of practical rationality as a lens for research, I conclude by challenging those of us in mathematics and mathematics education to use this same lens as a means to look introspectively at our practice. What is the rationality that undergirds the way we represent doing and teaching mathematics in our own courses? Do our normative practices include opportunities for authentic mathematical work?

**Endnotes**

1. Here I assume that “authentic mathematical work” would correspond to the work of mathematicians.

2. This experience includes sixteen years of full-time university teaching including nine years in a Department of Mathematics and seven years in a Graduate School of Education.

3. After reading Herbst’s plenary paper, I used my familiarity with his work to pen a draft of my response. To be sure that Herbst’s ideas were accurately represented, I reviewed his work including that of some of his students. I was struck when I first read Weiss’ dissertation at how much my response overlapped with his study. While the final version of this paper has not changed much from the draft, I would encourage anyone who is interested in the issues I have raised to read Weiss’ dissertation, which develops the idea of mathematical sensibility and attempts to answer some of the questions that I have presented.

4. Existence is involved in relatively simple, yet impossible, activities like: Form a triangle with sides of lengths 2 cm, 3 cm and 10 cm. It is also involved in more complicated problems like: Find a circle tangent to two non-equidistant points from the vertex of an angle, such that one point lies on one ray of the angle and the second point lies on the other ray of the angle. This...
second problem is shown as a part of an instructional episode modeled in the ThEMaT (Thought Experiments in Mathematics Teaching) animations found at http://grip.umich.edu/themat.

5. An obvious example of allowing students to consider uniqueness would involve the SSA case of triangles.

6. For example of a what-if-not application, consider how a compass and straightedge are used to construct a perpendicular bisector for a given line segment. Applying the “what-if-not” strategy could lead to the following questions. What if you wanted to construct a bisector that was not perpendicular to the line segment? How could you construct a perpendicular that did not bisect the segment?

Learning progressions (LP) are playing an increasingly important role in mathematics and science education (NRC, 2001, 2007; Smith, Wiser, Anderson, & Krajcik, 2006). They are strongly suggested for use in assessment, standards, and teaching. In this article, I discuss the nature of learning progressions and related concepts, and I illustrate issues in their construction and use. I also highlight the different ways that LP represent learning for teaching.

Definitions and Constructs

According to the National Research Council, “Learning progressions are descriptions of the successively more sophisticated ways of thinking about a topic that can follow one another as children learn about and investigate a topic” (2007, p. 214). A similar description of LP is given by Smith et al. who define a LP “as a sequence of successively more complex ways of thinking about an idea that might reasonably follow one another in a student’s learning” (2006, pp. 5-6). Unlike Piaget's stages, but similar to van Hiele's levels, it is assumed that progress in LP is not "developmentally inevitable" but depends on instruction (Smith et al., 2006, pp. 5-6).

Common Characteristics of the LP Construct

In the research literature, LP possess several commonalities and differences. The characteristics most common to descriptions of LP are as follows:

- LP are based on research syntheses and conceptual analyses” (Smith et al., 2006, p. 1); "Learning progressions should make systematic use of current research on children’s learning " (NRC, 2007, p. 219).
- LP "are anchored on one end by what is known about the concepts and reasoning of students [entering the period covered by the LP]. … At the other end, learning progressions are anchored by societal expectations. … [LP also] propose the intermediate understandings between these anchor points that " (NRC, 2007, p. 220).
- LP focus on how core ideas, conceptual knowledge, and connected procedural knowledge (not just skills) develop. LP organize "conceptual knowledge around core ideas" (NRC, 2007, p. 220).
- LP recognize that not all students will follow one general sequence (NRC, 2007).

Differences in LP Construct

There are several differences in how the LP construct is used in the literature.

- LP differ in the time spans they describe. Some progressions describe the development of students' thinking over a span of years; others describe the progression of thinking through a particular topic or instructional unit.
LP differ in the grain size of their descriptions. Some are appropriate for describing minute-to-minute changes in students' development of thought, while others better describe more global progressions through school curricula.

LP differ in the audience for which they are written. Some LP are written for researchers, some for standards writers, some for assessment developers (formative and summative), and some for teachers.

LP differ in the research foundation on which they are built. Some LP are syntheses of extant research; some synthesize extant research then perform additional research that elaborates the syntheses (the additional research may be cross-sectional or longitudinal).

LP differ in how they describe student learning. Some numerically "measure" student progress, while others describe the nature or categories of students' cognitive structures.

Learning Trajectories (LT)

A construct that is similar to, different from, and importantly related to, LP is that of a "learning trajectory." I define a LT as a detailed description of the sequence of thoughts, ways of reasoning, and strategies that a student employs while involved in learning the topic, including specification of how the student deals with all instructional tasks and social interactions during this sequence. There are two types of LT, hypothetical and actual. Simon (1995) proposed that a "hypothetical learning trajectory is made up of three components: the learning goal that defines the direction, the learning activities, and the hypothetical learning process—a prediction of how the students' thinking and understanding will evolve in the context of the learning activities" (p. 136). In contrast, descriptions of actual learning trajectories can be specified only during and after a student has progressed through such a learning path. Steffe described an actual LT as "a model of [children's] initial concepts and operations, an account of the observable changes in those concepts and operations as a result of the children's interactive mathematical activity in the situations of learning, and an account of the mathematical interactions that were involved in the changes. Such a learning trajectory of children is constructed during and after the experience in intensively interacting with children" (2004, p. 131). Clements and Sarama's (2004) view of LT emphasizes the relationship between levels in the LP and the sequence of tasks in which this progression occurs.

One critical difference between my definitions of LP and LT is that trajectories include descriptions of instruction but that progressions do not. One of the most difficult issues facing researchers who are constructing hypothetical LT for curriculum development is determining how instructional variation affects trajectories. That is, how specific is the trajectory to the instructional sequence that accompanies it? How do trajectories vary with curricula? How similar are trajectories for the same concept within similar and different curricula? If one constructs a prototypical hypothetical LT for a particular topic, how do the actual LT for individual students vary about this prototypical path? One might think of a prototypical trajectory as a "mean" of the actual student pathways, so the "standard deviation" of the distribution of actual trajectories is also relevant.

Purpose: Fixedness versus Reactivity

A major difference between LP and LT arises from the purposes for which they are developed. If one is developing curricula, one is more likely to develop a LT, with a fixed sequence of learning tasks. If, in contrast, one is focusing on formative assessment, one is more likely to develop LP (with associated assessment and instructional tasks), arranged in ways that...
allow the flexibility and reactivity needed in day-to-day and moment-to-moment teaching. Indeed, if one is taking a constructivist approach to teaching, flexibility and reactivity are key. For instance, Simon argues that hypothetical LT should help teachers with (a) "advanced planning and spontaneous decision making," and (b) making instructional decisions based on their "best guess of how learning might proceed" (Simon, 1995, p. 135). I believe, however, that LP can accomplish the same thing for expert users who use their understanding of LP and underlying learning mechanisms to generate local hypothetical LT "on-the-fly." Thus, from the constructivist perspective, hypothetical LT and LP must help teachers understand, plan, and react instructionally, on a moment-to-moment basis, to students' developing reasoning.

**Theoretical Frameworks for Learning Progressions**

LP can also be differentiated by examining their theoretical frameworks. For instance, van Hiele related progress through his levels to his phases of instruction. In contrast, Battista used constructivist constructs such as levels of abstraction to describe students' progress through the van Hiele levels (see also Pegg & Davey, 1998).

*The Nature of Levels*

A critical component of LP is the notion of "levels" of sophistication in student reasoning. Because the concept of level is not straightforward, and because how one defines levels determines how one views (and measures) level attainment, I examine this concept in more detail, using the van Hiele levels as an example. The issues discussed in the van Hiele context are critical because any attempt to develop, assess, and use levels in LP must address these same issues.

*Levels, Stages, and Hierarchies*

Clements and Battista (1992) differentiated researchers' use of the terms *stage* and *level*. A *stage* is a substantive period of time in which a particular type of cognition occurs across a variety of domains (as with Piagetian stages). A *level* is a period of time in which a distinct type of cognition occurs for a specific domain (the size of the domain is an issue).

*Types of Hierarchies*

Hierarchies of levels in LP come in two types. A "weak" hierarchy is a set of levels that are ranked in order of sophistication, one above another, with no class inclusion relationship between the levels. A "strong" hierarchy is a set of levels ranked in order of sophistication, one above another, with class inclusion relationships between the levels; that is, students who are at level $n$ are assumed to have progressed through levels 1, 2, … (n-1). The van Hiele levels were originally hypothesized to form a strong hierarchy (which is generally supported by the research), while Battista's length levels (discussed below) form a weak hierarchy.

*Being "At" a Level*

What, precisely, does it mean to be "at" a level? Battista (2007) argued that students are *at* a van Hiele level when their overall cognitive structures and processing causes them to be disposed to and capable of thinking about a topic in a particular way. So students are "at" van Hiele Level 1 when their overall cognitive organization and processing disposes them to think about geometric shapes in terms of visual wholes; they are at Level 2 when their overall cognitive organization disposes and enables them to think about shapes in terms of their properties. Also
in this view, when students move from familiar content to unfamiliar content, their level of thinking might decrease temporarily; but because students are disposed to operate at the higher level, they look to use that level on the new material, and quickly become capable of using that level (Battista, 2007). However, even if we develop an adequate definition for what it means to be "at" a level, the periods of time when students meet the strict requirement for being at levels may be short, with students spending much time "in transition."

A Different Approach: Vectors and Overlapping Waves.

Some studies indicate that people exhibit behaviors indicative of different van Hiele levels on different subtopics of geometry, or even on different kinds of tasks (Clements & Battista, 2001). So an alternate view of the development of geometric reasoning is that students develop several van Hiele levels simultaneously. Consistent with this view, Gutiérrez et al. (1991) used a vector to indicate the degrees of acquisition of each van Hiele level. Similar to the vector approach, several researchers have posited that different types of reasoning characteristic of the van Hiele levels develop simultaneously at different rates with overlapping waves of acquisition, and that at different periods of development, different types of reasoning are dominant (Clements & Battista, 2001; Lehrer et al., 1998).

Although these alternate models of the van Hiele theory have merit, they both face an important issue—intermingling of type of reasoning from level of reasoning. That is, sometimes the term visual-holistic is used to refer to a type of reasoning that is strictly visual in nature, and sometimes it is used to refer to a period of development of geometric thinking when an individual’s thinking is dominated and characterized by visual-holistic thinking.

Level Determination

Empirical determination of individual students' levels of thinking is a major issue in LP. For instance, consider some of the different ways that researchers have determined van Hiele levels. Gutiérrez and Jaime (1998) defined four mental processes that were used in each van Hiele level then used these processes as indicators of a student’s level of reasoning. In a collaborative effort, Battista, Clements, and Lehrer developed a triad sorting task, that, with variations, was used in separate research efforts (Battista, 2007). Students were presented with three polygons, such as those in Figure 1, and were asked, “Which two are most alike? Why?”

![Figure 1. Triad polygon sorting task.](image)

Lehrer et al. (1998) construed each triad as an indicator of type of reasoning. So students’ use of different types of reasoning on different triads was taken as evidence of jumps in levels. In contrast, Clements and Battista (2001) used a set of 9 triad items as an indicator of student levels. To be classified at a given level, a student had to give at least 5 responses at that level. If a student gave 5 responses at one level and at least 3 at a higher level, the student was considered to be in transition to the next higher level.

Another difference between these researchers’ approaches is that Lehrer et al. (1998) classified student responses solely on the basis of type of reasoning, while Clements and Battista (2001) also accounted for the “quality” of reasoning—each reason for choosing a pair in a triad...
was assessed to see if it correctly discriminated the pair that was chosen from the third item in the triad. The van Hiele levels for students were determined using a complicated algorithm that accounted for both type of reasoning and discrimination score1.

**Cognition Based Assessment (CBA): Levels, Progressions, Trajectories, and Profiles**

I now describe my work on CBA to illustrate the relationship between LP, LT, and levels of sophistication as *representations of learning for teaching*2.

*The CBA View of Learning and Instruction*

According to the "psychological constructivist" view of learning with understanding, the way students construct, interpret, think about, and make sense of mathematical ideas is determined by the elements and organization of the relevant mental structures that the students are currently using to process their mathematical worlds (e.g., Battista, 2004). A major component of psychological constructivist research is its attention to students' construction of meaning for specific mathematical topics. For numerous topics, researchers have found that students' development of conceptualizations and reasoning can be characterized in terms of "levels of sophistication" (Battista, 2001). These levels lie at the heart of the CBA conceptual framework for understanding and building upon students' learning progress. Selecting/creating instructional tasks, adapting instruction to students' needs, and assessing students' learning progress require detailed, cognition-based knowledge of how students construct meanings for the specific mathematical topics targeted by instruction.

**CBA Assessment and Instruction**

To implement mathematics instruction that genuinely and effectively supports students' construction of mathematical meaning and competence, teachers must not only understand cognition-based research on students' learning of particular topics, they must be able to use that knowledge to determine and monitor the development of their own students' reasoning. CBA supports these activities with four critical components.

1. Descriptions of core mathematical ideas and reasoning processes that form the foundation for students' sense making and understanding of elementary school mathematics.
2. For each core idea, research-based descriptions of levels of sophistication (LP) in the development of students' understanding of and reasoning about the idea.
3. For each core idea, coherent sets of assessment tasks that enable teachers to investigate their students' mathematical thinking and precisely locate students' positions in the cognitive terrain for learning that idea.
4. For each core idea, descriptions of instructional activities specifically targeted for students at various levels to help them move to the next higher level.

**Learning Progressions and Trajectories for Length**

The CBA levels of sophistication, or LP, for a topic (a) start with the informal, pre-instructional reasoning typically possessed by students; (b) end with the formal mathematical concepts targeted by instruction; and (c) indicate cognitive plateaus reached by students in moving from (a) to (b). As an example, the table below outlines the CBA LP for length.
### Non-Measurement Reasoning

<table>
<thead>
<tr>
<th>Level</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>N0:</td>
<td>Student Compares Objects’ Lengths in Vague Visual Ways</td>
</tr>
<tr>
<td>N1:</td>
<td>Student Correctly Compares Whole Objects’ Lengths Directly or Indirectly</td>
</tr>
<tr>
<td>N2:</td>
<td>Student Compares Objects’ Lengths by Systematically Manipulating or Matching Their Parts</td>
</tr>
<tr>
<td>N2.1:</td>
<td>Rearranging Parts to Directly Compare Whole Shapes</td>
</tr>
<tr>
<td>N2.2:</td>
<td>One-to-One Matching of Parts</td>

<td>M1.1:</td>
<td>Iterates Non-Length Units (e.g., Squares, Cubes, Dots) and Gets Incorrect Count of Unit-Lengths</td>
</tr>
<tr>
<td>M1.2:</td>
<td>Iterates Unit-Lengths but Gets Incorrect Count</td>
</tr>
<tr>
<td>M2:</td>
<td>Student Correctly Iterates ALL Unit-Lengths One-by-One</td>
</tr>
<tr>
<td>M2.1:</td>
<td>Iterates Non-Length Units (e.g., Squares, Cubes) and Gets Correct Count of Unit-Lengths for Straight Paths</td>
</tr>
<tr>
<td>M2.2:</td>
<td>Iterates Non-Length Units (e.g., Squares, Cubes) To Correctly Count Unit-Lengths for Non-Straight Paths</td>
</tr>
<tr>
<td>M2.3:</td>
<td>Explicitly Iterates Unit-Lengths and Gets Correct Counts for Straight and Non-Straight Paths</td>
</tr>
<tr>
<td>M3:</td>
<td>Student Correctly Operates on Composites of Visible Unit-Lengths</td>
</tr>
<tr>
<td>M4:</td>
<td>Student Correctly and Meaningfully Determines Length Using only Numbers—No Visible Units or Iteration</td>
</tr>
<tr>
<td>M5:</td>
<td>Student Understands and Uses Procedures/Formulas for Perimeter Formulas for Non-Rectangular Shapes</td>
</tr>
</tbody>
</table>

The CBA LP for length is graphically depicted in Figure 2a. Also shown, are an ideal hypothetical LT (solid path) and a typical actual LT for students (dotted path). The CBA LP represents the "cognitive terrain" that students must ascend during an actual LT.

![Figure 2a.](image)

**Figure 2a.**

**CBA Levels of Sophistication Plateaus and LT**

A CBA LP for a topic describes not only cognitive plateaus, but what students can and cannot do, students’ conceptualizations and reasoning, cognitive obstacles that obstruct learning progress, and mental processes needed both for functioning at a level and for progressing to higher levels. The levels are derived from analysis of both the mathematics to be learned and empirical research on students' learning of the topic. The jumps in the ascending plateau...

---

structure of a CBA levels-model represent cognitive restructurings evidenced by observable increases in sophistication in students' reasoning about a topic. A CBA LP indicates jumps in sophistication that are small enough to fall within students "zones of construction." That is, a student should be able to accomplish the jump from conceptualizing and reasoning at Level N to conceptualizing and reasoning at Level N+1 by making a significant abstraction, in a particular context, while working to solve an appropriate problem or set of problems.

Because the levels are compilations of empirical observations of the thinking of many students, and because students' learning backgrounds and mental processing differ, a particular student might not pass through every level for a topic; he or she might skip some levels or pass through them so quickly that the passage is difficult to detect. Even with this variability, however, the levels still describe the plateaus that students achieve in their development of reasoning about a topic. They indicate major landmarks that research has shown students often pass through in "constructive itineraries" or LT for these topics.

Delving Deeper into LP/LT Representations

The LT depicted in Figure 2a are simplifications of actual LT traversed by individual students. To illustrate, I describe one portion of the actual LT of fifth grader, RC, who was having great difficulty with the concept of length (the trajectories of other students were usually much simpler). Figure 2b shows RC's LT for 34 consecutive length items (starting with the white circle, end with the black circle). This actual LT is extremely complex because it contains so much back-and-forth movement between levels.

Figure 3 provides a better representation of this complicated portion of RC's LT. The period shown starts with RC's levels on initial assessment items, moves to his responses during an instructional intervention, and ends with his reasoning on reassessment items.

But even Figure 3 does not adequately portray RC's actual LT in enough detail to be maximally useful for instruction. We need to return to the data to develop a summary characterization of RC's reasoning in terms of the CBA conceptual framework for length. Although space does not permit showing the data, I carefully re-examined the critical period of instructional intervention in which RC made progress (see the three starred items in Figure 3).
Given the data on RC's reasoning, how should we represent his current knowledge structure with respect to length in a way that is most helpful for instruction? Rather than using an actual LT, the CBA approach is to construct a "profile" of RC's reasoning. To see what this profile looks like, the data indicate that on problems like Item 23, in which the "wires" could be stretched using actual inch rods, RC saw empirically that counting unit lengths could predict which was longer. So, for these problems, he adopted the scheme of comparing wires by counting unit lengths in them. At first, he checked his answers by physically straightening a set of inch rods for each wire; but he curtailed this physical check on the last problem. We can conclude that in this context, RC had abstracted a particular reasoning scheme. However, in the different contexts used in the reassessment, where dots and squares were salient, RC did not apply his new scheme (but he also did not apply his original M0 scheme).

So, in future instruction, we need to help RC reconnect to the scheme he abstracted for Item 23. To broaden his scheme to these new contexts, RC needs to iterate inch rods (M2.3) and connect this iteration to straightening paths (N2.1). For instance, in problems in which the lengths of paths appearing on square-inch grids had to be compared, we would encourage RC to use inch rods to check his answers. [Using this type of intervention, many students constructed more generally applicable schemes, overcoming the fixation on the visually salient squares.]

Importantly, the best instruction for RC is determined not by knowing the predominant level number of RC's reasoning, but by using the constructs of the CBA LP to analyze and characterize RC's reasoning. It is this conceptual profile that enables us to appropriately characterize and diagnose RC's reasoning.

**Qualitative versus Quantitative Approaches to Developing LP**

I believe that both qualitative and quantitative methods are equally rigorous and "scientific" for developing LP. Generally, both approaches involve (a) synthesizing, integrating, and extending previous research to develop conceptual models of the development of student reasoning about a topic (hypothesized LP); (b) developing and iteratively testing assessment tasks; (c) conducting several rounds of student interviews in support of steps (a) and (b); and (d) iteratively refining LP levels. In qualitative approaches, the cycle of iteration, testing, and revising eventually "stabilizes" into final levels, as determined by current levels being used to reliably code all data. Quantitative methods compare observed data to statistical model predictions (often with mathematical iteration) to adjust assessment item sets and levels.

**Rash Rush to Rasch? Issues with Quantitative Methods**

There have been numerous recommendations to use quantitative techniques to develop LP (e.g., NRC, 2001), with a hint that using non-quantitative techniques is less "scientific." For example, Stacey and Steinle state that there have been "repeated suggestions made by colleagues over the years, which implied that we had been remiss in not using this Rasch analysis with our data" (2006, p. 89). However, using Rasch and other IRT approaches raises serious issues that are often ignored.

First, Rasch/IRT models are "measurement" models. For instance, Masters and Mislevy state that "The probabilistic partial credit model … enables measures of achievement to be constructed" [italics added] (1991, p. 16). Wilson describes Saltus as an example of "psychometric models suitable for the analysis of data from assessments of cognitive development" (1989, p. 276). However, the whole enterprise of "measuring" in psychological research has been criticized, with less than compelling rebuttals (Michell, 2008).
Second, many of the assumptions of numerical models do not seem to fit our understanding of the process of learning and reasoning in mathematics. For instance, the Saltus model "assumes that each member of group $h$ applies the strategies typical of that level consistently across all items" (Wilson, 1989, p. 278). Or, "The Saltus model assumes that all persons in class $c$ answer all items in a manner consistent with membership in that class…. This means that a child in, say, the concrete operational stage is always in that stage, and answers all items accordingly. The child does not show formal operational development for some items and concrete operational development for others" (Draney & Wilson, 2007, p. 121). But LP levels do not necessarily form a strong hierarchy, making quantitative models problematic:

*When [situations in which students appear to reason systematically] arise, evidence about student understanding can be summarized by [numerical] learning progression level diagnoses, and educators can draw valid inferences about students’ current states of understanding. Unfortunately, inconsistent responding across problem contexts poses challenges to locating students at a single learning progression level and makes it unclear how to interpret students’ diagnostic scores. For example, how should one interpret a score of 2.6? A student with this score could be reasoning with a mixture of ideas from levels 2 and 3, but the student could also be reasoning with a mixture of ideas from levels 1, 2, 3, and 4 (Steedle & Shavelson, 2009, p. 704).*

Thus, use of Rasch-like models to examine cognitive development, such as Wilson's Saltus model or latent class analysis, assumes that students are "at a level," which returns us to the problem discussed earlier about a student being at a level. Research on learning suggests that quite often, the state of student learning is not neatly characterized as "being at a specified level," which causes problems for interpretation of model results: "Students cannot always be located at a single level … Consequently, learning progression level diagnoses resulting from item response patterns cannot always be interpreted validly" (Steedle & Shavelson, 2009, p. 713).

Third, Rasch/IRT models are based on measures of "item difficulty," which might not capture critical aspects of the nature of student reasoning, as Stacey and Steinle argue:

*Being correct on an item for the wrong reason characterises DCT2 [their decimal knowledge assessment]. It is one of the reasons why the DCT2 data do not fit the Rasch model, because these items break with the normal assumption that correctness on an item indicates an advance in knowledge (or ability) that will not be ‘lost’ as the student further advances. … A student’s total score on this test might increase or decrease depending on the particular misconception and the mix of items in the test. This does not fit the property of Rasch scaling … that ‘the number right score contains all the information regarding an examinee’s proficiency level, that is, two examinees who have the same number correct score have the same proficiency level’ … Neither the total score … nor Rasch measurement estimates provides a felicitous summary of student performance (2006, pp. 87-88).*

Indeed, Stacey and Steinle further state that, "Conceptual learning may not always be able to be measured on a scale, which is an essential feature of the Rasch approach. Instead, students move between categories of interpretations, which do not necessarily provide more correct answers even when they are based on an improved understanding of fundamental principles" (2006, p. 77). They concluded that there is nothing to gain in applying the Rasch approach to...
their study and many others. "Learning as revealed by answers to test items is not always of the type that is best regarded as 'measurable', but instead learning may be better mapped across a landscape of conceptions and misconceptions" (2006, p. 89)\(^3\). Even more, how to place rote performance on items becomes extremely problematic in such models. For instance, in Noelting's hierarchy for proportional reasoning, in the formal operational stage the "child learns to deal formally with fractions, ratios, and percentages" (Draney & Wilson, 123). But using a formal procedure rote is not a valid indication of formal operational reasoning.

**Methods for Collecting Data on Students' Levels in Learning Progressions**

The most accurate way to determine students' levels in LP (once the framework has been developed) is administering individual interviews, which are then coded by experts, using the LP levels framework. Many teachers can learn to make such determinations, both with individual interviews and during class discussions. However, the difficulty with this approach is that it is time consuming. Another way to gather such data is using open-ended questions. Again, students' written responses must be coded, and many students do not write enough—far less than they say in interviews—for proper coding.

An alternate, less time-consuming, way to gather data is through multiple choice items that have distracters that are generated from interviews and that correspond to specific levels (Briggs et al., 2006, have labeled this format "Ordered Multiple-Choice [OMC]"). CBA has also experimented with having students orally describe their reasoning to a teacher or a classroom volunteer, who then chooses an option on a multiple-choice-like coding sheet. However, beyond convenience, there are several issues that one must consider when using these alternate formats. For instance, how accurate are Open-Ended and OMC tasks in revealing students' thinking (e.g., Alonzo & Steedle, 2008; Briggs & Alonzo, 2009; Steedle & Shavelson, 2009)\(^4\)? For example, students may not recognize which OMC choice matches the strategy they used to solve a problem even when a researcher-generated description of their strategy is one of the choices.

When assessments are used summatively, taking a numerical approach can be both practical and useful. However, to use numerical data for instructional guidance, teachers must consult the theoretical model on learning that underlies the levels framework.

**Summary**

When using quantitative methods to develop levels in LP, the validity and usefulness of interpretations of results depends on (a) the adequacy of the underlying conceptual model of learning, (b) the fit between the statistical model (including its assumptions) and the conceptual model of learning, and (c) the fit between the data and the statistical model's predictions. Unfortunately, use of quantitative methods often ignores (b). For example, adopting the Saltus model might cause one to neglect explicit consideration of the critical issue of what it means to be at a level. Also, although many users of quantitative approaches argue that implementing such approaches enables them to test their models, too often, these tests are restricted to factor (c). Researchers in mathematics education need to resist external pressures to apply quantitative techniques without deeply questioning their validity, because such adoptions result in the techniques being applied in ways that we would call in other contexts instrumental or rote procedural. Instead, researchers must investigate much more carefully the conceptual foundations of these techniques, reconciling them with our research on learning (a daunting task, given the statistical/mathematical complexity underlying the procedures)\(^5\).

---

Endnotes

1. Quantitative methods for determining levels face many of the same issues as qualitative methods. For instance, with Saltus there can be many students who cannot be clearly placed at a level (e.g., Draney & Wilson, 2007).

2. Much of the work described in this paper was supported by the National Science Foundation under Grant Nos. ESI 0099047 and 0352898, DRL 0554470 and 0838137. Opinions, findings, conclusions, or recommendations, however, are those of the author and do not necessarily reflect the views of the National Science Foundation.

3. Proponents of Rasch-like methods might argue that the PCM model is more appropriate in the Stacey and Steinle study. Debate on this issue should carefully examine the match between the model's assumptions and the learning theory it proposes to model.

4. Also at issue is whether Rasch techniques appropriately model OMC tasks (Briggs & Alonzo, 2009).

5. Also at issue is whether Rasch techniques appropriately model OMC tasks (Briggs & Alonzo, 2009). One way to investigate the conceptual foundations of the approaches is to apply both to the same sets of data.

A Critique and Reaction to

REPRESENTATIONS OF LEARNING FOR TEACHING: LEARNING PROGRESSIONS, LEARNING TRAJECTORIES, AND LEVELS OF SOPHISTICATION

OPTIMIZING RESEARCH ON LEARNING TRAJECTORIES

Susan B. Empson
The University of Texas at Austin
empson@mail.utexas.edu

As I was thinking about my response to Michael Battista’s informative overview of learning trajectories (this volume), I wondered what it was about learning trajectories that was new and helpful. After all, have we not been involved in studying learning since the inception of our field? I thought about Piaget and his colleagues and their careful analyses of the development of children’s domain-specific thinking (Piaget et al., 1960, for example). I thought about chains of inquiry that had stretched over decades. There was Glenadine Gibbs’s (1956) study of students’ thinking about subtraction word problems, which helped to pave the way for later researchers such as Carpenter and Moser (1984) to create frameworks portraying the development of children’s thinking about addition and subtraction; and Les Steffe’s and John Olive’s recent (2010) book on Children’s Fractional Knowledge, which detailed the evolution of children’s conceptual schemes for operating on fractions. I even thought about Robert Gagné (1962), whose task analyses represented a topic as a hierarchy of discrete tasks learnable through stimulus-response associations. It seemed that the idea of learning trajectories was not new at all.

Yet the term has only recently become popular in research on thinking and learning and is regarded as a new construct. It seems to be making an impact. There have been special journal issues (Clements & Sarama, 2004; Duncan & Hmelo-Silver, 2009) devoted to learning trajectories in mathematics and science and it, or its cousin learning progressions, has shown up in prominent policy documents, such as the recently released Common Core Standards in Mathematics (CCSM) (2010), whose authors asserted that the “Development of these Standards began with research-based learning progressions detailing what is known today about how students’ mathematical knowledge, skill, and understanding develop over time” (p. 4). Researchers, curriculum designers, and standards writers are turning their attention to learning trajectories as a way to bring coherence to how we think about learning and the curriculum.

As I continued to think about Battista’s paper, I was drawn to reread Marty Simon’s influential 1995 paper on Hypothetical Learning Trajectories. It was the first instance I could recall of the use of the term learning trajectory in mathematics education. The most important things I noticed were that a) a learning trajectory did not exist for Simon in the absence of an agent and a purpose and b) the term was introduced in the context of a theory about teaching. A hypothetical learning trajectory is a teaching construct – something a teacher conjectures as a way to make sense of where students are and where the teacher might take them. In Simon’s framework, teachers are agents who hypothesize learning trajectories for the purposes of planning tasks that connect students’ current thinking activity with possible future thinking.
activity. A teacher might ask, “What does this student understand? What could this student learn next and how could they learn it?” and create a hypothetical learning trajectory as a way to prospectively grapple with these questions.

This musing led me to think more critically about what learning trajectories were and what their potential for us as researchers and educators could be. They are complex constructions that include, according to Clements and Sarama (2004), “the simultaneous consideration of mathematics goals, models of children’s thinking, teachers’ and researchers’ models of children’s thinking, sequences of instructional tasks, and the interaction of these at a detailed level of analysis of processes” (p. 87). Yet, because the term is almost faddish in its popularity, the idea is frequently simplified as “a sequence of successively more complex ways of thinking about an idea” (Smith et al., 2006, cited in Battista).

Spurred by reading Battista’s paper, then, I pose three talking points for us to consider as we continue to conduct research on learning trajectories:

1) Learning trajectories do not exist independently of tasks and learners’ interactions around tasks. And especially, they do not exist independently of teaching.
2) Learning trajectories tend to focus on content and leave out disciplinary practices.
3) Learning trajectories need to be useful for teachers and teaching to survive and flourish in the ecology of the classroom.

Learning Trajectories Do Not Exist Independently of Tasks and Teaching

I’ve noticed that when we talk about learning trajectories, it’s easy to forget that they exist only in relationship to other education constructs. For example, Battista reminded us, the National Research Council (2007) described learning progressions as “successively more sophisticated ways of thinking about a topic that can follow one another as children learn about and investigate a topic” (p. 214). This characterization ignores the significance of tasks and teaching to the development of students’ thinking and implies that students’ thinking unfolds following a natural, singular path.

Many researchers point to the fact that how students think about a topic depends upon the types of tasks in which they have been asked to engage. Take fractions, a topic that teachers often find difficult to teach. Many typical misconceptions could be avoided if teachers used tasks that supported reasoning about fraction relationships, instead of using all-too-common tasks that reduce children’s fraction reasoning to counting parts. For example, Equal Sharing problems create the need for students to partition units that they have previously conceptualized as “one” (Empson & Levi, in press; Streefland, 1991). Measurement problems create the need for students to iterate subunits of measure (of their own creation) to account for measures that are between whole-number measures (Brousseau, Brousseau, & Warfield, 2004; Davydov & Tsvetkovich, 1991). Simon and Tzur (2004) underscored the necessary relationship between tasks and student thinking in learning trajectories when they said, “the selection of learning tasks and the hypotheses about the process of student learning are interdependent” (p. 93).

Beyond tasks, students’ mathematical thinking and its development also interacts with teaching. This fact may be more difficult to take into account in learning trajectories. Design experiments are one solution to this problem. They allow researchers to see the possible interactions between teaching and learning under conditions that are conducive to optimizing student learning. Often the teachers are researchers themselves. But then there is the question of how student learning and its interaction with teaching are represented. The easiest and most common solution is to represent the development of students’ thinking as snapshots at different

levels, developmentally arranged. The teaching is essentially not represented; it is treated as a condition to produce student learning but not represented as integral to student development. More complex solutions would include representing teaching in terms of mechanisms of learning or its relationship to significant changes in students’ thinking.

Battista noted that “One of the most difficult issues facing researchers … is determining how instructional variation affects trajectories.” This variation is a product of tasks, as many researchers recognize, and to a profound extent, teaching. What would it mean for researchers to not only be cognizant of the possible interaction of teaching with trajectories of learning but to incorporate it in a meaningful way?

Learning Trajectories Tend to Focus on Content Over Disciplinary Practices

Usually, when we talk about what we want students to learn in mathematics it involves a complex and integrated set of content understanding and disciplinary practices (e.g., Kilpatrick, Swafford, and Findell, 2001; National Council of Teachers of Mathematics, 2000). Not only do we want students to understand the major concepts of a given domain, we also want them to be able to solve problems, construct models, and make arguments. One of the ways that researchers have made the study of mathematics learning more tractable is by focusing narrowly, such as on conceptual development in a specific content domain. Steffe and Olive’s (2010) research on the development of fraction concepts and Battista’s research on children’s understanding of measurement are examples of such an approach. This work, like a great deal of the research in mathematics education including my own, is informed by a Piagetian-like view of learning, if not in its emphasis on levels, then certainly in its emphasis on a conceptual trajectory, in which less sophisticated concepts give way to more sophisticated concepts. We have learned a lot about children’s learning in this way.

However, only part of what we value as a field about mathematics is represented in this kind of trajectory. Research on students’ mathematical argumentation and modeling (Lehrer & Schauble, 2007; Lesh & Doerr, 2003), for example, highlights some of the practices that are just as critical to a well developed capacity to think mathematically but are less amenable to analysis in terms of sequences of development. One difficulty for researchers may be that students engaged in these practices draw on multiple content domains. Another may be that these practices, ideally, involve several students engaged in a complex task that has many possible resolutions (e.g., Stroup, Ares, & Hurford, 2005).

Our challenge as a field is to integrate research on learning the content and practices of mathematics, in order to better understand learning and to better inform teaching and the design of curriculum. When the CCSM first appeared, I was pleased to see a focus on mathematical practices, which included standards such as “make sense of problems and persevere in solving them,” “construct viable arguments and critique the reasoning of others,” and “model with mathematics” (pp. 6-7). But in the body of the document, these practices were just listed in a box at each grade level, isolated from the content standards, which were elaborated in detail (e.g., see pp. 10 & 53). There are no guidelines in the CCSM for integrating the learning of mathematics content and practices and the risk is that, in practice, educators will focus on content standards with a quick nod to the practice standards.

Some researchers have cautioned that representations of learning as progressive sequences of content understanding could lead teachers to funnel students through the sequences at the expense of allowing students to “express, test, and revise their own ways of thinking” (Lesh & Yoon, 2004, p. 206; see also Sikorski & Hammer, 2010). A focus on integrating mathematical
content and practices in our representations of learning may lead us away from the notion of a trajectory, in the sense of a sequenced development or pathway.

**Learning Trajectories Need to Be Useful for Teachers and Teaching**

I agree whole heartedly with Battista when he writes that one purpose of learning trajectories is to help teachers “understand, plan, and react instructionally, on a moment-to-moment basis, to students’ developing reasoning.” I believe that a critical part of our mission as researchers is to produce something that is of use to the field and serves as a resource for teachers and curriculum designers to optimize student learning. But what makes a learning trajectory useful?

We may find some guidance for answering this question in emerging research on teacher noticing (Sherin, Jacobs, & Philipp, in press). Useful representations of learning trajectories would draw teachers’ attention to specific aspects of students’ mathematical thinking activity, such as solving problems or making arguments, and help teachers to interpret them and respond to them instructionally. What is a reasonable unit of students’ mathematical activity for teachers to notice? If a unit is too small or requires a great deal of inference (e.g., a mental operation), then teachers in their moment-to-moment decision-making may not be able to detect it and respond to it; likewise if a unit is too broad, or stretches over too long a period of time (e.g., “abstract thinking”). The most productive kinds of units of mathematical activity would allow teachers to see, or notice, clearly defined instances of student’s thinking during instruction and to gather information about students’ progress relative to instructional goals. For example, in research in elementary arithmetic, strategies and types of reasoning are productive units because we know that teachers can learn to differentiate students’ strategies and use what they learn about students’ thinking to successfully guide instruction (e.g., Fennema, et al., 1996). Battista’s work on creating assessment for teachers to use that are informed by research on learning trajectories appears to be another promising route.

**Conclusion**

The idea that students progress in some way as a result of instruction is at the very heart of the enterprise of mathematics education in which we are engaged. Research on learning trajectories has the potential to move the field forward. Yet the notion of learning trajectories is not a panacea to the many difficulties that we face in educational research and practice. In this paper I have raised some issues and posed some challenges.

Learning trajectories are essentially provisional. We can think of them as the provisional creation of teachers who are deliberating about how to support students’ learning and we can think of them as the provisional creation of researchers attempting to understand students’ learning and to represent it in a way that is useful for teachers.

I urge researchers to continue to create, test, and refine empirically based representations of students’ learning for teachers to use in professional decision-making and, further, to investigate ways to support teachers’ decision-making without stripping teachers of the agency needed to hypothesize learning trajectories for individual children as they teach. This focus would add new layers of complexity to our research on learning. Instead of researching children’s learning alone, we would be researching how teachers incorporate knowledge of children’s learning into their purposeful decision-making to support children’s learning in classrooms. I do not know if research on learning trajectories can or should be optimized. But I do know that it is worth thinking hard about what learning trajectories are and how they can be used by teachers and in teaching to optimize the development of students’ capacities to think mathematically.

COLLEGE STUDENTS’ REFLECTIVE ACTIVITY IN ADVANCED MATHEMATICS

Kyeong Hah Roh
Arizona State University
khroh@math.asu.edu

This study explores how an instructional intervention, called the ε-strip activity, would help students understand the meaning of the convergence of sequences in advanced mathematics. The subjects of this study were undergraduate mathematics students in a real analysis class. Dewey’s theory of reflective thinking was used as a theoretical framework to characterize students’ activity in the class. Results show that the students initially felt perplexed and confused due to uncertainty about the meaning of convergence. However, the students developed their conception of convergence compatible with the ε-N definition as they engaged to the ε-strip activity. The students continued reflecting on the ε-strip activity when they worked on subsequent problems related to the convergence of sequences.

Introduction

The ε-N definition of the convergence of sequences is fundamental in studying advanced mathematics, such as advanced calculus and real analysis; however, many students experience difficulty understanding it. Research related to students’ conceptions of limit and convergence has been well developed by mathematics education researchers (e.g., Cornu, 1991; Williams, 1991). Students’ difficulties with the ε-N definition are, on one hand, influenced by their images of limit, which is not compatible with the ε-N definition (Davis & Vinner, 1986; Roh, 2008); on the other hand, these difficulties are related to their confusion over multiple quantifiers in the ε-N definition (Duran-Guerrier & Arsac, 2005; Roh, 2010).

An aim of this paper is to explore how an instructional intervention would help students understand the limit of a sequence. This study suggests the ε-strip activity as the instructional intervention and examines how students induce an image of limit that is compatible with the ε-N definition of convergence. This study also explores how the ε-strip activity promotes the students’ reflective thinking in the case of the limit of a sequence.

Theoretical Framework

In this study, Dewey’s theory of reflective thinking is used to analyze students’ activities in understanding the limit of a sequence. According to Dewey (1933), reflective thinking consists of (1) the pre-reflective situation, “a perplexed, troubled, or confused situation” (p. 106); (2) the reflective situation, “an act of searching, hunting, inquiring” (p. 12) as an effort to resolve the perplexity; and (3) the post-reflective situation, “a cleared-up, unified, resolved situation” (p. 106). This study relates these three situations of reflective thinking to the development of student understanding by (1) experiences of perplexed feeling or confusion, (2) reasoning and (mental) actions to figure out the problem, and (3) experiences of mastery and enjoyment, respectively. A powerful instructional intervention for students’ reflective activity should create a situation that gives rise to intellectual problems, fosters mathematical reasoning to figure out the problem, and represents fundamental underlying ideas in the context. This paper aims to illuminate how the ε-strip activity plays a role, as an instructional intervention, in promoting students’ reflective thinking in the case of the limit of a sequence.
Research Methodology

This study was conducted as part of a larger study from a semester-long design experiment (Cobb et al., 2003) at a southwestern public university in the USA. The author of this paper, as the instructor of the course, conducted a series of teaching sessions with 22 students in a real analysis course. The students were mathematics students or preservice/inservice secondary mathematics teachers, and they had already completed calculus and a transition-to-proof course. During the entire semester, the class worked in small groups, each of which consisted of 4 to 5 students.

In the days of this study, the students in groups first determined the convergence of a sequence by exploring the existence of limits of sequences via their own conceptions of limit. The sequences that the instructor suggested to the class included monotone, constant, and oscillating sequences. The students then examined whether or not their conception of convergence could be regarded as proper to determine the limit of a sequence.

Second, the $\varepsilon$-strips were then introduced to the class as follows: “The $\varepsilon$-strips are made of translucent paper of a rectangular shape. You may imagine each $\varepsilon$-strip as a strip with indefinite length and constant width. The center of each $\varepsilon$-strip is marked with a red line, and half of the width of an $\varepsilon$-strip is called ‘$\varepsilon$’.” The students were then asked to put $\varepsilon$-strips of different widths on the same graph of a sequence to cover a possible limit value of the sequence. They were also asked to determine how many points on the graph of the sequence are outside/inside each $\varepsilon$-strip. After providing enough opportunities to work with the graphs of the sequences and the $\varepsilon$-strips, the instructor introduced two statements (called $\varepsilon$-strip definitions A and B) to students as follows: “($\varepsilon$-strip definition A) A certain value $L$ is a limit of a sequence when for any $\varepsilon$-strip centered at $L$, infinitely many points on the graph of the sequence are inside the $\varepsilon$-strip; ($\varepsilon$-strip definition B) A certain value $L$ is a limit of a sequence when for any $\varepsilon$-strip centered at $L$, only finitely many points on the graph of the sequence are outside the $\varepsilon$-strip.” Afterwards, the students applied $\varepsilon$-strip definitions to particular sequences and evaluated whether or not the $\varepsilon$-strip definitions gave the correct answers to the sequences.

Third, the instructor induced the $\varepsilon$-$N$ definition from $\varepsilon$-strip definition B. Also, the instructor asked the class to evaluate $\varepsilon$-strip definitions A and B, to compare $\varepsilon$-strip definition B with the $\varepsilon$-$N$ definition; and to construct proofs of properties about convergence, for instance, “the sequence $\{1/n\}_{n=1}^\infty$ does not converge to 1/10,” and ”every convergent sequence is a Cauchy sequence.”

Results

Pre-Reflective Situation: Students Feel Frustrated, Perplexed, and Confused

Although the students took calculus and learned the limit of a sequence in their previous calculus classes, most of them did not seem to feel confident on the topic.

Steve: Oh, Jesus! I haven’t seen these [sequences] since I was a senior [in high school].
Sean: I hated sequences.
Stan: I like them…Aah, heck yea. Tell us about thing, geometric [series].
Susie: I don’t even really remember being that far. [Laughs]

As shown above, the students also felt perplexed and frustrated in talking about the notion of sequences, which is a characteristic of the pre-reflective situation.
Reflective Situation: Suggestion and Intellectualization

The students then suggested some ideas about the meaning of convergence to each other, seeking a proper justification to their claim. Some of their initial suggestions for the convergence of sequences were not accepted by other students. For instance, Sean asked to his group if a sequence should decrease or increase toward a value in order for it to be convergent. This idea was declined by Steve, who suggested a counterexample of a sequence that does not decrease but oscillates and converges to 0. However, Steve’s idea was not accepted by Susie because, according to her conception of convergence, an oscillating sequence does not have a limit and Steve’s example was an oscillating sequence. At this moment, none of the students in the group agreed upon the meaning of oscillating sequences. Steve seemed to agree with Susie; however, he believed his sequence is not oscillating because his sequence is not a sine or cosine function. Sean was then against Steve’s conception of oscillating sequences and believed that Steve’s sequence was in fact “a version of sine or cosine” function.

Sean: Doesn’t it, for it to converge, wouldn’t it have to— every succeeding— every succeeding point have to be either decreasing or increasing towards a value?
Steve: No, you can have something like this. Or like, if you have a grid, if you have a graph that goes like this [drawing a graph of an oscillating convergent sequence] and it goes back and forth across as it \(n\) goes infinity. And that [sequence] converges to 0.
Susie: I thought that [the limit of Steve’s sequence] didn’t exist because it is now oscillating.
Stan: No, that’s alternating series.
Steve: No, an oscillating would be like sine or cosine.
Sean: But that’s a version of a sine or cosine. That’s oscillating.

On the other hand, when Stan examined the convergence of the sequence \(\left\{(-1)^n / n\right\}_{n=1}^{\infty}\), he in fact thought of a p-series \(\sum_{n=1}^{\infty} (1 / n)^p\) with \(p=1\), and hence he believed it to be divergent. However, at the same time, he also believed that the sequence would have a limit. Then he got frustrated by the fact that the sequence is divergent but has a limit.

Stan: So that’s, it would be like something like \(a_n = (-1)^n / n\). Well, I think that converges. You could, you could… No, it doesn’t though, does it? Because it’s not a p-serie...
Sean: I don’t remember what the definition of it [p-series] is.
Stan: I can’t remember. Well, p-series is where your variable and numerator, umm, denominator, when the exponent [of the denominator] is greater than, or greater than 1, strictly greater than 1, then it converges. But this is \(1/n\), so I don’t know if that converges. Umm …. I don’t think it comes fast enough, but it still has a limit though. So it doesn't converge. Convergence and diverging is different than a limit, huh?

As shown above, the students were unable to properly account for the meaning of the convergence of sequences. From this moment, the students’ own conceptions of convergent
sequences became a true intellectual problem to them, which is another characteristic of the reflective situation.

Reflective Situation: Students Continue Conjecturing, Reasoning, and Testing the Ideas

After the students realized that their conceptions of the convergence of sequences were inaccurate to account for the convergence and the limit of a sequence, the instructor suggested $\varepsilon$-strip definitions A and B. The students then discussed whether $\varepsilon$-strip definitions would properly describe the notion of convergence. Their first conjecture was that only $\varepsilon$-strip definition A would be proper for a description of the limit of a sequence. It should be noted that the students instantly accepted $\varepsilon$-strip definition A without seeking for a justification. On the other hand, it took a while for the students to understand the meaning of $\varepsilon$-strip definition B. In fact, the students seemed not to recognize that the convergence of a sequence is equivalent to the finiteness of the number of terms outside any given error bound. Instead, they seemed to think that an infinite number of points clustered around a point would be essential for the convergence. When Sean pointed out that $\varepsilon$-strip definition B does not describe the points inside $\varepsilon$-strips, Steve and Susie rejected $\varepsilon$-strip definition B for a proper description of the limit of a sequence.

Sean: I think A, I like A so far. I’m gonna get to B.
Group: [silence]
Stan: So they [B]’re saying that the when…
Sean: So the points that aren’t covered are finite.
Susie: Yeah.
Stan: The points that aren’t covered are finite.
Sean: But it [B] doesn’t say anything about the points covered being infinite.
Susie: Yeah, that’s true.
Steve: It [B] doesn’t say anything about the points covered being infinite. So that would incorrectly describe a limit.
Susie: Right.

Now the students tested their conjecture, which is another characteristic of the reflective situation. In particular, Sean suggested that his group should look for some examples of sequences and check the number of points inside and outside the $\varepsilon$-strips. The sequence he chose first was a sequence whose odd terms were defined as 1 and even terms were defined in the form of $1/n$. The students then observed that for some $\varepsilon$-strip, when it was centered at $y=1$, infinitely many points of the sequence are inside the $\varepsilon$-strip. Therefore, accepting $\varepsilon$-strip definition A would force them to determine 1 as a limit of the sequence, which contradicted their belief of the divergence of the sequence.

Sean: […] Let’s look for examples. We have the graphs, we have two…Where’s those—where’s those graphs at? [Choosing the sequence $a_n = 1$ when $n$ is odd; and $a_n = 1/n$ when $n$ is even; then placing an $\varepsilon$-strip on $y=1$ so that all points on the x-axis are outside the $\varepsilon$-strip] So if we could cover finite or infinite ….can we?
Susie: But that one [the sequence] doesn’t have a limit to begin with.
Sean: Well, I know, that’s what I’m trying to say. I’m trying—, I’m saying we’re setting an $\varepsilon$-strip here [$y=1$], and we’re covering an infinite amount.
Susie: Right.
Sean: [pointing to the dots on y=0] And we’re not covering in it, an infinite amount too. So, but it doesn’t have a limit—I don’t know.

Stan: Well…

Steve: Hmm….

Group: [silence]

After realizing that ε-strip definition A would not work for the sequence, the students seemed to deliberate making a change in their conjecture. Sean proposed ε-strip definition B to be a better description for the convergence, whereas Susie suggested combining ε-strip definition A with ε-strip definition B. Since accepting the combination of ε-strip definitions A and B would force them to describe both points inside and outside the ε-strip, the students seemed to consider Susie’s idea more informative than Sean’s idea. Consequently, they followed Susie’s idea at this moment.

Sean: B is better.

Group: [silence]

Susie: Maybe it’s a combination of both.

Sean: Yeah.

Susie: The number of points in the strip has to be infinite, and the number of points not covered by the strips has to be finite.

Steve: Isn’t that what A was saying?

Sean: No.

Susie: No.

Sean: They only talk about only one or the other, so we can combine them. Let’s go with that. That’s right. That’s a right thing for now.

Susie: Okay.

Although the group seemed to be satisfied with combining ε-strip definitions A and B for a description of the convergence, Sean wondered why ε-strip definition B itself would not be proper for a description of the convergence.

Group: [silence]

Sean: So, I haven’t thought of any argument against why B can’t just be.

The instructor moved to the whole class discussion by collecting students’ conjectures on the ε-strip definitions. This group insisted on combining ε-strip definitions A and B, whereas another group said ε-strip definition B itself would be enough for a proper description of the convergence. The instructor then asked if ε-strip definition A would imply ε-strip definition B, or vice versa. The class tested the implications by putting particular ε-strips on various sequences as well as by imagining the compliment of an infinite set. The students then realized that ε-strip definition B would imply ε-strip definition A, but its converse would not always be true. From that moment, the class agreed that ε-strip definition B itself would be proper for a description of the convergence of sequences.
Post-Reflective Situation: Students Experience Their Confusion Cleared Up and Resolved

Once the students accepted $\varepsilon$-strip definition B as a proper description for the convergence of sequences, they developed their conception of convergence compatible with the $\varepsilon$-$N$ definition. Moreover, the students continued reflecting on the $\varepsilon$-strip activity whenever they worked on subsequent problems related to convergence of sequences. For instance, when the instructor asked them to discuss how they could tell the sequence $\{1/n\}_{n=1}^{\infty}$ does not converge to 1/10, the students attempted to show it via $\varepsilon$-strips. To be more precise, Susie aligned an $\varepsilon$-strip on $y=1/10$ and pointed out that only a finite number of points were inside the $\varepsilon$-strip. Since the rest of the points would then be outside the $\varepsilon$-strip, there should be infinitely many points outside the $\varepsilon$-strip. Sean agreed with Susie, but pointed out the necessity of specifying “what your $\varepsilon$ is” in order to show that infinitely many points would be outside. Steve then suggested 0.05 as an appropriate value for such an $\varepsilon$.

Susie: …Well, okay. So this is saying that $L$ shouldn’t be 1/10. If we say let $L = 1/10$, it has a finite number of points [inside the $\varepsilon$-strip].

Sean: But then we have to discuss what your $\varepsilon$ is gonna be first, because you can have $\varepsilon$ equals this [using two fingers to illustrate an $\varepsilon$-strip, a wider one than Susie’s $\varepsilon$-strip, that would cover the x-axis], that would cover it [0].

Susie: Oh, right!

Sean: That’s why I was saying we need to find $\varepsilon$ that’s less, so that we can [Susie: I see.] include the finite portion and exclude the infinite portion.

Sean (or Steve?): So we’ll let, first let $L$ equal .1 and $\varepsilon$ has to be <.1. We could just declare it first, ... Should we talk about it for all values of $\varepsilon$ is [less than] .1 or just $\varepsilon$ being .05? ’Cause we just have to find it for any $\varepsilon$, so we just have to disprove it for one $\varepsilon$.

Stan: Yeah.

Steve: So we should just use .05.

Sean: So $\varepsilon$ equals .05, sort of.

Next, the group explored how to show there would be only finitely many points inside a 0.05-strip. Sean suggested that by checking “the entry point and exit” point to the $\varepsilon$-strip, they would show there would be only finitely many points inside the $\varepsilon$-strip, which would then imply infinitely many points outside the $\varepsilon$-strip. The problem now became to solve an equation $1/n = 0.1 + 0.05$ for the entry point and an equation $1/n = 0.1 - 0.05$ for the exit point, and they were able to solve these equations successfully.

Sean: … So, would you have to say, would you have to find the, the two spots where you have your finite, like your first your entry point and your exit? And then that would show that you have finite numbers [inside the $\varepsilon$-strip] and then…

Susie: Yeah, I like that.

Stan: That’s cool. That would be the intersection of the $\varepsilon$-strip across uh… And we were just talking about sets, too, if these are sets, the intersection of sets.

Sean: So we’d have to solve for $1/n$ equals .15 and $1/n$ equals .05 [Susie agrees] and that would be these two points. So [the entering] $n = 1/.15$ and [the exit] $n = 1/.05$.  

---

Post-Reflective Situation: Sean’s Attempt to Prove “Every Convergent Sequence of Real Numbers is a Cauchy Sequence” via $\varepsilon$-Strip

The following episode illustrates another example of the post-reflective situation, in which Sean reflected on the $\varepsilon$-strip activity to prove that every convergent sequence is a Cauchy sequence. First, he and his group members tried to make sense of the definition of Cauchy sequences by comparing differences in symbols between the $\varepsilon$-$N$ definition of convergence and the definition of Cauchy sequences. They then set up their proof by assuming that a sequence is convergent. Accordingly, they imagined that for any $\varepsilon$-strip, every point but a finite number of points, $N$, of the sequence is contained in the $\varepsilon$-strip. In particular, Sean drew a graph of a sequence that was oscillating but converged to 0 (He seemed to draw the graph of $\{(−1)^n / n\}_{n=1}^{\infty}$).

He then marked $N$ in the $x$-axis and drew two lines, each of which was parallel to and had the same distance from the $x$-axis; thereafter, every term whose index was greater than $N$ was contained in the $\varepsilon$-strip. In fact, the region bounded by these two lines is the interior of an $\varepsilon$-strip, and hence Sean called such a region an $\varepsilon$-strip. He also chose two values on the $x$-axis, each of which was greater than $N$, and marked them as $m$ and $n$.

Sean: So you have like, here’s the big $N$ that satisfies it. Let’s say this is going like this, and so your $\varepsilon$-strip is such that everything in here is contained past that $N$. And you choose two values $n$ and $m$ regardless of where, like… Let’s say this one $[a_n]$ is here and this one $[a_m]$ is here …This distance $[|a_n-0|]$ here has to be less than this distance $[\varepsilon]$ here, right?

Since $m$ and $n$ were greater than $N$, students in his group could see that both $a_m$ and $a_n$ were within the $\varepsilon$-strip, and hence each of $|a_m-0|$ and $|a_n-0|$ was less than $\varepsilon$. Sean then realized that based on his reasoning, he could argue that the distance between $a_m$ and $a_n$ is less than $2\varepsilon$, i.e., $|a_m-a_n| < 2\varepsilon$. However, Sean was unable to conclude $|a_m-a_n| < \varepsilon$ because he knew that $\varepsilon$ was positive, and hence $2\varepsilon > \varepsilon$. Although Sean also checked $|a_m-a_n| < \varepsilon$ in the case of a monotone convergent sequence by drawing a graph of $\{1/n\}_{n=1}^{\infty}$, he believed that finding an example of a sequence satisfying the inequality $|a_m-a_n| < \varepsilon$ does not mean that such an inequality would always be true for any sequence.

Sean: … it would be for sure that this distance $[|a_m-a_n|]$ here would be less than $2\varepsilon$, because $2\varepsilon$ is this whole thing. But how can you be sure that this distance $[|a_m-a_n|]$ is going to be less than a single $\varepsilon$? I mean that's just in the special case, I mean other cases like, where it's just that and there's your $\varepsilon$-strip and your two values; obviously this distance here... [is less than $\varepsilon$].

The instructor moved to the whole class discussion by collecting students’ ideas of proving the given theorem: Every convergent sequence is a Cauchy sequence. Sean, on the other hand, was off task and continued his thinking to figure out how to fill the gap between what his group
had so far and what to prove at the end. The aha-moment came to him when he realized that the value of \( N \) in the definition of Cauchy sequences does not have to be the same as the value of \( N \) in the \( \varepsilon - N \) definition that he assumed in the beginning of his proof, although the same symbol \( N \) was used in each definition. He explained to his group that by choosing an index \( N \) in the definition of Cauchy sequences “farther down” than the index \( N \) in the \( \varepsilon - N \) definition of convergence, the difference between the two terms \( a_m \) and \( a_n \) would be less than \( \varepsilon \).

Sean: [whispering] Let me check this out. …
[Instructor talking to class]
Sean: [whispering] Oh wait!
[Instructor talking to class]
Sean: Yeah, this \( N \) [in the definition of Cauchy sequences] isn’t doing the same thing as it was doing before [in the \( \varepsilon - N \) definition of convergence].
Steve: Yeah, exactly.
Sean: So this could be farther down here, and this could be an \( N \) where it’s right here.
Steve: As long as…
Sean: It’s farther down.
Steve: … small \( m \) and small \( n \) are greater than [\( N \)]… yeah.
Sean: Yeah.

It is worth noting that Sean was no longer in the status of just comparing symbols in the \( \varepsilon - N \) definition of convergent sequences and the definition of Cauchy sequences. Rather, he realized that although the symbol \( N \) is used in both definitions, it does not mean their values are the same. In fact, he came to consider the symbol \( N \) in the definitions as a bound variable. Such a shift in understanding the role of the variable in the definitions seems to resolve the group’s obstacle in showing the inequality \( |a_m - a_n| < \varepsilon \). Sean and his group members also found that the instructor used the same oscillating convergent sequence with \( \varepsilon \)-strips to make sense of the theorem, and therefore they convinced themselves that their ideas would lead a proof to the theorem.

Discussion

This paper illustrates how the \( \varepsilon \)-strip activity plays a role in promoting students’ reflective thinking in the case of the limit of a sequence. Brousseau (1997), Cornu (1991), and Fischbein (1987) have proposed the necessity of creating a learning environment in which students are made aware of difficulties and given the opportunity to reflect on their own ideas. Concerning instructional treatment to help students reflect on their conception of convergence, it is worth noting that the \( \varepsilon \)-strip activity was effectively used in this class. The students were initially situated in such a way that they felt perplexed, frustrated, and confused due to the impreciseness of their conceptions of convergent sequences. Students’ preconceived notion of convergence became a true intellectual problem to them. Students then suggested one idea after another, seeking a possible way to properly describe the convergence sequences, and tested their hypotheses by (mental) actions with \( \varepsilon \)-strips. It is also worth noting that after the \( \varepsilon \)-strip activity, the students continued reflecting on their new conception of convergence and utilized it to make sense of other properties of convergent sequences by using the \( \varepsilon \)-strips.

FACTORS OF CALCULUS STUDENTS’ MATHEMATICAL PERFORMANCES AND PREFERENCES FOR VISUAL THINKING

Erhan Selcuk Haciomeroglu
University of Central Florida
erhansh@mail.ucf.edu

Leslie Aspinwall
Florida State University
laspinwall@fsu.edu

Eric Chicken
Florida State University
chicken@stat.fsu.edu

From the perspective of developmental research, this study completed a research cycle of a new instrument, the Mathematical Processing Instrument for Calculus (MPIC), to examine calculus students’ mathematical performances and preferences for visual or analytic thinking regarding derivative and antiderivative tasks presented graphically. It extends previous studies by investigating factors mediating calculus students’ mathematical performances and their preferred modes of thinking. Data were collected from 183 Advanced Placement calculus students. Students’ performances on the MPIC were not influenced by gender or visual preference. There was no significant difference between the two sexes, but AP high- and low-performing students differed in terms of visuality. Thus, the results suggest stronger preference for visual thinking was associated with higher mathematical performances.

Introduction

Past studies analyzing factors of differences in mathematical performance have generated inconclusive findings. We hypothesized that preferred mode of thinking might underlie differences in mathematics learning and designed a new instrument, the Mathematical Processing Instrument for Calculus ([MPIC], Haciomeroglu, Aspinwall, Presmeg, Chicken, & Bu, 2009), to determine students’ mathematical performances and preferences for visual or analytic thinking regarding derivative and antiderivative tasks presented graphically. This study sought to investigate factors mediating calculus students’ mathematical performances and their preferred modes of thinking.

Interest in the relationships between gender, spatial ability, and mathematical performance has existed for decades, and spatial ability and its various definitions constitute a long-standing topic of discussion within the mathematics education community (e.g., Clements, 1979; Bishop, 1980; Lohman, 1988). Many researchers have used diverse definitions to examine components of spatial ability (e.g., Guay & McDaniel, 1977; Lohman, 1979; McGee, 1979; Bishop, 1983; Linn & Petersen, 1985; Tartre, 1990).

The problems associated with working with multiple, and at times divergent, definitions are exacerbated by several issues that have been reported in literature. Spatial tests may be complicated by analytic strategies (Bodner & Guay, 1997), or students with spatial ability may prefer not to use visual methods (Krutetskii, 1976; Clements, 1984; Presmeg, 2006). Moreover, spatial tests with inconsistent correlations measure various components of spatial ability, and these tests often measure different abilities as they relate to individual differences in solution strategies (Guay, McDaniel, & Angelo, 1978; Lohman, 1979). Generally spatial tests use visual or pictorial tasks, but visual strategies can be used for visual or non-visual tasks in any content area of mathematics (Bishop, 1983). Bishop (1989) contends that the psychometric approach might not be appropriate for studying the visualization process due to students’ idiosyncratic approaches to solving spatial tasks. Since research conclusions are varied, this study omits spatial tests and instead investigates the relationship between students’ solution strategies.

determined by the MPIC and their mathematical performances based on the number of correct answers on the MPIC.

There is extensive research relating differences in mathematical performance to solution strategies. Halpern and Collaer’s (2005) extensive literature in this field suggests that gender differences in mathematical performance may be related to strategies males and females use to solve visual or spatial tasks. Fennema and Tartre (1985) reported a study in which students in grades 6, 7, and 8 were classified as either high or low in spatial visualization and verbal skills. They found that boys with low spatial visualization and high verbal skills had the highest mathematics achievement scores compared to boys with high spatial and high verbal, girls with low spatial and high verbal, or girls with high spatial and high verbal. Moreover, high spatial/low verbal and low spatial/high verbal students differed in their strategies, but not in their ability to solve problems. This is consonant with Battista’s (1990) observation that logical reasoning was an important factor in geometry achievement and geometric problem solving and that low achieving geometry students used more visual solutions than analytic. Linn and Petersen (1985, p. 1492) attributed gender differences on spatial tasks to the selection of efficient strategies: “The pattern of sex differences could result from a propensity of females to select and consistently use less efficient or less accurate strategies for these tasks.” In a longitudinal study with elementary students, Fennema, Carpenter, Jacobs, Franke, and Levi (1998) concluded that there were no gender differences in solving problems but strategies used to solve problems were different throughout the study. Gallagher and De Lisi (1994) examined solution strategies of high-ability students with high mathematics scores on the Scholastic Aptitude Test (SAT–M) on routine and non-routine SAT–M problems and found differences in performances on routine problems favoring females and on non-routine problems favoring males. Gallagher and De Lisi attributed the results to gender differences in solution strategies, suggesting that the use of conventional and unconventional strategies were significantly high for female and male students respectively.

Krutetskii (1969, 1976) went so far as to exclude visual thinking from essential components of mathematical abilities. In his studies, Krutetskii identified types of mathematical giftedness based on students’ preferences for analytic (or verbal-logical) or visual (visual-pictorial) thinking. According to Krutetskii, the ability to visualize abstract mathematical relationships and the ability for spatial geometric concepts are not essential components of mathematical abilities; that is, the level of mathematical abilities is determined by the strength of the analytic component of thinking, and the visual component, which is not considered to be of the components of mathematical giftedness, determined the type (though not the extent) of mathematical giftedness. Lean and Clements (1981) reported a similar finding: spatial ability and knowledge of spatial conventions were not factors significantly affecting mathematical performance of engineering students, and that the students who preferred analytic thinking outperformed those who preferred visual thinking on both spatial and mathematical tests. Moses (1977) and Suwarsono (1982) analyzed students’ solutions strategies to determine their visuality and concluded that visuality and problem solving performance did not correlate significantly. Presmeg’s (1985, 1986) study confirmed Krutetskii’s findings and reinforced the roles of differences in preferred mode of thinking in learning mathematics. Other studies (e.g., Clements, 1984; Habre, 2001; Presmeg, 2006; Haciomeroglu, Aspinwall, & Presmeg, 2010) have also shown that students who have the ability to visualize may prefer not to do so. Ben-Chaim, Lappan, and Houang (1989) investigated the effect of instruction on middle school students’ preferences for visual or analytic solutions and performance in solving spatial tasks. Before the instruction, boys and girls did not differ in their preferences and performances. After the instruction, there were significant differences.
between the two sexes in the preference of solutions but not in solving the tasks. Girls preferred mixed and visual solutions, whereas boys demonstrated strong preference for visual solutions.

The work of Lean and Clements (1981), Moses (1977), Suwarsono (1982), Presmeg (1985), Ben-Chaim et al. (1989), and Lowrie and Kay (2001) stands apart from other research on students’ mental processes because they identified students’ thinking processes based on their preferences for visual or analytic solutions and compared their mathematical performance in their preferred mode of thinking. We have seen a relationship between preferences and mathematics learning, and preferred mode of thinking might underlie differences in mathematics learning. In our review of existing literature, we have found a dearth of research studies examining mathematical performances of students with different preferences. Our students have developed a preferences to think visually or analytically, and their preferences can be different from their abilities to think visually and analytically (Haciomeroglu et al., 2009). Differences in students’ mathematical performances may arise from their preferences and not necessarily from their abilities. We believe this suggests research studies focusing on students’ preferences, and that a distinction has to be made between studies focusing on mathematical ability testing and studies focusing on students’ preferences.

The primary goal our study was to examine possible factors contributing to calculus students’ mathematical performances and preferences. In the present study, the following research questions were investigated in high schools:

1. Differences in Performance. Do gender, visual preference, and AP performance affect mathematical performance on the derivative and antiderivative tasks of the MPIC?
2. Differences in visual preference. Do males and females and high- and low-performing students differ in preferences for visual thinking?

Methods and Data Collection Procedures

Sample

We visited ten classrooms in five high schools in two school districts in North Florida in the United States and collected data from 188 Advanced Placement (AP) calculus students with seven teachers. The students were enrolled in five AB and five BC calculus courses. All 188 students in the ten classes agreed to participate in the study. Five students who failed to take both the derivative and the antiderivative test were excluded from the data. There were 103 (56%) students in AB and 80 (44%) students in BC calculus courses. Eighty-two (45%) of the participants were female, and 101 (55%) of the participants were male. Of the 183 students who completed the MPIC, we were able to collect 174 students’ scores on AP calculus test at the end of the year. Therefore, results are based on the most available data in this study.

The Mathematical Processing Instrument for Calculus (MPIC)

In the study, we have administered the MPIC whose reliability and validity are well established (see Haciomeroglu et al., 2009). The MPIC is designed to determine students’ mathematical performances and preferences for visual or analytic thinking as they attempt to sketch derivative and antiderivative graphs. The MPIC consists of graphical tasks because research (e.g., Eisenberg & Dreyfus, 1991) has shown that most calculus students tend to use analytic strategies to compute derivatives and integrals, and this tendency makes it more difficult to infer students’ visual strategies when they are solving procedural tasks.

The MPIC consists of two main sections — Derivative and Antiderivative — and each section consists of five graphical tasks requiring students to draw derivative (see Figure 1)
or antiderivative graphs (see Figure 2) of basic functions. Every graphical task has at least two possible ways of obtaining a solution because we think that visual students prefer to work directly from graphical information, and analytic students prefer to translate to an algebraic representation when this option is available. We use the terms visual and analytic to mean graphical and algebraic solutions respectively. We will use the terms interchangeably and think this is an advantage for the analysis of students’ methods of solutions.

Graphical solutions such as estimating slopes are considered as visual solutions. Algebraic solutions such as estimating equations are considered to be analytic solutions. One task from each section of the MPIC is illustrated in Figures 1 and 2. We considered a solution to be analytic if the student estimated and integrated the equation of the graph to draw its derivative or antiderivative graph. We considered a solution to be visual if the student estimated the slopes of tangent lines at various points on the graph of the function and used this to draw the graph of the derivative or antiderivative. Upon completion of the Derivative or the Antiderivative section of the instrument, students were given the Method part, a questionnaire, consisting of an analytic and a visual solution method for each task, and asked to choose for each task a method of solution that most closely described how they sketched their graphs.

Variables

To further explore the students’ preferences for derivative and antiderivative tasks presented graphically, we administered the MPIC, which yielded two scores for each student: 1) a score of mathematical performance determined by the number of correct responses, and 2) a score of visual preference. There were two mathematical performance variables: AP calculus test scores (AP) and Antiderivative/Derivative scores on the MPIC (AD).

On the MPIC, to determine the students’ visual preference scores, Vd (Derivative), Va (Antiderivative), and VdVa (Derivative/Antiderivative), for the derivative and antiderivative tasks presented graphically, they were given a score of 0 for each analytic solution and 1 point for each visual solution regardless of whether their answers were correct or incorrect. When determining preference on the MPIC, the primary goal was to identify the students’ methods as visual or analytic; whether their answers were correct or incorrect mattered less than their method(s) in determining preference. In assessing students’ understanding of the calculus derivative or antiderivative graphs, the students were given a score of 0 for each incorrect answer and 1 point for each correct answer. Thus, for each of the two sections, the total possible score is five points.
For instance, in the derivative section consisting of five tasks, for a visual preference score of 0 ($V_d$) and a derivative score of 5 ($D$), we can say that the student solves all the tasks correctly and has a strong preference for analytic thinking. In the antiderivative section consisting of five tasks, a visual preference score of 5 ($V_a$) and an antiderivative score of 0 ($A$) indicate a strong preference for visual thinking and an incomplete understanding of the antiderivative graphs.

In our analyses, we made use of $V.\alpha$ based on the best combination of the visual preference scores, $V_a$ (Derivative) and $V_d$ (Antiderivative), from the MPIC ($V.\alpha = 0.23 \times V_a + 0.77 \times V_d$). Moreover, logistic regression (see Figure 3) was used to model the probability of being visual (or analytic), given a student’s score on the MPIC. Figure 3 illustrates the likelihood that a student’s solution will be 0 (analytic preference) or 1 (visual preference) given a visual preference score of the student on the MPIC. Since it is the lowest on the left, and the highest on the right, and the steepest in the middle, $V.\alpha$, the visual preference score of the derivative and antiderivative tasks, is the best model (see Figure 3).

To compare visual and analytic students’ performances on the MPIC, we used their visual preference scores, $V.\alpha$, to distinguish between visual and analytic preferences. If a student has a $V.\alpha$ score greater than 0.5, then the student has a visual preference. If the student has a $V.\alpha$ score less than 0.5, then the student has an analytic preference. We also divided the students into subgroups based on their scores on the AP tests. The students with AP scores of 4 or 5 were considered as high-performing and those with AP scores of 1 or 2 as low-performing. The students with a $V.\alpha$ score of 0.5 or an AP score of 3 were excluded from these analyses. All students could be classified as visual or analytic in preference since no students had a $V.\alpha$ score of 0.5.

Results

Differences in Performance

We used Antiderivative/Derivative (AD) as the measure of mathematical performance on the MPIC, and the students were divided into subgroups according to their gender, visual preference, and AP performance. A three-way analysis of variance (ANOVA) was conducted to explore the effects of visual preference, gender, and AP performance on AD.

The overall F-test showed that there was a difference in the AD means due to the factors \( p < 0.001 \). As expected, the ANOVA showed there was a significant effect due to AP performance \( p < 0.001 \). The mean AD score for the high-performing AP students was 0.77, while the mean AD score for the low-performing AP students was 0.56. Additionally, there was a significant effect due to the interaction of AP performance with visual preference \( p = 0.02 \). There were no significant effects for gender \( p = 0.80 \) or any of the other interaction terms. Figure 4 shows the mean AD scores on the vertical axis and AP scores on the horizontal axis. Visual and analytic students are denoted by the dashed and solid lines respectively. If these students are divided into subgroups according to their preferences for visual or analytic thinking (see Figure 4), the increase for the analytic students is not as large as the increase for the visual students.

Differences in Preferences for Visual Thinking

We used V.alpha, the continuous measure of student visual preference, to determine whether the subgroups (i.e., males and females; high- and low-AP-performing students) differed in terms of visual preference scores. The two-way ANOVA was borderline significant \( p = 0.06 \). However, from the two-way ANOVA analysis, there was significant effect on V.alpha due to the AP score \( p = 0.035 \), but no significant effects on V.alpha due to gender or the interaction of gender and AP score. The high-performing students had a mean V.alpha score of 0.59, while the mean V.alpha score for low-performing students was 0.46.

Conclusions

In the present study, we investigated contributing factors to calculus students’ mathematical performances and preferences. Our results suggest that gender and visual preference were not significant factors influencing the students’ performances on the derivative and antiderivative tasks presented graphically on the MPIC. There was a significant difference in scores for high- and low-performing students. Moreover, the interaction between visual preference and AP performance in their effect on MPIC scores was significant, and thus there was a difference in scores over AP performance for the visual and analytic students. Students’ gender did not have a significant influence on their preferences for visual or analytic thinking, which is in agreement with the findings reported by Ben-Chaim, Lappan, and Houang (1989). Statistically significant differences in visual preference scores were found among high- and low-performing students. The high performing students had significantly higher visual preference scores than the low-performing students. Thus, the results suggest that stronger preference for visual thinking (or solutions) was associated with higher mathematical performances. Our results are not consistent with the results of the study by Lean and Clement (1981) and do not support Battista’s (1990) contention that low achieving students used more visual methods.

Our work with AP calculus students and the Mathematical Processing Instrument for Calculus has generated new information about calculus students’ mathematical performances and preferences. Considering students’ differing and idiosyncratic methods, we suggest that differences in mathematics learning can be explained by students’ preferences to think visually.
or analytically, not necessarily by their ability to think visually or analytically. Our field tests confirm the potential for use by researchers and teachers to identify students’ preferences and to understand students’ comprehension of derivative and antiderivative graphs and difficulties associated with their preferences. We think these are topics worthy of continued study and additional research cycles with the MPIC in calculus classrooms.

PART / WHOLE METAPHOR FOR THE CONCEPT OF CONVERGENCE OF TAYLOR SERIES

Jason H Martin  
Arizona State University  
Jason.H.Martin@asu.edu

Michael Oehrtman  
Arizona State University  
Michael.Oehrtman@asu.edu

During a detailed analysis of interviews conducted with university calculus, real analysis, and numerical analysis students concerning the convergence of Taylor series, we discovered that several students consistently relied on a single metaphor throughout several tasks. In this paper we characterize one such metaphor based on Part / Whole relationships. We provide a detailed illustration of one student’s commitment to this metaphor (emphasis) and the degree to which it influenced his reasoning (resonance).

Introduction

Taylor series are frequently used in physics and engineering to simplify complicated mathematical models and play a foundational role in the theory of complex analysis. In introductory-level calculus sequences, Taylor series are typically developed in four or fewer sections of the textbook emphasizing computation and algebraic manipulations (e.g., Hass, Weir, & Thomas, 2007; Larson, Edwards, & Hostetler, 2005; Stewart, 2008). Students are likely to revisit Taylor series in more theoretical or applied depth in courses such as differential equations, introductory analysis, numerical analysis, complex analysis, modern physics or physical chemistry, or a variety of engineering courses. We ask the question, what images guide students’ reasoning about the convergence of Taylor series as they establish their initial conceptual foundation?

Background

Portions of this paper are part of an initial study conducted in partial fulfillment for a degree of Doctor of Philosophy in Mathematics (Martin, 2009). The initial study sought to analyze and describe expert and novice conceptualizations of the convergence of Taylor series by identifying and categorizing particular reasoning patterns while accounting for different levels of exposure to series. To address this goal, data were collected from 131 undergraduate students, 10 graduate students, and 6 faculty from a mid-size four-year university and from a regional community college. To help better account for the effect of the amount of exposure undergraduate participants had with Taylor series and with series in general, undergraduate student participants were selected from calculus, real analysis, and numerical analysis classes after having prior exposure to Taylor series. All 131 students completed an in-depth questionnaire about their understanding of Taylor series, and eight of these students subsequently participated in no more than two face-to-face, task-based, individual interviews. Martin (2009) categorized some of the different ways in which these experts and novices conceptualized Taylor series using the construct of concept images developed by Tall and Vinner (1981), as well as other influential work on Taylor series and limits in general (e.g., Alcock & Simpson, 2004, 2005; Kidron, 2004; Kidron and Zehavi, 2002; Oehrtman, 2002; Williams, 1991).

For the purposes of the study represented in this paper we focused our attention primarily on undergraduate student participants, and attempted to identify patterns of metaphorical reasoning employed by individual students.
Theoretical Framework

We analyzed interview data for student reasoning employing a theoretical perspective of conceptual metaphor based on Max Black’s (1962, 1977) interaction theory and as used by Oehrtman (2002, 2009). In general, metaphorical reasoning involves conceiving of unfamiliar aspects of a target domain in terms of similar aspects of a more immediately understood metaphoric domain. Black distinguished emphasis and resonance as necessary characteristics of strong metaphors, those that have the potential to be ontologically creative for the user. Emphasis is the degree to which the user is committed to applying the chosen metaphorical domain and resonance is the degree to which the metaphor can support “elaborative implication,” the development of additional inferences not contained within the original metaphor. According to Black (1977) strong metaphors require an active response in the conceptualization of the metaphorical domain as well as projection of aspects to the target domain. The resulting dialectic allows for conceptual innovation that far exceeds what is possible by reasoning entirely within either domain.

Results

Some of the metaphors that emerged from our analysis of calculus and analysis students reasoning about convergence of Taylor series include the approximation, collapse, and proximity metaphors as previously described in Oehrtman (2002, 2009). An additional metaphor based on part/whole relationships emerged as distinct from those already observed by Oehrtman. In this metaphor partial sums are seen as “part” of a bigger whole (the infinite series) and convergence may be viewed as being accomplished through a “massing” of points from the whole that contributes to a preponderance of evidence for convergence.

In this section we will highlight one student, Brian’s, use of such a “part/whole” metaphor when discussing tasks related to Taylor series convergence and the influence of this metaphor on his understanding of Taylor series. In the following excerpt, one can see Brian hinting toward an idea of a large number of points yielding a resulting limit.

Interview Task 3: What is meant by the “=” in “\[ \cos x = 1 - \frac{1}{2!} x^2 + \frac{1}{4!} x^4 - \frac{1}{6!} x^6 + \cdots \] when \( x \) is any real number?”

Brian: I’m thinking it has something to do with like a Riemann sum. That’s just what comes to mind. Uh, if I add up, if I were to add up all of these it would give me a definite point.

In this excerpt Brian appeared to cue off of his prior notion of Riemann sums. Even though it is unclear what “these” was for Brian (he did not explicitly say that “these” meant the terms of the Taylor series), the effect of adding up “all” of them yielded a “definite point.” Brian will eventually refer to this effect as a “massing” of points.

Following his comments in the first excerpt, Brian was asked to elaborate about the meaning behind his reference to “Riemann sum.” In response, Brian initially took note of the order of the terms in the series and then appeared to notice that the denominators of each term in the Taylor series were going up by multiples of two. In the next excerpt, Brian detailed some of the meaning behind his reference to “Riemann sum” and continued to allude to the effect of all points “massing”.

---

I’m thinking that because these are all fractions [pointing to the terms of the series] of I guess cosine curve or function, it’s gonna give me one single point. Um, kinda of a sum-, it’s gonna, it’s gonna give me a summary more or less is what I’m thinking since it’s all these little points adding up to one point. I’m thinking it’s gonna converge into something.

It appears very possible that the “fractions” that Brian was referring to were the coefficients of \( x \) in the expanded Taylor series. Alternatively, he may have imagined plugging in a number for \( x \) in each term of the Taylor series obtaining “fractions” to be added up. In either case, Brian conceived of “all fractions” as giving “one single point” that may be a “summary” of the larger whole. Again in this same excerpt, Brian alluded to “all these little points” that add up to “one point.” Subsequently in the interview, Brian was asked what he meant by his reference to “converge into something” found at the end of the above excerpt, and Brian reiterated that he meant that “it’s going to come to a point” and that this point was a specific number.

Later in the same interview, when asked “How would you go about estimating \( \sin(103) \)?” Brian responded by saying the following:

Well, I'm thinking that if we did go, just for arguments sake, to 103, I mean that would be any every number from 1 to 103. So just, I'm thinking the summation of all those numbers would probably get me that one number that we're looking for.

Although Brian clearly exhibited confusion in this excerpt, it is important to note that in the first three excerpts Brian persisted in his references to “all’s”, whether the all be composed of terms of a Riemann sum, fractions of a Taylor series, a collection of little points, or numbers, that through some limiting process, like an “add up” process, yield a single result, usually in the form of a point or a number that is sought after. In these cases, the “all’s” may be seen as the “whole” which has a characteristic of “massing” around a single point. The following excerpts will reveal further entailments of Brian’s “part / whole” metaphor and the emerging role of “massing”. Consider his response to Interview Task 4:

Task 4: What is meant by the “\((-1,1)\)” in, “\(1/(1-x) = 1 + x + x^2 + x^3 + L \)” when \( x \) is in the interval \((-1,1)\)?

Brian: Well it uh. I didn’t really look at it there. Um, I’m guessing those are the parameters. I mean, it’s gonna go, if I were to set up an integral, you know, it would be from one to negative one, any infinite amount of numbers between negative one and one. Um, let’s see, I know it can't be, well I'm thinking it can't be one for this particular function [pointing to \(1/(1-x)\)] just because it doesn't exist.

I: Okay.

Brian: Negative one would be two, so I'm thinking it might be equal to a negative one and just up to one. So, just any infinite amount of numbers in between there.

As Brian was attempting to make sense of the interval of convergence of this Taylor series, he first appeared to focus on the interval \((-1,1)\) and referred to setting up a definite integral using –1 and 1 as “parameters” for the limits of integration. Based on his response to the previous task found in the first excerpt in which he referred to the Taylor series of cosine as having “something to do with like a Riemann sum”, it appears possible that the definite integral may have been triggered in Brian’s mind because of its relationship to Riemann sums. The generating function \(1/(1-x)\) gained Brian’s attention as he pointed to the function and commented that it does not

---

exist at 1 and the value is 2 when \( x = -1 \) (seemingly referring to the value of the denominator). Twice Brian talked about the infinite amount of numbers between –1 and 1, prompting the interviewer to ask his next question.

I: Okay, and what can we do with this infinite amount of numbers between there?
Brian: Well, like in number 3, I'm thinking in these infinite amount of numbers you're going to find some type of mass. I mean it's gonna be… If I were to add up all of them, it would somehow equal one finite number [holds both hand up as if holding something between] as opposed to all these infinite numbers [moves both hands away from each other]. I mean, it's gonna be just around this number consist-consistently.

This excerpt illustrates Brian’s use of “mass” in which an infinite amount of numbers are “around” some “number consistently.” He then appears to have nearly duplicated his response to Task 3 when he said “If I were to add up all of them, it would somehow equal one finite number [holds both hand up as if holding something between]”. Based on his previous responses it appears that “all of them” may have referred to the infinite amount of numbers in the interval \([-1,1]\). Although mathematically imprecise in his language, his usage of “all” and how it can be “added up” to yield one “finite number” is consistent with his prior usage of “all” found in his preceding excerpts.

When discussing how to estimate sine using its Taylor series, Brian said, Well, it's called an estimate because it's not exactly that specific number that it's, uh, revolving around. It’s just gonna be somewhere in the ball park of that specific number.

Following these comments, Brian alluded to plugging in numbers whose numerical representation contained several “9’s” following the decimal, and then concluded

If I were to think of a [holds both hands up with palms facing each other], just a number line, you know, I'm coming from the left hand side [moves left hand inward], I'm coming from the right hand side [moves right hand inward], and this is the number it's gonna stop at [moves both hands very close to each other]. It's an estimate, it's not exactly reaching it, but it's the best we can do.
In the previous two excerpts, Brian revealed a variation of his “part / whole” metaphor. Previously, he spoke of a specific number or point that may be sought after using some limiting process applied to the “all”, but in these excerpts, he addressed the role of estimation and concluded that an estimation is “not exactly” but in the “ball park” of the sought after specific number. The estimation is seen as dynamic in that it may be “revolving around” the “specific number”, and when being viewed as a “number line”, estimates “come from the left”, “come from the right”, and “stop”. Taken together, all excerpts indicate an iconic representation of convergence on a number line in which points “mass” around a sought after specific number (see Figure 1).

The next excerpts will illustrate the roles of the “part” and “whole” in Brian’s “part / whole” metaphor. Brian begins with a spontaneous analogy using Google Maps.

Interview Task 8: What is meant by the “approximation” symbol in $\sin(x) = x - x^3/3! = a$ Taylor polynomial for sine when $x$ is near 0?"

Brian: Just because it says approximation and nothing else, I’m, I'm guessing it's gonna equal only a portion of what the whole Taylor series would equal. It's not gonna equal the whole answer, it's just gonna get me one little section of it [holds up left hand with thumb and index finger extended close together]. So-like it may be close to divergence, but it's not gonna be-it's almost like Google Maps. I'm gonna show you know, [holds up left hand with thumb and index finger extended close together] this one little section, but if I, if I pan out or whatever, gonna show me [circular motion with left hand] exactly everything. I think the Taylor series is like the whole view [holds up both hands extended across body with palms facing each other]. And any time I show an approximation [pointing to the Taylor polynomial in Interview Task 8], it's just gonna give me that [holds up right hand with thumb and index finger extended close together] little piece.

![Figure 2. Brian's "Part / Whole" Metaphor for Taylor Series](image)

In the above excerpt, Brian viewed the third degree Taylor polynomial $x - x^3/3!$ as equaling a “portion of the whole Taylor series” that does not equal the “whole answer” but merely a “little section” of the “whole answer”. Furthermore, the “little section” of the Taylor series “may be close to divergence.” He then proceeded to reason by analogy in which a “little section” of Google Maps was equated with the Taylor series “approximation” by Taylor polynomials and the “panned out” view of Google Maps corresponded to the “whole view” of Taylor series. It is also worth noting that when talking about the “little section” of Google Maps and the “approximation” using Taylor series, he used the exact same gesture of extending an index finger and thumb as if grasping the “little section” or “approximation” between these two small
appendages. In contrast to this small gesture, when “panning out” on Google Maps or discussing the whole view of the Taylor series his gestures embodied a larger scale. These utterances and gestures reveal a structure of the “part / whole” metaphor for Taylor series illustrated in Figure 2.

In the next excerpt, Brian describes a portion of the whole Taylor series, a Taylor polynomial, as an approximation that can be made more accurate by using more terms from the Taylor series.

How can we get a better approximation for sine than using $x - x^3 / 3!$?
Brian: I'm thinking that if we were to keep with the Taylor series we'd go, we'd keep going on, you know, with more of the actual equation. So $x$, you know, equals five over five factorial, and $x$ equals seven. I mean-
I: Uh-huh.
Brian: -sorry, $x$ to the fifth over five factorial, and then $x$ to the seven over seven factorial.
I think that would give a better approximation.

Even though, Brian alluded to increasing accuracy by increasing the degree of the Taylor polynomial, the extent to which Brian understood this increasing accuracy relative to the degrees of the Taylor polynomials is unclear in the above excerpt. For example, Brian made no reference to the graphical effect of adding more terms to the Taylor polynomial. Therefore, the interviewer asked Brian what adding more terms to the Taylor polynomial did “graphically”?

Graphically I think it just, it gives us more, it gives us more numbers to consider when trying to find the absolute number, like the number that we're looking for as far as converging or diverging. If it's to converge, I think the more numbers that you have, you know, the better feel you get for what type of convergent it's going to go to. It's like, it's like a grading scale, you know, you can have two tests in one semester and if you, you know, if both are, if one's an F and one's an A, you're not going to know which one the student was. If you got a couple more, you know, well maybe this student's more of an A student and that one F was just a fluke. I'm thinking if this one little piece of the Taylor series [pointing to the Taylor polynomial] shows, just this one little piece [holds right hand up with thumb and index fingers extended close together], it's not going to give as much as opposed to maybe, you know, these other numbers are around that but it's going to zero in [points hands at each other with palms facing toward body] or home in on [points hands at each other with palms facing toward body] something more definite.

Brian initially equated adding more terms with giving “more numbers to consider” for finding the “number that we’re looking for.” He then stated that “more numbers” yield a “better feel” for the sought after cluster point. He then extended his analogy to a student’s grades in which knowing only a couple of grades were not enough to correctly determine the student’s overall grade. Only more grades will better reveal the student’s actual grade and allow the teacher to determine if the F was just a “fluke”. Here, the idea of looking at only a couple of grades which only give a small, potentially misleading piece of the student’s actual grade was equated with the Taylor polynomial which only gives “one little piece” of the Taylor series which is not “much” compared to when more terms are added. Just as more grades can better reveal a student’s overall grade, “other numbers” can “zero in or home in on something more definite.” When later asked what the Taylor polynomial approximation gave, Brian elaborated on his reference to it not giving “much” found above. At first he simply restated that the Taylor
polynomial gave an “approximation”, he then added that it gives what the Taylor series “might be” and “could be” in the form of an “estimate” and a “guess” that is “just one piece of the puzzle.”

Discussion

Throughout the entire questionnaire and subsequent interviews Brian never revealed a formal graphical understanding of Taylor series convergence. He was unable to draw Taylor polynomials when given a graph of a generating function and was unsuccessful in stating any relationship to Taylor series when given graphs of Taylor polynomials. As the previous excerpt illustrates, even when presented directly with task of describing graphically the effect of adding more terms to a Taylor polynomial, Brian responded in non-graphical language. Therefore, his reference to “little pieces” of Taylor series and accompanying gestures with thumb and index finger extended, should not be interpreted as suggesting intervals but “pieces” of formulas of expanded Taylor series. On other occasions, his gestures suggest a graphical understanding of convergence restricted to a number line. For example, in one of the previous excerpts Brian gestured by moving his hands inward when approaching a number from the left and right and later he pointed his hands at each other for “zeroing in or homing in” on a number. Thus, one should not view Brian as having no graphical understanding of Taylor series convergence, but instead, like many students encountering Taylor series for the first time, he has an emerging graphical notion of Taylor series convergence that has not yet clearly distinguished itself from prior graphical notions of convergence, such as convergence on a number line.

Even though Brian’s understanding of Taylor series may be less than desirable, all of these excerpts point to a similar structure used to reason about convergence across various contexts. We call this structure the “part / whole” metaphor. Evidence of this structure is not only seen in his consistency of language across the different contexts, but in his consistency of gestures. Depending on the context, the “part” may be composed of some points on a number line, the first few terms of a Taylor series, a “little section” zoomed in on a map, or a couple of grades. It was embodied as minimalist gestures, such as “thumb and index finger extended close together” or “moving both hands very close to each other with palms facing each other.” The “whole” is all the points on the number line, all the terms of the Taylor series, a “panned out” view of a map, or all the grades. It was embodied as global gestures, such as “moving both hands away from each other” or “circular motion with left hand.” The “part” was consistently viewed as an insufficient portion of the “whole” that could potentially lead to a misleading estimation of the “whole”. The ”part” can give one a “better feel” for the “whole” as more “pieces of the puzzle” are added to the “part.” Once all the pieces are in place to yield the “whole,” a sought after convergent can be clearly determined. In the context of the number line, this determination is achieved by noticing where points “mass.” The implications of the “part / whole” metaphor elaborated above gave Brian a facility to discuss convergence in multiple contexts, and thus, demonstrated the high degree of the metaphor’s resonance within Brian. His commitment to this metaphor throughout the interview tasks and his omission of other metaphors indicate the high degree of emphasis that Brian placed on the “part / whole” metaphor.

What separates this metaphor from other metaphors previously identified (see Oehrtman, 2002, 2009) lies in the entailments of the metaphor. For example, the approximation metaphor, which is commonly used by students engaging in Taylor series activities, contains entailments referencing the remainder. However, the “part / whole” metaphor contains no direct entailments to the remainder because in this metaphor, there is only the “part” and the “whole” and the

difference between the two is ignored. The insights gained by understanding this metaphor can help instructors recognize students utilizing this metaphor and engage them in a productive discourse that reveals the metaphor’s potential pitfalls and develops scientific reasoning.

THE IMPLIED READER IN CALCULUS TEXTBOOKS

Aaron Weinberg
Ithaca College
aweinberg@ithaca.edu

Textbooks have the potential to be powerful tools to help students learn mathematics. However, many students struggle to read in a meaningful way. This paper presents a framework to analyze the implied reader of a mathematics textbook; this idea is adapted from the field of reader-oriented theory and enables us to identify the skills and understandings that are required of a student to learn mathematics by reading a textbook.

Introduction

Textbooks are an integral part of most undergraduate calculus courses. They serve many purposes, acting as a compendium of homework problems and examples, a reference for definitions and theorems, and a “road map” through the course content. In addition, most calculus textbooks are designed to be read by students, as evidenced by their detailed exposition of calculus concepts. Educators have suggested many ways to encourage their students to read their calculus textbook (e.g. Boelkins & Ratliff, 2001). However, students often have difficulty using their textbook as a tool for learning mathematics. For example, consider the excerpt from a widely used calculus textbook in Figure 1:

2.7 DERIVATIVES AND RATES OF CHANGE

The problem of finding the tangent line to a curve and the problem of finding the velocity of an object both involve finding the same type of limit, as we saw in Section 2.1. This special type of limit is called a derivative and we will see that it can be interpreted as a rate of change in any of the sciences or engineering.

TANGENTS

If a curve $C$ has equation $y = f(x)$ and we want to find the tangent line to $C$ at the point $P(a, f(a))$, then we consider a nearby point $Q(x, f(x))$, where $x \neq a$, and compute the slope of the secant line $PQ$:

$$m_{PQ} = \frac{f(x) - f(a)}{x - a}$$

Figure 1. Excerpt from Stewart (2007, p. 143)

Many instructors would have little difficulty interpreting this excerpt in a meaningful way: they could tell that the authors are formally defining the concept of “tangent” and connecting this to the concepts of slope, secant, velocity, and function. However, students often complain that explanations such as this one are difficult to understand: they describe the textbook as simultaneously “too chatty” and “too technical.” For example, the following is an excerpt from an interview with an undergraduate calculus student:

Interviewer: Are there some [parts of the textbook] that you look at more than others?
Student: I think with the textbook I’m using now, I kind of skip to the definitions and the highlighted parts, especially if I’m in a hurry…. A lot of times I just feel like they’re just kind of rambling or reiterating things.

Interviewer: Do you think your books do a good job presenting… the “big ideas” in the chapter? Or… you [were] talking about how sometimes they seem to ramble on a little bit and maybe aren’t particularly clear at expressing those big ideas?

Student: I feel like the big ideas are there, but when I start to break it down, sometimes the terminology or the wording they use, you can tell it makes perfect sense to them, I’m trying to decipher it and I have to read a few sentences over a couple of times in order to get it straight in my head

In order to help students view reading their textbook as a useful way to learn mathematics, instructors need to understand what skills and characteristics a student needs to successfully read their textbook. This paper presents a framework that enables us to describe these characteristics and explain why students struggle to read meaningfully. Although the framework will be specific to calculus textbooks, it can be easily adapted to describe other mathematics textbooks. After describing the framework, we will present an example of how it may be used and discuss implications for pedagogy.

**Implied Reader Framework**

In order to explain why students express these difficulties with reading their textbooks, we will use the idea of the *implied reader*, which is a concept that originated in the field of reader-oriented theory. Much like the way modern theories of learning posit that students actively create their own understanding of mathematics, reader-oriented theory conceives of readers as actively constructing the meaning of a text as they read (Rosenblatt, 1938). When reading a textbook, each person uses their own ideas and experiences to construct an interpretation of the textbook that they find personally meaningful: as Morgan (1996) notes, “the meanings constructed from a text by its readers will vary with the resources of individual readers and with the discourse(s) within which the text is read” (p. 3).

Although the idea of the implied reader was created to describe aspects of literary texts (e.g. Wilson, 1981), Weinberg and Wiesner (In-press) extended the definition to apply to technical texts such as textbooks: they define the *implied reader* of a mathematics textbook to be “the embodiment of the behaviors, *codes*, and *competencies* that are required for an empirical reader to respond to the text in a way that is both meaningful and accurate.” These aspects are determined by the text itself, as opposed to being determined by the author. (In contrast to the implied reader, the author’s image of the reader is called the *intended reader*; the person who actually reads the textbook is called the *empirical reader*).

**Codes**

Based on ideas from semiotics (e.g. Eco, 1976), a *code* is a way of ascribing meaning to symbols, words, and other elements in a text. A reader’s codes enable him or her to interpret the textbook. While there are multiple ways to interpret an element of the text, there are only a handful of interpretations that will be valid and meaningful. Consequently, the implied reader of the textbook possesses a specific collection of codes. In addition to the codes that are required to interpret “regular” literary works, the implied reader of a calculus textbook has codes for interpreting the formatting, language, and symbols that are specific to these texts.
Formatting codes

Love and Pimm (1996) note that the formatting in the text—such as font size or color—imbues the words with particular significance. In Figure 1, the implied reader interprets the italicized words *derivative* and *tangent* as terms that are being defined. In contrast, interpreting these words as simply being emphasized would not allow the reader to understand their true significance. Similarly, the formatting of the phrases “Derivatives and Rates of Change” and “Tangents” indicate that they are describing the main idea of the section; this allows the reader to connect the ideas within the section back to this main idea. If an empirical reader does not possess these codes, they may interpret the formatting as simply a cue to begin and end reading.

Formatting codes can be categorized in the following ways:

- Typeface (e.g. font, boldface, italics, color)
- Page layout (e.g. indentation, positioning of figures)
- Delimiters (e.g. text boxes or background colors)

Language codes

Words and phrases that are used in mathematical writing often have particular meanings that go beyond their everyday usage. These can be classified into four categories: mathematical words, definitions, logical statements, personal pronouns, and imperative verbs.

There are many words that have specific meanings when used in mathematical contexts. The implied reader interprets mathematical words such as “approach,” “point,” and “curve” as having specific meanings in a mathematical context. If the empirical reader lacks these codes, he or she will not be able to think about the mathematical objects and ideas in appropriate ways. These mathematical words can be divided into four categories: words that have been formally defined for the reader in a mathematical context (e.g. “limit” or “equation”); words that are not formally defined (e.g. “let” or “exist”); metaphorical use of words (e.g. “nearby” and “approach” rely on a metaphor of position); and terms from other domains (e.g. “velocity” and “displacement”).

The implied reader has codes to recognize and interpret definitions of terms, definitions of notation, and basic logical statements. For example, phrases such as “a curve $C$” and “the point $P(a, f(a))$” indicate both that a mathematical object is being created and that it is being connected with the notation and that a mathematical object is being created. Statements such as “If a curve $C$... then we consider...” create a logical relationship between the two clauses. The implied reader to mentally creates a “curve” and then responds to the imperative in the second clause. If the empirical reader lacks this code, he or she will not see the important conceptual relationship.

The use of the personal pronoun “we” is pervasive in mathematics textbooks. Morgan (1996) notes that there are two ways it is used: to invoke the authority of the community of mathematicians or to include the reader as an active participant in the mathematical activity (p. 5). The implied reader of a calculus textbook distinguishes between these two uses and thinks of their relationship with the textbook in the corresponding way.

Textbooks contain numerous imperative verbs, some of which appear as part of “we...” statements (such as “we consider” and “we... compute”). Rotman (2006) describes two basic functions of these verbs: inclusive verbs invite the reader to “establish a shared domain, ... introduce a standard, mutually agreed upon ensemble of signs,” and “share some specific argued conviction about an item in such a world” (p. 104); examples of inclusive verbs are “consider,” “define,” and “prove.” In contrast, exclusive verbs “dictate that certain operations meaningful in an already shared world be executed” (p. 104); examples of exclusive verbs include “integrate”,

---

“count”, and “compute”. The implied reader distinguishes between inclusive and exclusive forms to determine how they must interact with the ideas in the textbook.

**Codes for mathematical symbols and pictures**

In addition to words, calculus textbooks typically contain many printed symbols and pictures. For example, in the symbol string “\(P(a, f(a))\),” the implied reader of the textbook interprets this string of symbols in a mathematical context as opposed to a literary context. Then the implied reader recognizes the symbol \(P\) as the name of a point and the outer parentheses as delimiting the point’s coordinates; the \(a\) is interpreted as a specific (but undetermined) value of the independent variable and the \(f(a)\) is interpreted as the corresponding value of the dependent variable (using the previously-defined equation \(y = f(x)\)).

The symbols used in calculus textbooks are primarily algebraic; these are most frequently used to represent numbers, variables, functions, infinitesimals (e.g. \(dx\)), arithmetic operations, limits, and operators (such as derivatives and integrals). In addition to these symbols, calculus textbooks frequently include Cartesian graphs, pictures (such as a depiction of a falling object) and other diagrams. The implied reader has codes to interpret the common features of graphs (e.g. axes, units, points, lines, curves, intervals/distances). The codes that are required to interpret other pictures and diagrams vary widely. For example, consider the graph in Figure 2 (which appears in the textbook after the excerpt in Figure 1). In addition to the “standard” codes for a Cartesian graph, the implied reader also has codes to interpret the three points labeled \(Q\) as depicting multiple steps in a limiting process in which secant lines approach the tangent line at \(P\).

![Figure 2. A graph/picture from Stewart (2007, p. 144)](image)

**Competencies**

While codes enable readers to interpret symbols, words, and phrases, competencies enable readers to work within the established context. These competencies are comprised of the reader’s mathematical knowledge, skills, and understandings, their knowledge and understanding of real-world concepts, and their ability to “objectify” mathematical ideas.

For example, in the excerpt in Figure 1, the implied reader knows that a function is a relationship between inputs (\(x\)) and outputs (\(y\) and \(f(x)\)), has a graphical representation (a “curve”), and is comprised of coordinate pairs; the implied reader also knows how to compute the slope between any two points. In terms of real-world concepts, the implied reader knows what “velocity of an object” and “rate of change” are, how position can be thought of as a function, and how velocity can be computed by finding the slope between two points. If the empirical reader lacks these competencies, they will be unable to understand functions in a meaningful way or connect and use the abstract ideas in other contexts.

There are many concepts in algebra and calculus that must be thought of as having both process- and object-like properties. For example, a reader might think of the symbols \(P(a, f(a))\) or \(Q(x, f(x))\) as representing the process of picking an \(x\)-coordinate and computing the value of...
However, to correctly work with the concept that is described by the phrase “then we let $Q$ approach $P$,” the implied reader thinks of $P$ and $Q$ as “objects” that can be manipulated and can themselves act by “approaching” one another. Morgan (1996) described this transformation of processes into objects as “nominalization” and other researchers have described similar transformations (e.g. Sfard, 2000).

**Behaviors**

*Behaviors* are sequences of actions (either physical or mental) that the implied reader performs in order to understand the textbook. Calculus textbooks contain both *structurally embedded behaviors* and *directives*.

**Structural embeddings**

Calculus textbooks are “linear” in that each chapter, section, sub-section, paragraph, and sentence in the textbook “presumes that the functions and tasks assigned explicitly or implicitly to the reader have been carried out satisfactorily” (Love and Pimm, 1996, p. 381). Consequently, the implied reader develops ideas, vocabulary, and symbolism in the same order as the book presents them.

**Directives**

In Figure 1, phrases such as “we consider” and “compute” require that the implied reader imagines the appropriate point or thinks about computing the slope; these imperative statements are examples of explicit directives. After interpreting the directive, the implied reader undertakes various actions such as following a procedure or engaging in more complicated mental behaviors.

In addition to these explicit directives, the implied reader also responds to requests that are not made explicit. For example, the opening clause—“The problem of finding the tangent line to a curve”—prompts the implied reader to recall the “problem” that the text previously described. Similarly, when the implied reader sees the expression $x \neq a$, they imbue this with meaning by referring back to the definitions of these symbols. These are examples of *implicit directives*.

The behaviors undertaken by the implied reader in response to these imperatives and directives can be classified in the following way:

- Make a connection with the ideas, symbols, or definitions in another text section
- Make a connection to an external idea (from real life)
- Generalize important mathematical ideas from examples
- Follow a procedure (e.g. follow and replicate the steps of an example)
- Engage in other mental behaviors

**Applying the framework**

The method for identifying the implied reader of a calculus textbook is for an expert reader to read and recognize what he or she must know, understand, or do in order to generate a correct interpretation. The excerpt in Figure 1 is analyzed here; all of the numbers referenced in the analysis refer to the corresponding numbered boxes in the figures.

**Analysis of Codes**

First we can investigate the language codes in Figure 3. The personal pronouns (L6, L8, L12 and L17) serve to include the reader as an active participant by inviting them to share the goals and mathematical activity of the author. For the same reason, the imperatives in L12 and L17 are
inclusive: they ask the reader to seek motivation for defining the “tangent line,” examine the “nearby point,” interact with the points “Q” and “P,” and name and construct the concept of “tangent line.”

In contrast, L19 requires the reader to produce a new mathematical object by operating in an already-established semiotic space. There are numerous mathematical words that the implied reader interprets, some of which have been defined (L1, L5, L11, L20, L21) and others that may not have been defined (L2, L10, L15). There is a reference to a physical concept (L4) and several places in which the implied reader applies a metaphor of physical position (L13, L14, L18). The implied reader recognizes that L7 is connecting a term with its definition, while L10, L11, L15, and L21 are defining notation. In addition, the reader must interpret the logical connection in the “if… then” pair (L9 and L16) as described previously.

Next, we can investigate the formatting and symbol codes in Figure 3. The italics indicate that “derivative” is being defined (F3) and also that the letters represent mathematical entities (e.g. F4, F5). The position and typeface of words in F1 mark the beginning of the section and also describe its main idea; the indentation (F2) indicates that the subsequent text is an elaboration on this idea. The symbol groups S1, S3, S4, and S6 indicate that a mathematical object is being named, with S1 representing an object with one component and the others representing objects with two coordinates or endpoints. In S2, S3, S4, S5, and S7, the \( x \) and \( a \) are interpreted as a variable and an undetermined value of the variable, which are connected to the concept of a coordinate pair by equating \( y \) and \( f(x) \). The equals signs in S2 represents an identity between two different types of objects; in S5 it shows the (non-)identity of the same type of object, while in S7 it serves to define notation.

**Analysis of Competencies**

Figure 4 shows the competencies of the implied reader. The implied reader knows that a curve is a geometric representation of an algebraic relationship (1, 5, and 7) and thinks of it as an object that possesses properties (6). The implied reader knows that the curve is comprised of points (9), each of which has coordinates (10, 12) that are linked by the underlying function, which can be expressed algebraically (7). The implied reader understands the concept of slope (14), how it is computed (16), that two points (11, 13) can be connected to form a secant line (15) which approximates a tangent line at a point (1, 8) through a limiting process (3) which generalizes the idea of slope. The implied reader understands and is fluent with the algebraic notation (e.g. 13, 16), interprets the notation as an algebraic generalization, thinks of the notation

---

as representing an object (16), and connects all of these ideas to their understanding of real-world concepts of rate and velocity (2, 4).

Figure 4. Analysis of competencies

Analysis of Behaviors

Figure 5 shows the behaviors of the implied reader. The structurally embedded behavior means that the implied reader will have read previous sections of the textbook prior to the section in the excerpt; the implied reader also reads all of the numbered boxes in order.

There are three explicit directives (8, 9, and 10) that the reader follows. There are also numerous implicit directives. In 1 and 2, the implied reader makes a connection to the previous text sections in which the indicated “problems” were first described. In 3, the implied reader connects these two problems and then connects the problems to the concept of “type of limit” in 4, referencing the previous section in the text as necessary in 5. In 6, the implied reader connects these ideas to the real-world concept of “rate of change”. In 7, the implied reader assigns meaning to the symbol “C” and associates this definition with the concept and symbolism of the “equation” (this behavior is replicated when the symbols P, Q, PQ, and \( m_{PQ} \) are defined). After
the implied reader assigns meaning to the individual symbols in 11, they mentally perform the indicated arithmetic operations and think of the result as a new mathematical object.

**Analysis**

The concept of the implied reader enables us to describe what an empirical reader must understand and do in order to read a mathematics textbook meaningfully. In the analysis of the implied reader, we see that the reader must perform a wide range of mental activities, that each text element may have multiple associated codes, competencies, and behaviors, and that there can be many of these “components” in a very short space.

The analysis of the textbook excerpt (Figure 1) sheds light on why instructors may view a textbook as a useful source of explanations but students may find it difficult to read. Instructors are more likely than students to possess the codes, competencies, and behaviors of the implied reader, which enables them to construct correct mathematical meaning while reading.

The students’ difficulties can be explained by the characteristics of the codes, competencies, and behaviors of the implied reader as well as the density of these components. If the components are similar to those that students already possess, then students should be successful at constructing knowledge from reading their textbook; if the implied reader’s codes, competencies, and behaviors are closer to those of a mathematician, or if they are too densely packed, students will struggle to interpret the text correctly. As a result, students might view a textbook as “rambling” when they do not possess the correct codes to understand the underlying meaning, and they may see it as “too technical” when many components occur close together.

Analyzing the implied reader of a textbook can be useful for instructors, who play an important role by mediating the way students interact with the textbook (Luke, de Castell & Luke, 1989); that is, instructors choose the textbook, decide which parts of the book to use, and encourage particular uses of the textbook. In order to help students use a textbook as an effective tool for learning mathematics, instructors need to identify the codes, competencies, and behaviors of the implied reader and then help their students develop these characteristics. However, instructors must take care not to solely focus on “translating” specialized mathematical vocabulary, syntax, and symbolism. The theoretical foundation of the idea of the implied reader rests on the notion that the reader actively constructs the meaning of the text. Consequently, instructors must help their students build the codes, competencies, and behaviors of the implied reader in a way that enhances their ability to generate meaning as they read. This use of the textbook is in contrast to a typical perspective of the use of mathematics textbooks, in which reading is seen as “only… a necessary kind of ability in order to become active in situations where learning can take place (i.e. solving given tasks)” (Osterholm, 2006, p. 326).

The idea of the implied reader also has consequences for authors of textbooks. Specifically, calculus textbook authors should analyze their own writing to identify the codes, competencies, and behaviors that will be required of their reader. Even though some textbooks claim to be written in “plain English”, the implied reader may still possess sophisticated aspects that will make the reading process difficult for undergraduate mathematics students.

**Endnotes**

1. Each type of mathematics textbook requires specific types of knowledge and interpretations. For example, an undergraduate abstract algebra textbook typically follows a “theorem-proof-example” format and requires the student to understand particular types of logical arguments; this is very different from a college algebra or a calculus textbook.

CALCULUS STUDENTS’ CONCEPT IMAGES OF ASYMPTOTES, LIMITS, AND CONTINUITY OF RATIONAL FUNCTIONS

Girgia Nair-Hart

University of Cincinnati Clermont College

nairhaga@ucmail.uc.edu

This study was designed to investigate college students’ concept images of rational functions, asymptotes, limits and continuity beyond the algorithmic knowledge. A two-hour long problem solving interview was conducted by the use of CORI, the problem solving instrument. Nineteen students taking a university calculus course participated in the video taped one-to-one interview.

Introduction

During the past few years, I was confronted with high school and college students’ incomplete conceptions regarding asymptotes of rational functions. Inconsistent conceptions often interfere with students’ learning of mathematical concepts. The identification of asymptotes plays a central role in the study of rational functions and its limit properties. The study of asymptotes and the exploration of rational functions are based on algebraic manipulations of expressions. Students don’t always fully understand the concept. They still move on to calculus courses. There, they are introduced to the concepts of limits and continuity. They do not fully understand them either. During the instruction of limits, asymptotes are touched upon again. The formal definition of continuity is presented again in terms of limits and students struggle with this definition too. May be the concepts of asymptotes, limits, and continuity together could be emphasized so that students’ understanding of all of these concepts could be enriched. Before doing that, it is important to find out student notions of these concepts beyond the algorithmic level.

Theoretical Framework

According to Piaget (1970), students do not come to our classes as blank slates. They might have encountered certain aspects of a concept before that concept was formally introduced to them. Therefore, at times, their prior experiences with a certain concept could interfere with the newly introduced aspects of the concept. In this case, learners will need to modify their pre-existing internal schemes of the concept in accordance with the new conceptual input. According to Piaget, schema stands for a person’s internal conceptual configurations. Similar to Piaget’s view Tall and Vinner (1981) stated that mathematical concepts that students learn informally are often incomplete. They referred to students’ interpretations of the concept definition, which were influenced by their pre-existing notions of the concept, as concept images. Misconceptions or incomplete conceptions occurred as a result of students viewing the concept definition through the lens of pre-existing concept images that are at odds with the formal concept definition. For example, before formally learning the concept of limits, students are familiar with the terminology limit in daily life. The meaning of this word is interpreted differently by different people. For example, when referred to an off limits situation, the meaning of limit cannot be attained is implied while in another situation such as age limit 5, the implication is that the limit cannot be surpassed. Due to this confusion, students acquire different meanings and interpretations while dealing with the concept of limits. One such dilemma causes uncertainty in students whether limit can be obtained, or can be surpassed. Students’ incomplete conceptions
could be analyzed from the perspectives of the innate nature of mathematical truth (Moru, 2006; Cornu, 1991; Grey & Tall, 1994), the limitations of instruction and instructional resources (Clement, 2001; Sajka, 2003; Zaslavsky, 1997), and students’ beliefs and attitudes regarding the nature of mathematics knowledge and the goals of mathematics instruction (Szydlik, 2000).

**Research Questions**

1. What are student notions of rational functions?
2. What conceptions do students possess regarding asymptotes, in particular the horizontal and vertical asymptotes of rational functions?
3. What connections do students make between the concepts of asymptotes, continuity, and limits of rational functions?

**Methodology**

Qualitative methodology was used to conduct this research. Nineteen Calculus 2 students from a large midwestern university participated in the study. Participants were freshmen students among which, 15 of them were engineering majors, one a mathematics major; one a psychology major, and two geology majors. Student conceptions regarding rational functions, asymptotes, limits, and continuity were assessed using the Concept Organizer Response Instrument (CORI). Interview questions were semi-structured and were designed to gather information on students’ thinking. The goal of the interview was to gain an in-depth understanding of students’ thinking processes while solving problems. Students were asked to solve problems on the test booklet while talking aloud explaining their thought processes. In addition, the researcher asked probing questions of students to help further clarify the reasoning behind the work they performed.

The interviews were video taped. The video tape analysis was conducted and common traits in student responses were compiled. Students’ written work was examined to further clarify researcher’s interpretations of students’ explanations of the problems solved.

**Results**

Students’ incomplete concept images of rational functions fell mainly into three categories: the rational number image, the fraction image, and the discontinuity image. Students who possessed the rational number image described that the graphs of rational functions are “nice,” “whole,” “even,” and “symmetric.” They further clarified that the graphs of rational functions looked like that of linear and quadratic functions and that they were “one-piece,” “continuous,” and “without any complications.” Some students specified that like rational numbers, such as \( \sqrt{4} \) and \( \sqrt{9} \), these functions were “whole.” These students’ concept image of rational numbers were restricted to that of numbers like \( \sqrt{4} \) and \( \sqrt{9} \). The rational number conception was the most prevalent conception that students held of rational functions.

Some students believed that rational functions assumed fraction forms with no variable in the denominator. According to this conception, like fractions, rational functions could only have constants in the denominator. Those students who held the discontinuity image believed that all rational functions had variables in the denominator, and therefore were discontinuous- they came in several pieces, and had vertical asymptotes.

Student notions about asymptotes in general fell in to the categories of the three-piece graph image, the invisible line image, and the no-concurrency image. The three-piece graph image reflects graphs with two vertical asymptotes and one horizontal asymptote that were symmetric.
with respect to the Y-axis. Three-piece graphs were also comprised of graphs with two vertical asymptotes and no horizontal asymptote and were symmetric about the origin. Students also believed that asymptotes were dotted lines the graph approached but never reached. The no-concurrency images held by students lead them to believe that a graph must never be concurrent with any of its asymptotes.

Regarding particularly on vertical and horizontal asymptotes, students held a variety of notions. All students associated vertical asymptotes in connection with multiple views of undefinedness. Most students stated that vertical asymptotes occurred at points where the function was undefined. However, several students did not know when a rational function, such as

\[ f(x) = \frac{2x - 1}{3x + 5} \]

became undefined. Some believed that all functions including functions of the form

\[ g(x) = \frac{17}{x^2 + 1} \]

had a vertical asymptote since there was a variable in the denominator.

While 4 students knew about the possibility of having either a hole or a vertical asymptote at the points where the rational function was undefined, two students believed that both a hole and a vertical asymptote occurred simultaneously at points where a rational function was undefined. Such cases were described as point asymptotes by one student. In addition, the belief that vertical asymptotes could occur at jump discontinuities was also noted.

Among the students who knew about the possibility of having either a hole or a vertical asymptote at the points where the rational function was undefined, the majority of the students were unable to distinguish between the conditions under which a hole occurred for a rational function. Even though students had seen graphs with holes and have realized that the function would be undefined there, many of them were unable to differentiate between the function behavior around holes and around vertical asymptotes. The confusion between holes and vertical asymptotes seems to have stemmed from noticing no distinction between the \[ \frac{0}{0}, \frac{0}{b}, b \neq 0 \] forms.

In many ways, student notions of horizontal asymptotes were similar to that of vertical asymptotes. Some dilemmas were centered on the inability to find the equation of the horizontal asymptote, and the belief that a graph cannot be concurrent with its horizontal asymptote. Other problems seem to have stemmed from not knowing the function behavior around its horizontal asymptote, and the inability to identify horizontal asymptote from the limit form. The inability to use appropriate terminology while describing horizontal asymptotes and the failure to write the function term corresponding to a specified horizontal asymptote was also a problem. In addition students believed that horizontal asymptotes occurred at cusps.

In regards to the concept of limits, students experienced problems with the correct usage of terminology. While referring to limits, in regards to terminology, instead of stating “as x approached a, f(x) approached L,” the roles of x and y and x and f(x) were often interchanged, or instead of stating x, or f(x), or y, the word it was used. Other difficulties included problems with computing limits, and problems with connecting limits with asymptotic behaviors of functions. While computing limits students used direct substitution when there was no graphing calculator available. In some instances, students substituted infinity directly in place of x and wrote, \( \frac{\infty}{\infty} = \infty \), \( \infty/\infty = 0 \), \( \infty/\infty = \text{undefined} \). They were unable to compute infinite limits and limit at infinity.

While dealing with forms such as \( \frac{b}{0}, b \neq 0 \), \( \frac{\infty^2}{\infty}, \frac{\infty}{\infty}, \frac{\infty}{\infty^2} \) students gave up and stated that limit (not necessarily in the finite sense) cannot be found, or did not exist.

In addition, they were unable to recognize function limits from their graphs. Identification of limit from function graphs posed challenges for many students. Some students believed that no limit existed at a point if the function was undefined at that point. In some instances, students stated that if \( f(x) \) had a hole at the point \((2, -7)\), as \( x \) approached 2, the limit of the function would be \(-7\). However, if the function \( f(x) \) had a removable discontinuity at \((2, -7)\) such that \( f(2) = 3 \), then as \( x \) approached 2, \( f(x) \) would approach 3. Some students, while computing limits stated that in cases such as \( \lim_{x \to 7} \frac{11}{x - 7} \), which produced the \( \frac{11}{0} \) form, the function limit would be 11. In this student’s view, since \( \frac{11}{0} \) was *undefined* and therefore cannot be attained by the function, the limit of the function should be 11 the *attainable* part of \( \frac{11}{0} \).

Regarding continuity, some students believed that a function was discontinuous at sharp corners and a function was continuous everywhere in its domain if the domain was all real numbers. They also believed that both jump and removable, discontinuities produced vertical asymptotes at the points of discontinuity. Some others believed that whenever the left hand limit was equal to the right hand limit, the function was continuous at that point.

It must be noted that the majority of students demonstrated correct understanding of the concept of continuity by specifying that in order for the function \( f(x) \) to be continuous at a point, say, \( x = a \), \( \lim_{x \to a} f(x) \) must exist and must also be equal to \( f(a) \). While answering the question whether a function with all real number domains should always be continuous, several students immediately answered yes, but, as soon as they started sketching a function, they recanted their answer by creating a hole on the curve and placing a point that indicated a removable discontinuity. It should be noted that these students did not display a function with jump discontinuity as a counter example. Understandably, it would be a lot easier to alter a continuous function to one that had a removable discontinuity rather that altering it into a function with a jump discontinuity.

**Conclusion**

Nineteen Calculus II students’ concept images of asymptotes, limits, and continuity were investigated by the use of a problem solving interview. The instrument for this interview, CORI, was developed to solicit student intuitions by the use of atypical problems that required thinking *out of the box*. Each interview lasted about two hours. I was particularly interested in students’ incomplete concept images so that I could try to employ instructional methods that would help students reconfigure their inconsistent concept images.

Students generally possessed a process-oriented view towards mathematics problem solving. While holding numerous incomplete conceptions regarding rational functions, their asymptotes, limits and continuity, students failed to establish connections between these highly related concepts. Students were unable to explain the behavior of functions around its asymptotes and they were unable to relate the asymptotic properties of functions in terms of limits. Without being able to relate to the ways in which function behavior was affected by its asymptotes, students were unable to find limit at infinity and infinite limit without a graphing calculator.
Endnotes

1. This paper is a part of my dissertation, *College Students’ Concept Images of Asymptotes, Limits, and Continuity of Rational Functions*, completed under the direction of Dr. Douglas T. Owens; Professor, College of Teaching and Learning, The Ohio State University, Columbus, Ohio.

CALCULUS STUDENTS, FUNCTION COMPOSITION, AND THE CHAIN RULE

Aladar K. Horvath
Michigan State University
horvat54@msu.edu

This study focused on calculus students’ routines of function composition while working on chain rule tasks. The functions used in these tasks are functions with which they are familiar, somewhat familiar and not familiar. Previous research on the chain rule has indicated that function composition is an important concept for understanding the chain rule. The significance of function composition to the chain rule, provided a useful context in which to study function composition. Sfard’s (2008) commognitive framework was used to analyze transcript data and identify these routines. The results identify nine different routines across the different types of functions.

Introduction

Although the teaching and learning of the function concept has received much attention in the research literature (Ferrini-Mundy & Graham, 1991; Harel & Dubinsky, 1992; Monk, 1994; Oehrtman, Carlson, & Thompson, 2008; Vinner & Dreyfus, 1989) there have been few studies that have focused on student learning and/or understanding of function composition (Engelke, Oehrtman, & Carlson, 2005). That limited research has noted that students experience difficulties with the notation used for composite functions as well as the representation (algebraic, tabular, graphical) that they use. Meel (1999) noted that students interpreted both \((f \circ g)(x)\) and \(f(g(x))\) notations as function multiplication resulting with either \((f(x) \cdot g(x)) \cdot x\) or \(f(x) \cdot g(x)\). Hassani (1998) and Engelke, et al. both reported that students were more successful in tasks using algebraic representation than in either graphical or tabular representation. Engelke, et al. studied precalculus students at the end of their course and documented that these students answered function composition tasks correctly 94%, 43%, and 41% of the time algebraically, graphically, and tabularly, respectively. Similarly, Hassani performed a teaching experiment on calculus students. Students’ performance on function composition tasks on pre-review and post-review tests were all lower than those reported by Engelke, et al. for each representation. Hassani’s study, however, did not end there. Following the post-review test, the students were instructed on the chain rule. After this instruction, students’ performance improved remarkably and correctly answered function composition tasks 84% of the time graphically and 63% tabularly. She concluded that studying the chain rule improved students understanding of function composition. Additionally, she reported that this prior lack of function composition knowledge did not have a significant role in students’ understanding of the chain rule rather that the knowledge needed to be “gained by the time they apply the chain rule” (p. 193). She concluded that there seemed to be a relationship between the chain rule and function composition that improves the understanding of each.

Research on the learning of the chain rule has highlighted the importance of function composition to the chain rule concept (Clark, et al., 1997; Cotrill, 1999; Hassani, 1998; Webster, 1978). Using a teaching experiment Webster (1978) concluded that there was no significant difference on the chain rule post-test between the groups receiving extra instruction on function composition and those that did not. In contrast, Clark et al. (1997) using the APOS framework (see Asiala, et al., 1996) “came to the conclusion that the [students’] difficulties with the chain

rule…could be attributed to student difficulties in dealing with the composition and decomposition of functions” (p. 360). Cottrill (1999) completed a follow-up study to the Clark’s et al. study. Cottrill’s findings were inconclusive whether “understanding of composition of functions is fundamental to understanding the chain rule” (p. 58). Cottrill further suggested that a new study that collected data from interviews instead of a written questionnaire was needed to address this issue.

These mixed findings and conclusions about the relationship between the chain rule and function composition illustrate the need for both a clear research focus and good task design. Each of these studies were either broad or had purposes other than or in addition to studying function composition. These studies acknowledged that function composition played a role in understanding the chain rule, but its role was elusive to studies which had different foci. One major change in my study is that I am reversing the emphasis. Instead of studying the chain rule as the object of study and using function composition as a lens, function composition is the object of interest and the chain rule is being used as the lens.

Using chain rule tasks as a window to study function composition enables this concept to be observed in a rich context. As noted above function composition is an integral part of the chain rule. Furthermore, this extends the existing research beyond simply asking students to find $f(g(4))$ or $(f \circ g)(4)$ algebraically, graphically, and/or tabularly. In the chain rule context they must create a composite function from two given functions, take the derivative of the composite function which may involve function composition, and then evaluate the derivative function which again may involve function composition. Thus, the chain rule has the potential to create multi-step function composition tasks and students’ use of function composition concepts can be tracked across each step as well as the whole problem. This can give a wider and richer view of students’ use of function composition.

**Theoretical Framework**

This study utilized Sfard’s (2008) commognitive framework. As the term commognition suggests, this perspective combines communication with cognition. In this perspective thinking is a form of communicating. Thus thinking and communicating are merely “different (intrapersonal and interpersonal) manifestations of the same phenomenon” (Sfard, 2008, p. 296). Thus, observable words (and nonverbal forms of communication) are still just words and are studied as such. This is in contrast to a strictly cognitive perspective which considers observable words as pointers that are used to study and make claims about unobservable phenomena that exists inside the head.

The focus of this study will be on students’ routines. From the commognitive perspective a routine is a set of rules “that repeats itself in certain types of situations” (Sfard, 2008, p. 301). This means that it must happen a minimum of two times otherwise it does not satisfy the repetition requirement of a routine. A routine has three parts to it. First is the **applicability condition**. This is the set of rules that evokes or conjures up the need to start an action. The action itself is called the **course of action** or procedure of the routine (e.g., an algorithm). At some point the procedure comes to an end. These ending rules are called the **closure** or the indication to stop the course of action. The applicability condition and closure are part of the **when** of a routine, while the course of action is the **how** of a routine.

The when of a routine is difficult to identify. Two routines may differ only by the when of the routine. For example a mathematics student may learn the steps of an algorithm and does them the same way that his or her instructor does it. On a subsequent homework assignment or...
test the student encounters a problem that he or she is unable to solve. While the teacher considers this new problem as needing the algorithm discussed in class, the student did not have the same conditions that would evoke the need to apply the algorithm. Even though the course of action was the same for both the student and the teacher, the applicability conditions were different. Not only can the applicability conditions be different with the same course of action, but the closure can also be different between individuals. For example two individuals solving a system of linear equations may stop at different points. One person may stop when he or she comes to the statement $x = 5$ (or some number). Another may not stop until the equations are evaluated at $x = 5$ to check for consistency. All three parts are essential components of a routine.

**Research Methods**

While the focus of this study was on students’ routines, given the difficulty of identifying applicability conditions and closure, most of the findings are about students’ course of action(s). The specific question that guided this research was: What are calculus students’ routines of function composition in chain rule problems? Specifically, what do students do with functions with which they are familiar, somewhat familiar, and not familiar? The familiarity level of a function was determined by when students typically encounter each type of function (calculus, precalculus, never). For example, polynomial and trigonometric functions were classified as Familiar because students experience them in many calculus contexts including the chain rule. Transcendental functions were classified as Somewhat Familiar because students encountered them in precalculus, but at the time of this study they had not encountered them in any calculus context. A third task called the Flowers-Colors Task was classified as Not Familiar. It was expected that students had not come across functions like the ones used in this task. It involved functions with the names of flowers and colors. Figure 1 contains the Flowers-Colors task.

Flowers – Colors Task:
Suppose $\text{roses}(x)$, $\text{violets}(x)$, $\text{red}(x)$, and $\text{blue}(x)$ are all differentiable functions and have the following derivatives:

\[
\frac{d}{dx}(\text{roses}(x)) = \text{red}(x) \quad \frac{d}{dx}(\text{violets}(x)) = \text{blue}(x) \]

\[
\frac{d}{dx}(\text{red}(x)) = \text{red}(x) \quad \frac{d}{dx}(\text{blue}(x)) = \frac{3x + 1}{x^2}
\]

1. $f(x) = \text{roses}(\text{violets}(x))$
   a. Find $f'(x)$

2. Find the derivative of $h(x) = f(g(x))$ where $f(x) = \text{blue}(x)$ and $g(x) = \text{violets}(x)$
   a. Find $f'(x)$ and $g'(x)$
   b. Find $h'(x)$

3. Find the derivative of $h(x) = (f \circ g)(x)$ where $f(x) = \text{roses}(x)$ and $g(x) = \text{red}(x)$
   a. Find $f'(x)$ and $g'(x)$
   b. Find $h'(x)$

---

The Flowers-Colors Task needed to explain that these were names of functions and that these functions were differentiable. This task was modified from a task created by Webster (1978). Modifications included adding the derivatives of the functions \(\text{red}(x)\) and \(\text{blue}(x)\). These were added for two reasons.

First, so that it could be determined where students would stop multiplying by the derivative. Instructors of calculus informally consulted prior to data collection mentioned that students may answer part a by claiming that \(f'(x) = \text{red}(\text{violets}(x)) \cdot \text{blue}(x) \cdot \text{blue}'(x)\) with the extra \(\cdot \text{blue}'(x)\) in the answer. By including \(\frac{d}{dx}\text{blue}(x)\) in the problem statement, students that apply the chain rule in this manner would not be affected by this information being absent.

Second, the derivatives of the colors were made to be similar to transcendental functions. Thus \(\text{red}(x)\) is similar to exponential functions and \(\text{blue}(x)\) is similar to the natural logarithmic function in that the derivative is a rational expression. In a pilot study it was difficult to determine if and what kind of effect the rational expression in the derivative statement of \(\ln x\) had on students’ answers. This second rational expression was included to learn more about its effect.

Participants & Data Collection

Ten first-year calculus students enrolled at a large Midwestern university during the summer semester volunteered to participate in this study. The textbook being used for the course was Thomas’ Calculus \(11e\). Each participant was interviewed individually for approximately one hour. The task-based interviews took place after the students had been tested over the chapter that covered the chain rule (Chapter 3) and before any in-class instruction on differentiation techniques for transcendental functions (Chapter 7). Each interview was both audio- and videotaped. Additionally all written work of the participants was collected for analysis.

Data Analysis

The data was analyzed in multiple ways. First, transcripts were also made following the interviews detailing what was said and what was done. The relationship between what was said and what was done was also included on the transcript. Participants’ pointing helped to make clear the meaning of words like “this,” “that,” “here,” and “there.” Pointing also helped to identify what participants were considering when they were silently thinking.

The written work and transcript data was first evaluated for the correctness. Categories were then made that described the students’ solution methods. These categories came out of the data and were not decided upon prior to data analysis. Due to the complexity of the tasks, a single category could not appropriately or adequately describe students’ solution methods or course of action. For example given the functions \(f(x) = 5x + 7\), \(g(x) = x^2 + 3x\), and \(h(x) = (f \circ g)(x)\), one participant stated that \(h(x) = f(x) \cdot g(x)\) or \(h(x) = (5x + 7) \cdot (x^2 + 3x)\) and that \(h'(x) = f'(x) + g'(x)\) or \(h'(x) = 5 + (2x + 3)\). Since deriving a formula for \(h(x)\) involved multiplication and deriving a formula for \(h'(x)\) involved something that appeared similar to the addition rule, a more complex categorical system was needed.

This was achieved by dividing the tasks into two parts and each part receiving its own categorization. The first part was the participants’ solution methods to derive a formula for the composite function \(h(x)\). The three categories from this part of the task were Composition, Multiplication, and Addition. The Composition category involved the participant using
Chapter 1: Advanced Mathematical Thinking

The mathematical functions $h(x) = f(g(x))$ while the Multiplication and Addition categories involved $h(x) = f(x) \cdot g(x)$ and $h(x) = f(x) + g(x)$, respectively. The remaining part of a task was the solution methods participants used to find a formula for $h'(x)$. Eight categories emerged from this part of the data. Half of these were actual rules of differentiation which included the power rule, the product rule, the addition rule, and the chain rule. The remaining four categories included alterations to these rules. These categories were Composition & No Chain Rule, Multiply Derivatives, Chain Adding, and Chain Times-ing which involved $h'(x) = f'(g(x))$, $h'(x) = f'(x) \cdot g'(x)$, $h'(x) = f'(x) + g'(x)$, $h'(x) = f'(x) \cdot g(x) \cdot g'(x)$, respectively. For example if $f(x) = \sin x$ and $g(x) = x^2$, then Composition & No Chain Rule would be $h'(x) = \cos x^2$, Multiply Derivatives would be $h'(x) = (\cos x)(2x)$, Chain Adding would be $h'(x) = (\cos x) + (x^2) + (2x)$, and Chain Times-ing would be $h'(x) = (\cos x) \cdot (x^2 \cdot 2x)$. Further illustrations are included in the next section for each of these categories.

Since a routine is something that is repeated, a solution method was not categorized as a course of action until it appeared a minimum of two times. This minimal requirement could be satisfied in two ways: (a) a single participant doing the same solution method on two different tasks or (b) at least two different participants doing the same method on any of the tasks. If two different participants did the same method on different tasks, then the two times requirement was satisfied.

Results

This section is organized according the familiarity level of the functions in the tasks. The findings of familiarity tasks will be presented starting with familiar, then somewhat familiar, and ending with not familiar.

Familiar Tasks

The familiar tasks included the polynomial functions $f(x) = 5x + 7$ and $g(x) = x^2 + 3x$. All ten participants found $f'(x)$ and $g'(x)$ by using the regular Power Rule and Constant Rule. These were described as multiplying the coefficient by the exponent and subtract one from the exponent to form a new exponent and zero, respectively. The second part of this task defined $h(x) = (f \circ g)(x)$, the composition of $f(x)$ and $g(x)$. The specific task was to find the derivative of $h(x)$ at $x = 3$. All ten participants first derived a formula for $h(x)$ before proceeding to the derivative. To derive $h(x)$, six were categorized as Composition, three as Multiplication, and one as Addition. After deriving a formula for $h(x)$ the participants proceeded to find the formula for $h'(x)$. Six participants used the Power Rule, one used the Product Rule, two used the Addition Rule, and the remaining one used Chain Adding. After each participant derived a formula for $h'(x)$, all ten evaluated that formula at three in the same manner, which was to “plug in three for x.”

Somewhat Familiar Tasks

The Somewhat Familiar Tasks involved the natural logarithmic function. The first task defined the composite function $g(x) = \ln(-x^3)$ with the instructions to find $g'(2)$. The participants first derived a formula for $g'(x)$ and then evaluated $g'(2)$. Nine of the ten participants completed this task. The remaining participant focused on properties of logarithmic
functions (e.g., \( \ln x^2 = 2 \ln x \)) and decided that she could not do this problem because she could not remember all of the properties. All nine participants that completed this task derived a formula for \( g'(x) \) and then, as occurred in the Familiar task, plugged in 2 to evaluate his or her function. Five participants’ solutions were categorized as Composition & Chain Rule, three as Composition & No Chain Rule, and one as Composition & Chain Adding. For this task these categories took the form of \( \frac{1}{-x^2} \cdot 3x^2 \), \( \frac{1}{-x^2} \), and \( \frac{1}{-x^2} + 3x^2 \), respectively.

Each of these methods was similar in that they entailed composition. The \(-x^3\) term of \( g(x) \) was “plugged into” the \( x \) in the statement of the derivative of \( \ln x \). The only difference between these categories was the way in which the chain rule was applied. The participants classified in the Composition & Chain Rule category multiplied the rational term by the derivative of \(-x^3\), those in the Composition & No Chain Rule category left off the derivative of \(-x^3\) completely, while Mark, of the Composition & Chain Adding category added the derivative of \(-x^3\).

The second and third Somewhat Familiar Tasks involved \( f(x) = \ln(x) \) and \( g(x) = x^2 + 1 \). The categorizations of these tasks were similar. The second task included one as Product Rule, one as Addition Rule, five as Composition & Chain Rule, one as Composition & No Chain Rule, one as Composition & Chain Adding, and one as Multiplying Derivatives. The only difference for the third task was two as Product Rule and none for Composition & No Chain Rule.

In summary, the Somewhat Familiar tasks that were not pre-composed had more variability in the methods to derive a formula for the derivative than those that were already composed. Both pre-composed and non-pre-composed tasks used the methods Composition & Chain Rule, Composition & No Chain Rule, and Composition & Chain Adding. Additionally participants used the methods Product Rule, Multiply Derivatives, and Addition Rule for non-pre-composed tasks. Similar to the Familiar tasks, evaluating a derivative function at a specified value was always done by plugging in that value for the \( x \)’s in the formula.

**Not Familiar Tasks**

The Flowers-Colors Task was the final task related to the function familiarity research question. In it participants answered one question with a function already composed. The first Not Familiar Task used a function that was already in composed form. Seven of the participants used the Chain Rule to determine \( f'(x) \) and all of the participants used methods that have been discussed in previous sections. Table 1 shows these methods and how they compare to the other Not Familiar tasks and the previous tasks. Two additional techniques occurred on this task. Three students decomposed the function into two parts (e.g., \( f(u) \) and \( u = \text{violets}(x) \)) and another student attempted to solve a similar task with a function more familiar to him (e.g., \( \ln(3x) \)) and that had similar features to the function in this task. After seeing how the more familiar function behaved, he then applied the same principle, the chain rule, to the unfamiliar function. He explained the common features of his problem and the task in the following episode.

In the second Not Familiar Task the function was not pre-composed. All ten participants derived a formula for \( h(x) \) first and nine of them did so using the Composition method. More variability occurred when deriving a formula for \( h'(x) \) (see Table 1). This is the only task where the Chain Times-ing category appeared. This category is similar to Chain Adding in that it
contains all of the components of the chain rule only with different operations. In this task Chain Times-ing appeared as \( h'(x) = \frac{3x+1}{x^2} (violet(x)) \cdot blue(x) \)

The third Not Familiar task defined \( h(x) = (f \circ g)(x) \). Similar to other tasks, nine of the ten participants derived a formula for \( h(x) \) before finding \( h'(x) \). Again Table 1 lists the methods used to derive \( h'(x) \). Additionally, similar to the first Not Familiar Task one participant performed decomposed the \( h(x) \) that was just derived and another student solved a similar task with a more familiar function.

### Discussion

One of the driving questions of this study was: What are students’ routines with functions with which they are familiar, somewhat familiar, and not familiar? Based on the findings, there was less variety in these students’ methods to solve tasks which contained familiar functions. The somewhat familiar functions created the largest number of methods. This large number of methods may have been due to previous (potentially negative) experiences with logarithmic functions whereas the not familiar functions may not have come with the same kind of anxiety.

Also shown was that students used different operations (composition, addition, or multiplication) when finding the derivative \( h'(x) \) than they did for finding the original function \( h(x) = (f \circ g)(x) \). A majority of the students used the “plug g into f” method to find \( h(x) \), but up to half of the participants used other operations for the remaining portion of the task.

These results have implications for the teaching and learning of the chain rule. The participants that were the most successful in attaining the correct answer were those that were flexible in their use of function composition. They were able to see a composite function and create another one similar to it. They could compose and decompose functions in multiple notations (e.g., function and Leibniz or circle and parentheses). Thus, mnemonics or other teaching tricks to remember the chain rule may not be as effective as encouraging deeper understanding of composing and decomposing. For example the Outside-Inside rule currently found in many the chain rule section of calculus textbooks could be related to composing and decomposing functions as opposed to simply a way to perform the chain rule.

Additionally this study has shown the usefulness of commognitive research. By paying close attention to what the participant says and does, one is able to see what is correct as well as what

---

is wrong. For example the Chain Adding method would typically be quickly dismissed as completely incorrect once the plus sign appeared. Whereas it has been shown here that the three pieces of the chain rule \( f' \), \( g \), and \( g' \) are all there and that it was only the operation that was incorrect. Thus, students might not be closer to the correct answer than one might suspect.

Future studies could include an exponential function or another somewhat familiar function. It would be interesting to see if the relationships between familiar, somewhat familiar, and not familiar seen in this study hold with other functions. Additionally, determining a function with which students are not familiar but is more mathematical than the Flowers-Colors task could be useful. Tasks involving multiple representations could be designed to study the consistency of routines in different representations.

CHARACTERISTICS OF FIVE INTERNATIONAL MATHEMATICAL OLYMPIAD WINNERS BASED ON KRUTETSKII’S FRAMEWORK

Kyong Mi Choi
University of Iowa
kyongmi-choi@uiowa.edu

A lack in fundamental understanding of the gifted is one of the causes that hinder blooming their potential. To attain better understanding of them this study investigated attributes of five former Olympians. A series of interviews with these individuals is used as the method of the research. The five elements of “readiness for an activity” presented by Krutetskii (1976) were used to indentify characteristics of the five Olympians including four general psychological conditions in addition to natural ability. All five Olympians displayed combinations of five elements of the readiness for an activity. Findings of the study suggested that the mathematically gifted without numerical evidences or of early ages may be identified be careful observations by their caretakers.

Introduction

There is no single strategy or formula to develop all students’ abilities to their fullest, especially those who are highly gifted (Gallagher, 2006; Muratori, Stanley, Ng, Ng, Gross, Tao, & Tao, 2006). To serve these students successfully, first, proper identification should be conducted so that appropriate educational practices and environments can be created to develop students’ potential to their fullest.

Although the use of multiple identification methods is strongly suggested (Coleman & Cross, 2003), common numerical methods such as standardized test scores, which may not reveal students’ full potential, are still considered highly because of their convenience. Approaches to identify characteristics, not solely relying on test scores, of the gifted are imminently needed so that both students with manifested giftedness and those with latent potentials can be recognized. Krutetskii (1976) hypothesized and later confirmed that a child’s successful mathematical development derives from a combination of qualities, including a positive attitude toward mathematics; characteristic traits such as diligence, persistence, and self-discipline; a favorable mental condition to its implementation; a definite fund of knowledge, skill, and habit; and ability as demonstrated in Figure 1.

While schools and gifted programs vary in how they identify and admit students, common admissions criteria include standardized test scores, teacher recommendations, school grades, and interviews. Another criterion is performance from competitions. In fact, performances in Olympiads are widely used to indicate a young person’s potential, with the International Mathematical Olympiad (IMO) considered the most prestigious competition for mathematically gifted secondary students (Evered & Nayer, 2000; Karp & Vogeli, 2003). It is true that Olympians are very selective group of the mathematically gifted, however, their examples stand “as a benchmark for all gifted students” (Subotnik, Misrandino, & Olszewski-Kubilius, 1996).

Historically, Asian countries are among the top performers in international competitions. For instance, Korean teams have consistently demonstrated highly successful accomplishments in the IMOs, achieving 4th, 3rd, 3rd, and 5th places between 2005 and 2008, respectively. Other Asian countries such as China, Thailand, North Korea, and Japan have been among the top 10 countries in recent years. Therefore, to better understand the attributes of and influences on highly gifted
students, this study investigates factors that helped in shaping these students’ success so that more adequately developed systems of identification that take characteristics of mathematically gifted students into consideration can be created.

Figure 1. Suitability or Readiness for an Activity

Historically, Asian countries are among the top performers in international competitions. For instance, Korean teams have consistently demonstrated highly successful accomplishments in the IMOs, achieving 4th, 3rd, 3rd, and 5th places between 2005 and 2008, respectively. Other Asian countries such as China, Thailand, North Korea, and Japan have been among the top 10 countries in recent years. Therefore, to better understand the attributes of and influences on highly gifted students, this study investigates factors that helped in shaping these students’ success so that more adequately developed systems of identification that take characteristics of mathematically gifted students into consideration can be created.

Several practical implications are expected from this study. First, an analysis of former IMO winners’ characteristics based on Krutetskii’s (1976) study will reinforce understanding of the mathematically gifted and provide resources to educators, school personnel, and parents. Second, educators in the fields of mathematics education and gifted education will be able to explore unique characteristics of former IMO winners and ascertain whether characteristics that Krutetskii outlined are also present in the Korean context in spite of cultural and educational differences. Third, the selection processes that specialized schools and programs are using (e.g., teacher recommendation, the use of achievement scores, and previous achievements) to identify and admit students will be diversified. Lastly, parents and teachers who are interested in their child’s mathematical development will benefit in understanding such characteristics even if their child’s achievement score does not reflect a high level.

**Purpose of the Study**

The purpose of this study is to examine characteristics of highly gifted individuals, in particular, Korean students who have participated in IMOs in the past. School administrators, mathematics educators, and parents can employ these findings to assist in the development of mathematical potential of their students and children and for early identification of their mathematical giftedness. This study will answer the research question: What are characteristics of Korean mathematically gifted IMO winners based on Krutetskii’s (1976) readiness for an activity?

Theoretical Framework

Quite a few researchers have uncovered various characteristics of gifted individuals. Among them, this study is following models of three studies. First, Krutetskii’s characterization of psychological conditions was the model to categorize what former IMO winners possess and exhibited. Krutetskii studied individual children through qualitative methods such as interviews and observation, and, in this study, the interview is the method of research. Secondly, a study of two mathematicians, ‘former greatest child prodigies’ as the article calls, to revealed that various distinctive characteristics and influential factors were closely associated with their talent developments (Muratori et al., 2006). In-depth interviews with four individuals – two mathematicians and their fathers – enriched the understanding of their different personal qualities and environmental factors. The last model that this study follows is Karp’s (2003) study tracking former Olympians especially on the side to understand their perception in Olympiad experiences.

Krutetskii’s report (1976) on ‘readiness for an activity’ organizes characteristics of the mathematically gifted into four general psychological conditions in addition to ability, which covers most other classifications of characteristics of this special population. He examined the development of children’s inclination and interests; attitudes toward school subjects, especially in mathematics; and their character traits. After 12 years of experimental and non-experimental studies with 201 gifted children, he concluded that a student’s success was derived from the combination of five characteristics (p. 74): (1) an active, positive attitude toward the activity and an interest in and an inclination to study it, which becomes passionate enthusiasm at a high level of development; (2) character traits that primarily include diligence, self-discipline, independence, clearness of purpose, persistence, as well as stable intellectual feelings (a feeling of satisfaction from intense mental work, joy in creation and discovery); (3) a positive mental condition toward its implementation such as winning for competitions or high achievement in assessments; (4) a definite collection of knowledge, skill, and habits in the appropriate field; and (5) ability, that is, specific individual psychological characteristics (Figure 1). The combination of these attributes determines the suitability or readiness for an activity.

Krutetskii (1976) separated ability from the other four general psychological conditions. According to Krutetskii, mathematical ability consists of three components: obtaining, processing, and retaining mathematical information. Remarking on the importance of these three components in building giftedness, Krutetskii stated, “These components are closely interrelated, influencing one another and forming in their aggregate a single integral system, a distinctive syndrome of mathematical giftedness, the mathematical cast of mind” (p. 351).

Research Method

To answer the research question, a series of interviews was conducted with five IMO participants and their parents. This study used a qualitative case study approach. Participants were selected through Snowball sampling (Gay & Airasian, 2003) started from existing information provided on the official IMO website (http://www.imo-official.org).

According to the IMO official website, there were 120 Korean participants (some participants are counted more than once) since 1988, the first year of Korean team’s appearance to IMO. Past participants’ names taken from the IMO website were searched on web engines with a purpose to obtain their contact information. Initially, the email addresses of three Olympians were obtained. When the first contact was made with the three individuals explaining the purposes and description of the study, all three agreed to participate in the study. Through correspondences with these former Olympians by email, two other fellow Olympians were contacted and agreed...
to be involved in the study. Eventually, the sample consisted of these five former Olympians (Table 1). Moreover, three of the five participants agreed to have their parents contacted by the researcher and provided phone numbers. Contact was immediately made with all three parents, who were willing to spare time to be interviewed.

Before the interview, the participants were asked to provide basic information about themselves and their educational background to prepare individualized interview questions. At the beginning of the initial meeting for the interview, each interviewee was informed about the intent of the study and signed the consent form. Interview questions were partially structured with open-ended questions and their order of presentation was determined, however, follow-up questions were asked during the interview, if necessary. Interviewees’ responses were audio taped and immediately transcribed verbatim.

Three one-hour interviews were planned and conducted in Korea with each Olympian, with additional interviews scheduled if needed. During the first session, each interviewee was asked questions about their general background, such as educational and family experiences. After the initial meeting when the researcher and the interviewee became familiar with each other, the researcher posed more personal and in-depth questions in the following sessions. Additional interviews after the initial three hours were made with four of the five interviewees to gather all of the desired information. Further questions were asked depending on the circumstance to explore more detailed experiences of the interviewees. Several post-interview email corresponding were made to confirm and refine information gathered during interview sessions.

Parents were interviewed twice – the first time, on the phone, and the second, in-person – to verify or append the Olympians’ statements and provide anecdotal evidences. A consent form was signed by each at the beginning of the interview as well. For further questions that might arise during analysis of their responses, all parents agreed to be contacted by phone or email to elaborate on their responses.

Interviews with a total of eight people (five IMO winners and three parents) took place in various locations of their convenience. Each interviewee consented for the interview to be audio recorded. Interviews were immediately transcribed in Korean. The transcripts were translated into English except for technical remarks such as names of schools they attended, time and places that interviews took place. Then, two independent coders analyzed the translated transcripts sentence by sentence with keywords noted. Next, statements related to themes based on keywords were selected across the interviews. Notes about facial and emotional expressions...
during the interviews were also reviewed so the feelings and emotions expressed by the interviewees would not be lost.

In reviewing the transcripts, each interviewee’s responses were categorized based on Krutetskii’s characteristics. Next, their responses were categorized into themes. In this way, the constant comparison approach was carried out, where interpretation focuses on patterns and perspectives of the participants. Each interviewee’s response was coded based on each component/key word of Krutetskii’s characteristics until there is no more new ideas to what were already found about a category, its properties, and its relationship to the core category. Next, their responses were categorized into themes, where interpretation focuses on the patterns and perspectives of the participants.

Credibility of findings and interpretation depends on “careful attention to establishing trustworthiness” (Glesne, 1999, p.151). To ensure trustworthiness of a study, one must spend sufficient time in the field and make detailed observations (Lincoln & Guba, 1995). In this study, both factors were successfully executed. First, three one-hour interviews with each IMO winner were conducted. By meeting multiple times with the researcher, the interviewees became comfortable and provided personal thoughts and experiences. Also, by corresponding via email for additional information enabled the researcher to gather and explore more the data in more detail. Moreover, parent participation authenticated information provided by the Olympians, making the findings more trustworthy. Second, the transcripts were reviewed multiple times on separate occasions with two independent coders that increased the reliability of the findings. Transcript data were carefully and continuously reviewed when they were re-organized by keywords and themes.

Results

Indications of Natural Intellectual Abilities

It was apparent that all five former Olympians displayed the presence of ability not limited to mathematics from early ages. Some of them showed the presence of abilities through accomplishments from mathematics contests, while others were through episodes that were provided by their parents.

Indications of Krutetskii’s Psychological Conditions (Characteristics)

General psychological conditions or readiness for an activity that contribute to a student’s success include characteristic traits (i.e., persistence, motivated and self-disciplined behaviors), a positive attitude toward the activity, a positive mental condition, knowledge, skills, study habits in the field, and the presence of ability (Krutetskii, 1976). Interviews with the five participants revealed the presence of combinations of these psychological conditions, which are described below.

Characteristics traits that Krutetskii presented were revealed through self-asserted, disciplined, goal-oriented, competitive, confidence and acquisitive behaviors of the five former Olympians. All five Olympians clearly displayed some of these traits through their lives. Despite of parental advices and observing what professions in pure science would be like, remaining firm in pursuing mathematics showed independence, clearness of purpose, and persistence in one Olympian. Being self-motivated and competitive was also evident in two Olympians when they were clear about their goals. Studying and preparing mathematics Olympiads was not easy when resources are scarce for many former Olympians, however, their self-disciplined nature, a feeling
of satisfaction from intense mental work, and joy in creation and discovery were found to encourage and sustain them to reach the goal to win at IMO.

Knowledge, skills and good study habits were found among all five Olympians as well. In various occasions, these Olympians’ knowledge shined through their school works, accomplishments and while helping others. Study habits and skills contributed to individuals’ learning experiences and developing mathematical and academic advancement. Many Olympians not only enjoyed learning advanced mathematics but also looked for additional resources to learn more and loved reading them on their own.

Positive attitude toward mathematics and an interest in and an inclination to study mathematics, which becomes passionate enthusiasm at a higher level of development, was displayed by all five Olympians. Some of instances that uncovered positive attitudes toward mathematics were overcoming obstacles such as parental objection to study further in pure mathematics, reading and completing mathematics books for older pupils, returning back to mathematical competition after participating in science competitions, and completing assignments in an unexpectedly shorter period of time than older peers, and a presence of natural fondness in solving challenging problems. Fondness in mathematics of one Olympian was nourished through exploration of various academic fields such as computer science, philosophy, and others.

The fourth psychological condition, the positive mental condition favorable to its implementation was imbedded in four Olympians. Achievements from competitions served as a main implementation in these people. Also, tuition-exemption policies motivated some individuals to work harder. In general, goals or incentives were types of implementations that allowed these students to drive themselves to achieve highly.

**Discussion and Conclusions**

To create and provide an environment that gifted students are able to develop their potential to the maximum, it is vital to understand characteristics that they possess. Characteristics not only tell us how to identify such individuals, but also guide us to ways in how to educate and encourage them in a way that they respond to. Results from this study confirm that the five Korean IMO winners possess combinations of characteristics that Krutetskii (1976) found in mathematically gifted children in Russia. Thus, it will be a good guidance for educators to recognize hidden giftedness of a child without numerical indicators even though they were in different cultural contexts.

All of the former IMO winners hold characteristic attributes that Krutetskii (1976) found in his own study participants. Although each individual revealed different traits, all five former Olympians displayed persistence, self-discipline, self-assertiveness, competitiveness, confidence, and diligence throughout their life course. These characteristics are indicators of mathematical giftedness that teachers and parents can detect from careful observation and without holding expertise. Only when these traits are accurately recognized as a sign of mathematical giftedness, will underachieving mathematically gifted students be correctly identified.

First, all five participants displayed knowledge, skills, and good study habits, that are another strong gauge of mathematical giftedness. Krutetskii (1976) asserted that without having minimum knowledge, skills, and habits, a person might not be suited for mathematical activities no matter how great the person’s mathematical ability may be. Undoubtedly, these former Olympians have shown their mathematical knowledge in their accomplishments in competitions and as reflected in their GPAs. Two participants referred to themselves as lucky to have
possessed certain knowledge, which is extremely scarce to happen, in encountering familiar problems in competitions. Taking into consideration the small number of problems in these competitive exams (e.g., there are only six problems on the IMO and Final Korean Mathematical Olympiad), their so-called “luck” actually is reflective of their tremendous preparation and depth of knowledge.

Second, habits of learning and studying are another factor that distinguishes some of the Olympians from their peers. One interviewee with extreme anxiety in taking high-stake situations coped with it by being perfectly prepared, which helped build her confidence, and acquire a definite fund of knowledge so that she would not experience “bad luck” in forgetting what she had previously studied. Another Olympian also exhibited good study habits through hard work and effort. He showed high achievement in all subjects and significant mathematical knowledge by spending a large portion of his time after school studying mathematics. Therefore, teachers’ and parents’ observations of a child’s study habits and its consequences (e.g., knowledge acquisition) should not be disregarded simply as a personality trait but as a possible indicator of giftedness.

Third, a positive attitude towards mathematics or its achievement also points to mathematical giftedness. Some were fascinated by the “beauty” of mathematics and indulged in it by spending hours in solving challenging problems. For others, the goal was to do well in competitions and participate in summer camps where they could spend time with other similarly gifted peers, to enter prestigious colleges, to pursue free tuition programs, or to beat their own records they set previously. They invested time and energy, which they could have spent elsewhere, studying mathematics and relishing in it. Consequently, parents need to learn to recognize whether their child enjoys or dislikes studying mathematics because a successful test score does not necessarily indicate mathematical giftedness if the individual presents negative attributes in doing it.

Prevailing among all five Olympians was a display of mathematical ability from early ages. Some grasped mathematics information more quickly than others, including older peers and siblings. Others processed mathematical knowledge easily, reading mathematics books, solving higher level mathematics problems, and displaying quick calculation skills. Retaining mathematical information well was another aspect of their ability. While learning advanced mathematics at an early age, these students used what they previously learned as a stepping stone to learn at the next level. Without the retention of mathematical facts or concepts, it would be impossible for them to move on to the next advanced level of mathematics.

Although research has demonstrated the effectiveness of representational technologies in mathematics education, there have been barriers to broad use. Across multiple projects, we have refined an approach to curriculum development that lowers the barriers to the use of representational technologies—specifically through a dynamic math approach to mathematics learning—while ensuring that students can benefit from their unique affordances. In this paper we describe a set of principles for the design of units using a dynamic-math approach and discuss how they were applied to two different middle school units.

Introduction

Research has shown the effectiveness of using representational technologies in mathematics to scaffold and support student learning (Marzano, 1998; Mayer, 2005). However, there have been barriers to broad use, such as the perception that technology is too difficult to implement in diverse classrooms (Becker, 2000), and inconsistent findings on the benefits of educational technology in mathematics (Dynarski et al., 2007; National Mathematics Advisory Panel, 2008).

In this paper we describe our approach to curriculum development to help overcome these barriers and best ensure benefits to students who use the materials. We derive design principles based on lessons learned across multiple projects that relied extensively on representational technologies. We focus on two units using two different kinds of dynamic mathematics software and curricular approaches, both of which support student learning through use of technology-based representations: SimCalc Mathworlds™ and Geometer’s Sketchpad™ (GSP). In designing the units we incorporated the perspectives of different stakeholders—students, teachers, and school districts—to minimize barriers to implementation and increase the chance of having the intervention be successful with a variety of teachers. We addressed teacher and district concerns about current policy demands (e.g., NCLB and accountability testing) and the need to meet local standards. We considered multiple teaching styles and designed materials so teachers with a wide variety of mathematical and technological backgrounds could use them. Through representational technologies and scaffolded curriculum, we met the cognitive, linguistic, and social needs of a diverse student population. At the heart of this approach is a refinement in our conceptualization of the use of innovative technology in the classroom.

Perspective

For more than 15 years, research in dynamic math in general and the SimCalc project in particular has had the goal of ensuring that all learners have the opportunity to learn complex and important mathematics. For SimCalc, this is expressed in the mission statement “democratizing access to the mathematics of change and variation” (Kaput, 1994). A foundational belief of the dynamic math movement is that reconceptualizing middle and high school mathematics can yield...
a more coherent and fruitful mathematical experience for all learners, including those who have not traditionally been successful in mathematics (Kaput & Roschelle, 1997). Our work continues this tradition and attempts to remain faithful to the core principles of the tradition while incorporating new principles to allow for broader impacts in a wider variety of contexts.

**Results from the Use of Our Dynamic Math Materials**

A series of studies found our SimCalc unit to be successful in meeting the needs of a diverse set of students and teachers. Ninety-five seventh-grade teachers and their students across varying regions in Texas participated in a randomized controlled experiment in which they implemented a SimCalc-based 3-week replacement unit. An analysis of the results showed a large and significant main effect with an effect size of .8 (Roschelle et al., 2007; Roschelle et al. in review). This effect was robust across a diverse set of student demographics. Students who used the SimCalc materials outperformed students in the control condition regardless of gender, ethnicity, teacher-rated prior achievement, and poverty level (Figure 1 below). In addition, an implementation study in Florida, called the SunBay Digital Math project, used the same materials but with no control group. The SunBay project replicated the gains found in the Texas study (Figure 2 below), again with learning gains across a wide variety of teachers and learners.

![Figure 1. Mean student learning gains by subpopulation group](image)

**SimCalc Unit Content**

The SimCalc-based curriculum unit addressed core state standards and also included topics that were more challenging than those in the standards. Beginning with simple analyses of motion at a constant speed, the unit followed a learning progression that culminated in the more complex topics. The unit addressed unit rate and proportional functions—topics from the seventh-grade Texas standards that are also core to Florida standards—and ended with multirate functions and the meaning of positive, negative, and zero slope, expressed informally. It underwent minor revisions for use in Florida, but the core principles underlying the design remained the same.

By combining paper materials with guiding questions and SimCalc MathWorlds software files, the units provided a structured exploration of algebraic representations through their connections to real-world topics. The students had opportunities to use various motions and other “accumulation” contexts (distance is accumulated as a runner moves along; money is accumulated when added at a given rate). The unit presented soccer players running races and team buses traveling from one town to another, and students were to find speeds and write stories.

---

to explain patterns of motion. Non-motion contexts included saving money when buying uniforms and predicting how much fuel vehicles would use, in miles per gallon. Knudsen (2010) contains a more complete description of the content of this SimCalc unit.

**Results**

Many education research studies depend on curriculum as a vehicle for representing the researchers’ ideas in the classroom. We note that the curriculum teachers use and how they use it are influenced by factors that extend beyond the classroom, yet rarely is attention paid to design principles that account for this wide range of factors. The design principles should allow a faithful instantiation of the theories, ideas, and innovations of researchers while also resulting in materials that are accessible to and easily usable by the studies’ participants. The developers of the curriculum, then, have to pay attention to a number of contextual factors when writing curriculum and designing professional development.

Curriculum materials are used in settings with particular sets of *people, conventions, resources, and political considerations*. The minimal set of *people* to include is teachers and students. Teachers have a wide range of subject matter knowledge, comfort with technology, and teaching experiences. Students come to class with different languages and cultural traditions, as well as with levels of past success in mathematics. *Conventions* include the teaching practices expected in local classrooms and the relationship between teachers and parents. Relevant *resources* include available technology (or lack thereof), available support for the use of technology, release time for professional development, and even how many electrical outlets are in classrooms. The school, the district, the state, and the nation also provide *political considerations* that developers must take into account, including district policies and accountability expectations.

**People: Teachers and Students**

For our materials to be usable by a wide variety of teachers, they had to support a range of teacher math knowledge and a range of pedagogical styles and preferences. In the original Texas

---

Chapter 1: Advanced Mathematical Thinking

study, we addressed this variety in several ways, starting with the professional development (PD). Simple pedagogical routines were introduced and reinforced in the materials and PD, so that beginning teachers could simply establish the routine, and veterans could use it as a platform from which to improvise. The PD addressed basic and advanced content knowledge by having teachers study the math of the unit, the math that was prerequisite to the unit, and the math beyond the unit.

To support teachers as they were teaching the unit, we created the student workbook so that it could be used as a substitute lesson plan. This was based on our experience that most current teachers no longer create written lesson plans and typically teach from the student materials. In our materials, teachers could rely on the questions written in the student workbook as a template of key question and activities. The workbook, however, was not a prescriptive script. Experienced and knowledgeable teachers could easily use their own questions or use the teachers’ notes to create their own lesson plan. For additional support, the teacher notes provided an outline of the activity flow for each lesson, extra questions to ask students, and sample student responses. To meet teachers’ accountability needs, a list of standards addressed in each lesson was included. A suggested pacing chart was provided, and teachers also received forms they could use to write their own lesson plans.

These choices instantiate two key design principles. The first is that student materials meet teacher as well as student needs. The second is to design teacher notes to meet teacher needs without providing an overwhelming amount of information. For the SimCalc study, this meant including only what was necessary in the teacher notes. Today’s teachers rarely have the luxury of significant planning time and so, by definition, do not spend much time reading teacher notes. Bulleted, highly relevant information is most likely to be read and used.

Teachers may have been the first audience for the SimCalc materials, but students were the primary audience. Features of the units were designed to address the needs of a wide variety of students. Each unit’s theme provided continuity across the real-world contexts represented in the software simulations. Numbers used in these contexts were for the most part realistic, so that students could use their knowledge of speed and prices to gauge the correctness of their answers. The text used simple sentence structure and consistent vocabulary, never going beyond a fifth-grade reading level, in order to accommodate those with low-level reading skills and those learning English. The workbook used graphical conventions to indicate various kinds of activities and content; for example, definitions and other critical information appeared inside boxes on the page. The amount of white space provided with a question indicated the type and length of an expected answer. Even the fact that the workbook contained all the student activities physically bound together provided another organizational aid to students. Last, the workbooks were printed with as much color as the budget would allow to appeal to media-savvy students.

These choices instantiate the design principle that materials need to account for more than just mathematics content. This means adopting methods from special educators, from experts in second language acquisition, and others—as well as considering popular culture. Our units have been (and will continue to be) successively refined as we learn more about student needs and analyze student work with our materials.

**Conventions**

The SimCalc unit included a lesson on slope, connecting the lessons on steepness of lines quantified as rate to this highly related topic. As it turned out, teaching slope in the seventh grade was not conventional in Texas. The developers had mistakenly understood the opposite: that it
was important to introduce slope connected to rate. Fewer teachers used this activity than any of
the other activities in the unit. We inferred a design principle to be used in the future: Pay
attention to local conventions while at the same time retaining all the topics important to the
research project.

Access to Resources

Access to resources is always a concern when creating a dynamic math curriculum. Almost
by definition, dynamic math activities are technology-based activities—where the technology
could be computers, calculators, or even electronic whiteboards. Where these resources are
scarce, the curriculum can compensate by providing plenty of activities not dependent on
technology. It is essential, however, to ensure that non-technology activities contribute to the
progression of content and are not just filler. We addressed this problem in two ways in the
SimCalc unit: We created activities that leveraged technology where necessary, and we created
practice materials that did not require technology. Whereas our learning activities supported
student use of computers (and we strongly advocated student access to computers), we wrote our
curriculum to be flexible enough to support learning in a wide variety of technical contexts,
including one-to-one computer classrooms, classrooms in which members of a small group share
a computer, and even where only the teacher had the opportunity to drive the technology using
one computer at the front of the class.

The Political Context

Curriculum is used in a political context—at local, state, and national levels. At the national
level, No Child Left Behind and other federal policies set a tone that encourages a less open-
ended curriculum than had been popular in the previous decade. Current national policy requires
that school-wide test scores increase at a rapid rate, and these scores are based on tests designed
at the state level, so state-level standards become a critical influence on the curriculum. At the
building level, political “with a small p” considerations can include a teacher’s need to comply
with school policies by both producing good test scores and by keeping a fairly quiet classroom
atmosphere.

The SimCalc unit was shaped by these political influences in several ways but most
importantly by state standards. Not only did standards and standardized tests determine what was
taught in the classroom, but also many teachers followed the pacing guides telling them what to
teach each day, to make sure that they covered all the standards. These teachers needed special
assistance to match their guides with the suggested timeline in the unit, and they were
accommodated during training. The first part of the unit addressed content directly from the
standards, focusing on rate as a proportional linear function. The second part of the unit went
beyond state standards. A demarcation was clear in the materials and in the training. The
beyond-standards content was vetted with experts in state and local policy to ensure that teachers
would still be willing to use the materials, given pressures at the school level.

The general design principle to be derived here is to be aware of and respond to political
considerations at all levels. Design decisions made in response to federal policy might support
teachers at the school level—or not. The consequences need to be thoroughly considered. For
example, some teachers may be monitored by district officials to make sure that their teaching
methods are in line with local expectations. Replacing an activity that would require students
walking about the classroom with one that accomplishes the same goal with students in their
seats could help teachers stay in line with local policies and classroom behavior norms.

Ohio State University.
Applying Principles to and Deriving Principles from a Dynamic Geometry Unit

On the basis of the success of the SimCalc unit, we have designed and are in the process of implementing a geometry unit that uses Geometer’s Sketchpad. This unit is of a shorter duration (1 week) than the SimCalc unit, is designed to be used in Florida, and covers different mathematical content. Despite these differences, however, it is based on the same design principles discussed above.

Content. As in the SimCalc unit, the content of the geometry unit was designed to address core standards while also including topics more challenging than those in the standards. We determined that the most appropriate focus of the geometry unit would be geometric similarity, an aspect of proportionality that is in the Florida standards but was not addressed in the SimCalc unit. We again began with simple analyses and moved to more complex topics. In this case, we started with informal notions of similarity and followed a progression that ended in formal definitions of similarity that applied to all figures.

We again combined paper materials with guiding questions and different contexts. Early in the unit, students analyze images of the Statue of Liberty to investigate how nonsimilar images look warped or distorted. Later in the unit, they analyze images of currency (all are rectangular bills) and again determine which images are distorted and which are scaled proportionally. As a result of this activity, they are introduced to the notion that similar rectangles have the same height to width ratio. Students are presented with quadrilaterals with corresponding sides with equivalent ratios but without congruent corresponding angles. Students then are guided to revise their working definition of similarity to address polygons’ angles. Finally, students are presented with an activity to consider non-polygonal figures and introduced to a definition of similarity using dilation.

Design principles: people. The new unit is designed to meet particular needs of teachers and students. Teachers can use the student materials as a substitute lesson plan. As in our previous materials, the student guide provides a template for student activities and teacher questioning. We have also included teacher notes that contain additional questions for students and expected student answers. To meet the needs of students, we again use realistic contexts and numbers whenever possible and use the same formatting rules as in the SimCalc-based unit.

Design principles: conventions Dynamic geometry software and curriculum afford students with opportunities to make geometric constructions, creating and modifying software files. During the implementations of the SimCalc unit in Florida, however, we found that many teachers were uncomfortable with students altering software files. The local convention seemed to be more of a plug-and-play model of using the software. When our analysis of existing GSP lessons on similarity revealed that the lessons assumed a high degree of student fluency with the software, we knew that we would need to design new activities where students could explore the mathematical representations without requiring the fluency required to build such representations on their own.

Design principles: access to resources. As in our SimCalc unit, we again use technology judiciously to exploit the unique affordances of representational technology. As a result, about half our activities require technology, and half do not. In addition, we have found a significant difference in those resources available in the Texas SimCalc study and those now available in the SunBay study: the introduction of small-screen NetBooks. To ensure that our materials work with the resources available to our teachers, we are now creating new file sets that work on the smaller screens on NetBooks.

Design principles: politics and standards. We found that our SimCalc unit, which was originally created for Texas, only required a small number of changes to meet key Florida standards. In particular, our SimCalc unit was aligned with Florida’s Next Generation Sunshine State Standards’ Big Idea 1: Develop an understanding of and apply proportionality, including similarity. Although several possible Florida standards would have been appropriate to address using GSP, we determined that the most effective use of GSP was to continue to address Big Idea 1 and specifically the topic of geometric similarity. In so doing we created a set of materials with a consistent goal and that focus on one core aspect of Florida’s standards. On the other hand, the expectations within the standards focus on the application of similarity to find missing numbers, while our unit helps students devise increasingly sophisticated versions of the definition of similarity. This led us to pose the unit as a supplementary unit, to be used after the state tests are administered and to be used in addition to textbook chapters on similarity, rather than to replace them. This is an example of fulfilling local political requirements while still staying true to dynamic math ideas.

Conclusion

This paper described several aspects of the curriculum used in two experiments using a dynamic math approach with a wide variety of teachers and students. Paper materials and software served to guide students in an exploration of real-world contexts and associated mathematics representations, focusing in one unit on rate, proportionality, and linear function and in another on definitions of similarity. Developers of the unit took into account not only the mathematics that could be learned using a SimCalc approach, but also a set of other constraints on the curriculum. The developers addressed then-current political and social considerations, mostly about the dominant influence of state standards and assessments on instruction. Teachers were supported in their classroom use of the materials through a set of teacher notes and professional development that focused on teachers’ mathematics learning and effective implementation of the unit. Special considerations were made for the needs of teachers and students, including meeting local conventions.

Endnotes

1. This paper is based on work supported by the National Science Foundation (Grant number 0455868), by the Helios Education Foundation, Pinellas Country Schools, and by the Pinellas Education Foundation. Any opinions, findings, and conclusions or recommendations expressed in this paper are those of the authors and do not necessarily reflect the views of the National Science Foundation, the Helios Education Foundation, Pinellas Country Schools, or the Pinellas Education Foundation.

2. We focus on Hispanic students because they consisted of a majority of our student sample, numbers of other minority groups in the study were negligible, and Hispanic students have traditionally underperformed in measures of mathematics achievement (Education Trust, 2003).

3. We take as our measure of poverty the percentage of the campus eligibility for the free and reduced-price lunch program.

References

In the spirit of a series of studies by Selden and other collaborators (Selden, Mason & Selden, 1989, Selden, Selden & Mason, 1994, and Selden, Selden, Hauk & Mason, 2000), an analysis of student performance on a simple trigonometry problem shows it to be void of predictability and trends. We extend the analysis given by Selden et al to explain the phenomenon.

Introduction

In traditional pre-calculus courses like trigonometry and algebra, teachers must assess their students and, in doing so, it may be in their standard practice to develop problems that incorporate a variety of conceptual tasks. The number and the type of conceptual tasks involved in solving a problem will generally contribute to its perceived difficulty, and the most difficult problems will involve a number of these tasks which would be considered to be abstract. More abstract problems might come later in a course (and course of study), whereas those with fewer, less abstract concepts would come on assessments earlier in these courses. In Math 128: Trigonometry at West Virginia University, four regular midterm examinations are given throughout the term. The problems on the first examination largely review algebraic concepts and test the basic, simple concepts of trigonometry. By the second examination, students have been exposed to the unit circle – as we refer to it, the sines and cosines of the special angles between 0 and 2π radians – and have been using this information in problems for several weeks.

By the time of the second examination of the semester, the unit circle information is used regularly in lecture, appears regularly on the daily homework assignments, is referred to regularly in laboratory experiences, and, as expected, is embedded into many of the examination problems. Because of this level of exposure to unit circle information, performance on a problem that involves nothing more than recalling the basic tenets of unit circle trigonometry, combined with simple algebraic simplification, would be expected to be quite good. Contrary to this expectation, data collected from several terms of math 128 that includes more than 4500 attempts at one such problem shows uniformly poor performance. At WVU, we refer to this problem as the “killer problem”. This report begins an attempt to explain the killer problem phenomenon.

History

By 2006, math 128 at WVU had become deeply entrenched within the framework of a subset of the mathematics department known internally as the Institute of Math Learning (IML). The mission of the IML incorporates many components with regard to teaching, research and service, but on the surface, students of an IML course can expect to see a myriad of technological advances like applet-based interactive labs, online assessments, and the electronic personal response system, all of which are intended to supplement the teaching of courses in large lectures. In the case of math 128, every one of these technologies had already been in place, and so the maximum enrollment is generally equal to the capacity of the auditorium in which the course is held. In recent semesters that capacity has been on the order of 225 students.

With online assessments comes the vast archival of assessment data, and trends typically noted and perhaps discussed in classroom building hallways can be explored and analyzed. Such
is the case with the killer problem, an online problem embedded in the bank of examination problems used over several years. The killer problem involves little actual trigonometry and some basic algebraic simplification and so it is often expected that students will do generally well on it. Yet, the problem has produced uniformly poor results from students, hence its moniker and reputation. In every case between the fall semester of 2007 and the fall semester of 2009, the classes of students exposed to their first attempt at the killer problem earned less than 68% of the total points available to them, and this statistic is routinely on the order of 30% to 50%. In a tally of all 4583 online attempts at the killer problem over this period, only 53.2% of the points available to students were awarded.

Solving the killer problem involves an understanding of basic unit circle information and algebraic manipulation but the skills and knowledge required to solve it are essential. Because of this and the generally dismal results, the problem deserves to be examined. Is the killer problem phenomenon an issue that students have with algebra? Is the issue trigonometry? Or, is there a deeper explanation?

The Killer Problem

Because of its poor results, the killer problem is regularly assigned to several course examinations in any given term. It made twenty-three appearances on exams between the fall 2007 and fall 2009 terms. The counter-intuitive results have stood the test of time and variability. Four different instructors have taught the course at various times in this period in 6– and 15–week terms with a number of different textbooks using several formats of online and traditional homework platforms. Aside from one change in format in the killer problem itself which we discuss later, the correct solution to the killer problem has consistently proved to be elusive to students.

The actual title of the killer problem is Linear Combination of Trigs, and at least five versions of the problem exist in the bank of online assessment problems. For the sake of efficient communication, we focus on one of those versions, which looks like this:

Simplify $4 \sin \frac{2\pi}{3} - 8 \sin \frac{\pi}{6}$ so that it is expressed in the form $A + B \sqrt{C}$, where $A$, $B$, and $C$ are all integers (NO DECIMALS).

What is $A$? ___
What is $B$? ___
What is $C$? ___

The format of the killer problem is what makes it unique. If the original author (who is unknown) of the problem was interested in knowing only whether a student can use a calculator to compute $4 \sin \frac{2\pi}{3} - 8 \sin \frac{\pi}{6}$, then the problem would simply ask, “What is $4 \sin \frac{2\pi}{3} - 8 \sin \frac{\pi}{6}$?” In that case, a single solution field would have been sufficient and students would type in a numerical solution. This is because a student equipped with a calculator in radian measure mode can type in the expression $4 * \sin(2*\pi/3) - 8*\sin(\pi/6)$ and get the decimal approximation, $-0.5359$. Instead, the killer problem’s unorthodox method of reporting its solution eliminates the usefulness of all but a few advanced calculators without prohibiting their use for the assessment at large. Because of the format of the problem, a student must know that $\sin \frac{\pi}{6} = \frac{1}{2}$ and then be able to algebraically simplify the expression, arriving ultimately at $2\sqrt{3} - 4$.

If the problem had asked for a single numerical solution, then students with very little understanding at all can arrive at the correct solution. The killer problem intends to assess knowledge beyond this.

Tucker (1996) reports that calculators had been widely used in introductory undergraduate mathematics courses by the mid 1990’s. Regarding precalculus courses such as trigonometry, Quesada & Maxwell (1994) confirmed their merit by showing that students who were taught precalculus with the use of a graphing calculator scored higher on a comprehensive final exam than their counterparts who did not. Thus, the IML’s mission promotes the role of technology and, in particular, the use of graphing calculators. Still, many are concerned that technology can interfere with conceptual understanding and so this tactic of eliminating the usefulness of the calculator is implemented often in math 128 to span the dichotomy.

The killer problem asks for three numbers and so partial credit is given for any correct value reported. For example, in the version given above, the solutions are $A = -4$, $B = 2$, and $C = 3$, and so each of these values is worth one-third of the number of points allotted for the killer problem on the examination on which it occurs. For example, if the problem was given a weight of 12 points for an examination, then a student giving the solution $A = 4$, $B = 2$, and $C = 3$ would receive 8 points for getting $B$ and $C$ correct. Partial credit for each blank in the problem is binary; students are either given the points for a value or they are not.

Data and Evolution

The data below show the success rates for students on the killer problem in the terms for which data is available. For any particular term, the number in the column on the right gives the portion of the total points awarded for all attempts made at the problem (the number of points awarded for the killer problem varies by exam and term, and so portions must be used for comparisons). The statistic in the last column corresponds to two different point distributions. As an example, if all students got one of the three numbers in the killer problem correct and two incorrect, the percentage would be 33.3%. Alternatively, if one-third of the students got full credit and two-thirds of the students got no credit at all, the percentage in this case would also be 33.3%. Obviously both distributions are at work in these data.

In Table 1, a major change in the killer problem goes unnoticed. Because of the poor student performance, a hand-holding measure was introduced in the spring 2009 term. In the original version of the problem, many students failed to enter integers and instead entered non-integer numbers like 3.5 or irrational or nonsensical responses such as the syntactical “sqrt(3)” and so it appeared that failing to accurately follow instructions may have been responsible for a portion of the incorrect responses. This happened despite clear language in the problem specifying that all values should be integers. Those responses are clearly wrong and indicate meaningful information to the instructor, but in order to assist our students, the problem was reformatted to eliminate this type of incorrect response. The actual problem did not change, but the response format did. Instead of three blanks in which students could type anything, three drop-down menus appeared so that the student was presented with a limited number of options, from which they were to choose $A$, $B$, and $C$. Now, the problem looked like this:

$$4 \sin \frac{\pi}{3} - 8 \sin \frac{\pi}{6} = A + B \sqrt{C}.$$ Select $A$, $B$ and $C$ from the menus below.

<table>
<thead>
<tr>
<th>A</th>
<th>B</th>
<th>C</th>
</tr>
</thead>
</table>
The new format of the killer problem gave the same drop-down menu options for each of A, B, and C: the integers from -10 to 10. By doing this, students were now at least forced to follow the instructions of the problem. Integers were the only options, and this new format was scribed in time for spring 2009 examinations.

Pigeonholed by the drop-down menus, students did the best ever on an initial attempt (67.6%) at the newly formatted killer problem only to do dramatically worse (36.0%) on the next attempt in the same semester. From there, the killer problem continued to live up to its name with poor results. The chart below shows the success rates reported in table 1 with a vertical line separating the fill-in-the-blank format and the new drop-down format. It is clear that the new format had little, if any, effect.

---

F.I.T.B. = “Fill in the blank”

* For Exam 1 in the Spring 2009 term, an ambiguity was discovered in a new version of the problem and so data for that version has been removed for analysis.

** In both summer 2009 terms, two versions appeared on each student’s Exam 2 assessment.
Motivation

In their famous series of studies, Selden et al studied the phenomenon of non-routine problems in calculus courses and came to the conclusion that students who pass calculus (those who earned the grades A, B, or C) are generally unable to solve these problems (Selden, Mason & Selden, 1989, Selden, Selden & Mason, 1994, and Selden, Selden, Hauk & Mason, 2000). A non-routine problem, as defined by the researchers, is defined to be one “for which they had not been taught a method of solution” (1994, p. 19).

A student’s first attempt at the killer problem fits the definition the Selden studies use for non-routine problem because the problem does not appear on any prior assessments, is not taught in class, and had not been attempted by the student until that time. There are several reasons that it is not seen prior to the examination on which it first appears. First, the unorthodox format is not necessary outside an electronic testing environment. Secondly, there are too many different types of problems to cover them all as in-class examples. After the killer problem’s first appearance, there are typically questions about it by students which then may lead to an in-class algorithmic explanation, disqualifying latter attempts from fitting Selden’s definition of non-routine. For this reason, intuition borne out of the Selden studies would indicate that the results seen on the first attempt of the killer problem should in fact be expected. And, as it turns out, this intuition is accurate.

To see this more convincingly, it is helpful to separate the first attempts at the killer problem from latter attempts. Success rates, even at their best, are lower than one might expect given the simple nature of the problem. This view does, however, illuminate that some increase in student performance occurred after the change in format, but the overall success rate is still under 70% in all cases.
A Deeper Look

A few basic questions are essential to understanding students’ difficulties when confronted with the killer problem or any non-routine problem. Primarily, it is important to know whether students are fluent with the arithmetic and algebraic operations underlying the simplification of

\[ 4 \sin \frac{2\pi}{3} - 8 \sin \frac{\pi}{6}, \]

Would students have faired similarly well if the problem examined here had asked for \( A, B, \) and \( C \) in

\[ 4 \left( \frac{\pi}{2} \right) - 8 \left( \frac{\pi}{4} \right) = A + B \sqrt{C?} \]

One would imagine that a majority of students in trigonometry can correctly solve (2) because they either passed or were placed above algebra. Secondarily, is it that students’ difficulties with the killer problem pertain to knowledge of trigonometry? Mathematically, the only difference between the expressions in (1) and (2) is the conversion of \( \sin \frac{2\pi}{3} \) and \( \sin \frac{\pi}{6} \) to their exact values, and so a natural step is to assess a specific sample group of students, asking them to simplify \( 4 \left( \frac{\pi}{2} \right) - 8 \left( \frac{\pi}{4} \right) \) and to transform \( \sin \frac{2\pi}{3} \) and \( \sin \frac{\pi}{6} \) in separate problems. Student performance upon these tasks may expose deficiencies in Quantitative Knowledge (Gq) (Horn & Noll, 1997; McGrew, 2005, 2009) related to trigonometry or in algebra. The subset of students of specific interest to this inquiry are those who possess the Gq to simplify the algebraic expression and the ability to transform the transcendental expressions but who fail to solve the killer problem in its initial form, regardless of those abilities.

To be clear, solving (1) demands that students first recognize the necessity of performing two simple transformations using unit circle information and then to make those transformations, which are \( \sin \frac{2\pi}{3} = \frac{\sqrt{3}}{2} \) and \( \sin \frac{\pi}{6} = \frac{1}{2}. \) (Note that for \( \sin \frac{2\pi}{3} \), students are likely to implement a two-step process by first computing the sine of the reference angle \( \frac{\pi}{3} \) and then assessing its sign – positive or negative.) Thus, the difference between solving \( 4 \left( \frac{\pi}{2} \right) - 8 \left( \frac{\pi}{4} \right) \) and solving

\[ 4 \sin \frac{2\pi}{3} - 8 \sin \frac{\pi}{6} \]

(from a mathematical perspective) is solely confined to the concepts of the unit circle and leads to an important conclusion about the solver’s trigonometric knowledge.

If resolving (1) is not a matter of Gq pertaining to the trigonometric or algebraic functions, then is the issue not one of mathematics at all? The deficit these students are manifesting may not be related to their core understanding of the basic principles of unit circle trigonometry. Rather, a more plausible explanation in the face of any accumulated evidence is that the observed functional deficiency is related to students Quantitative Reasoning (Gr) ability rather than Gq. Gr is a sub-domain of Fluid Reasoning (Gf) (Horn & Noll, 1997; McGrew, 2005, 2009). Fluid Reasoning is a higher order cognitive function referring to the ability to execute deductive and inductive thinking. Reasoning inductively means employing strategies that work from the part to the whole, from the specific to the general, or from the individual instance to the universal principle. Reasoning deductively is the opposite; conclusions are derived from the general or universal to the specific.

Based upon the understandings of the cognitive processes at play, a reasonable explanation of students’ failure to resolve (1) is that the Gr process breakdown occurs in relation to the inductive rather than deductive aspects of reasoning. When students are confronted with parts of this multi-step problem they are unable to reason from the parts to grasp the universal principle.
This inductive failure requires additional explanation. As discussed above, the targeted defect is unlikely to be one of Gq. In other words, if cued we imagine these students will be capable of correctly recalling from their memory stores (Glr) (Horn & Noll, 1997; McGrew, 2005, 2009) the appropriate algorithm to execute a transformation of a trigonometric expression (in Piagetian (1928) terms the Gq could be thought of as a scheme or in Selden’s terminology a problem situation image). In general this seems to be the case based upon examination problems that specifically ask problems like $\sin \frac{2\pi}{3} = \pm \frac{X}{Y}$ and $\sin \frac{\pi}{6} = \pm \frac{X}{Y}$. The components that comprise the ability to make an inductive leap include

1. the recognition of the need to apply a specific element of Gq (the correct scheme),
2. fluent recall of the Gq, and
3. the Gq itself.

So the question remains, what is involved in recognizing the need to apply a specific Gq strategy? Or to restate the question, how is it that from the parts of (1) a student could perceive the expression in a context whereby the process of solving the killer problem is evident? To apprehend that a particular solution avenue is correct necessitates a glimpse of the big picture (an inductive process). The successful student executes this inductive leap perhaps because they can read the meaning in visual-spatial terms; they can quite literally see what is being asked.

The implied requisite cognitive abilities then include inductive Quantitative Reasoning (Gr), visual-spatial thinking (Gv), and long term memory (Glr). Though it may seem counter intuitive we hypothesize that working memory (Gsm) contributes little to no variance predicting the difference between those students who can and those who cannot solve the killer problem.

In a way, the killer problem in its simplicity presents a scenario that in the future can be more easily targeted by the assessment of cognitive functions than those used by Selden et al. Despite subtle differences, the fact remains that the killer problem presents to students a basic problem that they cannot reliably solve.

We conjecture that the analysis taken by Selden is robust enough to be applicable to a basic problem such as the killer problem but that the cognitive explanation offered by Selden et al should be extended. The problem situation image is defined in the third Selden report (2000) with the following statement. “When a problem situation is recognized, most of the features in its image do not immediately come to mind, i.e. into consciousness. Rather they seem to be partly activated” (p. 145). Our reading of the idea that “the features in its image do not immediately come to mind… they seem to be partly activated” is consistent with our suggestion that students’ failure to solve (1) is a failure of inductive Gr. The similarities between our account of the cognitive process involved and Selden’s account pertain to the inability of students to appreciate the problem’s gestalt though the differences are related to our various understandings of the cognitive origin of that failure. Selden seems to understand the students’ deficiencies in recall of long term memory stores by suggesting that students’ difficulties are attributable to an inability to sufficiently activate retrieval of Gq. Rather than a problem with long term memory, we suggest that neither the language of Baddeley’s (1996) central executive nor of Norman and Shallice’s (1986) Supervisory Attentional System accurately portrays the cognitive failure at work for these students. The issue in our view is not simply a problem of retrieval of a Gq scheme from long term memory, but rather a problem of interpreting and understand the semantic meaning of the expression (1) in a context whereby the process of solving the killer problem.
problem is conducted in a visual-spatial framework so as to trigger or cue (activate) retrieval of the appropriate Gq scheme.

As in non-routine problems, the killer problem strays from a student’s knowledge base due to its format and the fact that a linear combination of basic trigonometric expressions may not have been introduced before. Continuing with Selden’s argument, it is reasonable to suggest that students reach into this knowledge base for tentative solution starts, or “tentative general ideas for beginning the process of finding a solution” (2000, p. 145). Only an analysis of the work done in student attempts of the killer problem can confirm this suggestion. Unfortunately, because the killer problem is completed online, no archived data exists aside from the response given by each student. Future research might incorporate hard copy work done in attempting the killer problem, perhaps along with interview protocols to more specifically retrieve information.

To articulate a summary, we offer a simplifying analogy. Selden’s analysis suggests that students are for some reason or another unable to access the “folder” that contains the knowledge necessary to solve the killer problem, going to a filing cabinet of familiar mathematical facts and algorithms and rifling through them. We suggest that the students do not initially go to the filing cabinet; they look at the problem for something to tell them which folder to go to. The students are missing the appropriate cues that tell them, "it's in this folder."

One important difference between the killer problem and Selden’s non-routine problems lies in the subsequent attempts that were made by the students. If a problem is no longer non-routine after it has been seen by a student, then the consistently poor performance on later attempts of the killer problem remains unexplained. Future analysis may discern these attempts, find trends, and uncover why, after repeated attempts, students cannot solve the killer problem.

AN EXPLORATION OF FACTORS THAT INFLUENCE STUDENT ACHIEVEMENT IN DIFFERENTIAL EQUATIONS

Jennifer Czocher  
The Ohio State University  
czocher.1@osu.edu

This study is part of a larger curriculum comparison between two versions of a service course for engineering and physical science majors on differential equations (Baker, n.d. Boyce & DiPrima, 2009). The research questions stem from attempts to revise differential equations courses, and service courses in general, to be more relevant to non-math majors and to be in better alignment with the expectations of client departments. Thus, this investigation was oriented toward discovering what nonmajor students and faculty consider relevant. Of particular interest is whether the students, and their engineering professors perceive the content of their mathematics classes as related to the content in their chosen majors (Schoenfeld, 1989): (1) How do students in these courses perceive the role of mathematics, and the utility of differential equations in particular, in their majors? (2) How do engineering faculty characterize their own goals for a course on differential equations?

The study involved two lectures of engineering and physical science majors. The most common majors enrolled in the courses were Mechanical Engineering and Electrical/Computer Engineering and thus chosen as the target majors. Engineering faculty were invited to participate in semi-structured interviews to elicit their views the role of differential equations in their classrooms. The following data were collected: (1) a Likert-type questionnaire administered to ascertain student attitudes toward the utility of differential equations, and (2) interviews conducted with engineering faculty to assess the needs of the client departments and their expectations for the mathematics instruction of their students (Bingolbali & Monaghan, 2008). Questionnaires were administered to students at the beginning of the course and interviews with engineering faculty were conducted throughout the quarter. The questionnaires were analyzed using quantitative methods while the faculty interview transcripts were analyzed through the method of constant comparison.

CREATING MEANING FOR VECTOR EQUATIONS: SYMBOLIZING IN A CLASSROOM COMMUNITY OF PRACTICE

George Franklin Sweeney
San Diego State University
georgefsweeney@gmail.com

Symbolizing in mathematics is an important part of learning to do mathematics and is an important focus of analysis for mathematics education researchers (Arcavi, 1994; Duval, 2008). In the context of linear algebra, researchers have analyzed how students think about various symbolic representations involved in understanding systems of linear equations and vector equations (Sierpinska, 2001; Stewart & Thomas, 2007). These studies have focused on how individual students interpret the formal symbolic systems of linear algebra. Extending this work on how individuals construe meaning for symbolic systems, I focus on how a classroom community negotiates meaning for the symbolic forms of vectors and vector equations. As emphasized by Wenger (1998) the production of knowledge is a process of developing a collective experience of an object of scrutiny. In this particular case, the objects of scrutiny are vectors and vector equations. The presentation will discuss data collected from a recently completed classroom teaching experiment (Cobb, 2000) in linear algebra. Specifically, I focus on how the classroom community interpreted vectors and vector equations in relation to the central ideas of span, linear dependence/independence, and eigen-theory. In addition, I examine how the classroom negotiated between the geometric representations, systems of equations, and equations in vector form. The analysis considers verbal argumentation, gesture, and symbolizing that are prevalent in the classroom community. The significance of this work is that it illuminates the diversity of meanings that can be produced by a classroom community.

GIVING STUDENTS TO AN UNDERSTANDING OF THE FORMAL DEFINITION OF LIMIT

Beth Corey
Sam Houston State University
blc006@shsu.edu

Kenneth W. Smith
Sam Houston State University
kenwsmith54@gmail.com

While limits are foundational to the central concepts of calculus, our experiences with students as well as educational research abound with examples of students’ alternative conceptions about limits and infinity. Furthermore, most students struggle to make sense of the formal ε-N definition of the limit of a sequence. For the purposes of this study, we designed a series of lessons and a collection of dynamic sketches using The Geometer’s Sketchpad which we hoped would enable Calculus I students to value the formal limit concept and to construct the formal syYmbolic definition on their own. Rather than presenting students with the definition of limit at the outset, we used Heid’s (1988) approach of allowing concepts to develop first then attaching the symbolic definitions to the experiences of the students’ investigations. The lessons began by having students brainstorm about the colloquial meanings of the word “limit.” Students then investigated dynamic sketches of eight carefully-chosen sequences, using their intuitive ideas to decide if each sequence appeared to have a limit or not. After an in-depth class discussion, students were asked to evaluate the adequacy of possible informal definitions for the limit of a sequence. As students played the ε-N game using dynamic sketches of a variety of sequences, students attempted expressing the formal limit concept using both their own words and using formal symbolism.

We examined 17 college-level Calculus I students’ initial intuitive conceptions of limit and then investigated how their conceptions changed over the course of the lessons. Data were collected through a pre-test evaluating students’ initial understanding of limits, students’ written work, recordings of class discussion and individual interviews with six specific students, and a post-test. Analysis was conducted within the framework of conceptual change theory (Smith et al., 1993). Students initially held alternative conceptions of limit cited in the literature, such as the limit as unreachable conception, the limit as boundary conception, the notion that a constant sequence does not have a limit, or the idea that a sequence has a last term. Interestingly, intuitive ideas about cluster points and subsequences also arose. As the study progressed, students’ mental repertoire of sequences enlarged, thus allowing students to recognize the unproductiveness of certain conceptions in certain contexts. By the end of the study, many students could successfully explain the ε-N game in their own words, could express the formal concept symbolically, and could apply the formal limit concept graphically to conjecture if a sequence had a limit.

INDIVIDUAL AND COLLECTIVE ANALYSES OF THE GENESIS OF STUDENT REASONING REGARDING THE INVERTIBLE MATRIX THEOREM

Megan Wawro
San Diego State University
meganski110@hotmail.com

This poster presentation will be a summary of my dissertation, which has two aspects: (a) research into the learning and teaching of linear algebra, and (b) research into analyzing the development of mathematical meaning for both students and the classroom over time. Specifically, I analyzed how students—both individually and collectively—reasoned about and with the Invertible Matrix Theorem (IMT) over time. The IMT consists of over seventeen equivalent statements for $n \times n$ matrices, and these statements encapsulate the fundamental ideas of linear algebra that are developed over the duration of the course. Of methodological interest, I developed a way to coordinate the analytical tools of adjacency matrices and Toulmin’s (1969) model of argumentation at given instances during the semester as well as over time. Synthesis and elaboration of these analyses was facilitated by the notion of microgenetic and ontogenetic analysis (Saxe, 2002) and an approach for documenting classroom mathematics practices (Rasmussen & Stephan, 2008). Finally, a coordination of both the microgenetic and ontogenetic progressions documented by adjacency matrices and Toulmin was carried out in order to illuminate the strengths and limitations of utilizing both of these analytical tools in parallel on the given data set.

The data for this study came from a semester-long classroom teaching experiment conducted in an inquiry-oriented linear algebra course at a large university in the southwestern United States. The main data sources were video and transcript of whole class and small group discussion, as well as individual interviews with the five focus students for the individual component. My analysis revealed rich depictions of the ways in which students reasoned about and with the IMT that was not apparent through use of only one of the analytical tools. Adjacency matrices proved an effective analytical tool on arguments consisting of multiple connections that were for explanation, whereas Toulmin models proved illuminating for arguments with complex structure for the purposes of conviction. These and other results, as well as my methodological approach, will be discussed in the poster presentation.

REAL NUMBERS AND MATHEMATICAL THINKING

Robert Michael Baldwin
Virginia Tech
rbaldwin@vt.edu

Although it is universally agreed upon that a solid understanding of rational numbers is necessary for quantitative literacy (QL), little attention has been paid to the continuum both in school mathematics and in the research. Although, irrational numbers may not be necessary for the advancement of QL directly, a more complete understanding of the real numbers is important to the extent that incomplete knowledge of same may have some impact on the learners understanding of the rational numbers. The goal of this study is therefore, to explore pre-service teacher understanding and or misunderstanding of the real numbers. The motivation for this study may be attributed to work by Fischbein, Jehiam and Cohen (1995), involving the exploration of learner formal knowledge of the real numbers, real number hierarchy, definitions, and the location of various real numbers relative to the real line. With these concepts in mind a questionnaire was developed and administered to 26 undergraduate pre-service math teachers at a large university situated in the eastern United States. Drawing from this questionnaire, the focus was on four items:

1. Circle all the irrational numbers in the given set of numbers:
   \[ \{0, \sqrt{5}, \frac{1}{2}, (3\frac{1}{2})/7, 0.123152687943, \sqrt{\frac{1}{16}}, 3i + 5, 13, \frac{1}{2}/\frac{2}{3} \} \]

2. Irrational numbers are a subset of the rational numbers.
3. Rational numbers are a subset of the irrational numbers.
4. Can the exact location of \( \sqrt{7} \) be found on the real number line?

The findings of this study demonstrate that participants had either incomplete knowledge, uncertainty, or both, relative to the real numbers. For example, with respect to item 1, 88% of the sample correctly identified \( \sqrt{5} \) as irrational but only 46% circled only \( \sqrt{5} \). 54% of the sample identified rationals as irrational or mistook \( 3i + 5 \) as being irrational. With respect to item 4, 46% of the sample believed that it was not possible to find the exact location of \( \sqrt{7} \) on the real number line.

THE EFFECTS OF A NON-TRADITIONAL TEACHING METHOD OF THE CHAIN RULE ON MATHEMATICAL ACHIEVEMENT

Emily A. Price
Ohio University
ep311508@ohio.edu

In the wake of calculus reform, a number of interactive approaches have been proposed to better calculus teaching generally, and the chain rule in particular. Some use computer algebra systems and have found that students scored higher on tests of conceptual knowledge as a result (Palmiter, 1991). Students’ difficulties with the chain rule are symptomatic of a broader difficulty with functions, evidenced by Clark et al.’s (1997) finding that poor understanding of function compositions inhibits understanding of the chain rule, and Vinner and Tall’s (2004) description of how conceptual difficulties with topics such as the chain rule arise when a student’s concept image and/or concept definition are not the same as the formal mathematical definition.

The present study used a quasi-experimental approach with two freshman-level college calculus classrooms to explore the question: does a self-guided activity approach to teaching the chain rule increase student knowledge when compared to a traditional lecture approach?

The 120 participants were primarily engineering majors who were taught by the same instructor. The control group received a traditional teaching method grounded in a composition-of-functions approach while the treatment group engaged in a self-guided activity during which the instructor monitored progress, answered questions, and used the terms “inside” and “outside functions” in place of “composition” vocabulary. Students in the treatment group graphed functions and their derivatives on a handheld calculator while answering questions designed to probe the relationship between the two. The operating theory guiding the activity was that technology could promote conceptual reflection beyond procedural mimicry.

Pre- and post-test item comparisons showed no statistically significant gains in student knowledge resulting from the treatment. However, the treatment produced modest improvements in student understanding of the chain rule. An unanticipated outcome was the instructor’s satisfaction with the treatment activity and proposal to use the same activity in future classes.

TRIGONOMETRY AND DYNAMIC SITUATIONS: GESTURES, GRAPHS AND CO-VARIANT RELATIONSHIPS

George Sweeney
San Diego State University
georgefsweeney@gmail.com

A small group teaching experiment was conducted using an applet of a double Ferris-wheel. Three groups, with two students in each group, were videotaped solving a series of problems intended to help them symbolize the vertical movement versus time of a rider on the wheel. These students were part of a class for prospective teachers that examined topics in high school mathematics. Each set of problem-solving sessions lasted approximately 2.5 hours and was spread over two sessions. In this study, three episodes from two students’, Andrew and Oscar’s, interview demonstrate how these students made sense of the problem situation and the symbolization, and in turn used the symbolization to clarify and elucidate the dynamic system.

The theoretical perspective that this research takes extends from Freudenthal’s assertion that mathematics is a human activity. Freudenthal calls this activity mathematizing, which involves transforming realistic problems into mathematical symbols and then utilizing those symbols in order to derive greater understanding of the problem and the mathematics involved. Specifically, horizontal mathematizing is the development of informal ways of speaking, symbolizing and reasoning that students use in order to make sense of problem situations (Gravemeijer, 1999).

The analysis demonstrates how the two students made sense of the dynamic system through a process of horizontal mathematizing. Consistent with Rasmussen, et al. (2005) the students used their previous knowledge of trigonometry and algebra to symbolize the height versus time of the rider. In their creation of a graph of the height versus time of the rider on the double Ferris-wheel, they coordinated their gesturing of the movement of the wheel with their drawing of the graph. This led to a discontinuity between how they perceived the movement of the wheels (as each having constant velocity) with the inflection points on the graph. This argument came to a head in their symbolization of the angular velocity of each of the separate wheels. As they began to interpret their symbolization and make sense of the various co-varying quantities that had been symbolized, the students recruited the use of their gestures and body movement in conjunction with their argumentation in order to clarify how their symbolic function and graph fit their perception of the movement of the rider on the wheel.

The Ohio State University
somayajulu.1@buckeyemail.osu.edu

Using a mathematical problem solving test, we documented approaches used by thirty 8th grade students who had either completed or were enrolled in an Algebra I course at the time of data collection. In solving the problems, students could use and show their knowledge of linear equations and graphing. These topics were included since their mastery is considered the core goal of Algebra I curriculum. Results indicated that only 3 of the participants used algebraic techniques to solve problems. Prominent problem solving heuristics used included guess and check and setting tables. When children attempted to use algebra to solve problems they were not successful. Justifying and explaining results was problematic for all participants.

Introduction

The movement towards requiring an algebra course in the middle grades is widespread. More and more school districts across the country, particularly in urban communities, are now offering Algebra to 7th and 8th graders in hopes to increase enrollment in more advanced mathematics courses in high school. As a result of this push, in the past decade the number of students taking algebra and more advanced courses in 8th grade has increased by 30% (Loveless, 2009). An increase in the size of population taking Algebra however, can’t be interpreted as success in preparation (Smith, 1996). Opponents of the “pushing algebra down” movement have argued that while honorable in intention this push may not lead to desired results. Some empirical data indicate that these concerns are legitimate (Loveless, 2009). Political push for requiring Algebra in middle grades persists regardless, appealing it to be a civil right (Moses, 1996). Debates surrounding what middle school children may or may not gain, conceptually, from a formal course in Algebra remain prominent in the field (Silver, 2002). Many maintain that middle grades should be treated as a bridge between the informal and formal worlds of mathematics (Steen, 1996); hence study of symbolic Algebra should be delayed. Instead, students are better served if middle grades curriculum is focused on Algebra as multiple representations (Kaput, 1989) or ways in which it may be used to model real life contexts (NCTM, 2000). While a formal course focused on symbolic Algebra might be beneficial to a handful of students, time is better invested if middle grades children are immersed in activities that build their mathematical thinking and problem solving skills (Silver, 1997).

The purpose of the study we report here was twofold. First, we aimed to document how 8th grade children who had either completed or enrolled in a formal course in Algebra I would go about solving problems that utilized algebraic skills and techniques. Second, we wished to identify the problem solving heuristics that the participants commonly used. This study is a part of a longitudinal research project in which we trace development of mathematical thinking of approximately 80 students from grades 7 through 9 as the result of exposure to an after school
enrichment program. The data used for analysis in this paper was collected at the beginning of year I of the project and prior to program implementation.

**Context**

Algebra for all children was initiated in 1994 and motivated by a number of educational, political and social forces (Steen, 1999). The worthwhile goal attached to the agenda is allowing access to advanced mathematics courses in high school and ultimately increasing participation in STEM areas. National data indicate that the push for early algebra has in fact been successful. Not only more children are taking Algebra in Middle Grades, but also more students are taking courses in calculus and geometry in high schools. While the reported statistics speak positively to the enrollment of children in mathematics courses, a careful examination of students’ performance on achievement exams paints a grim picture of the conceptual gains resulting from this movement (Loveless, 2009). For instance, results of NAEP indicated that a large percentage of these students who scored in the lowest 10% of the eighth grade exam had either completed a course in Algebra or were enrolled in one at the time of testing. Further, many of the students who took Algebra or higher remain-intellectually and conceptually at a low achievement level. Indeed, Loveless (2009) found that an increasing number of lowest-performing students were those that were pushed into algebra in 8th grade The results of the 2005 NAEP scores of different student groups highlighted that the low performing eighth graders in advanced classes scored even below the average fourth grade students. Additionally, among the lowest-scoring 10% of children in the sample, nearly 29% were taking advanced math, showed skills typical of second-graders. According to Loveless (2009) Misplaced Students need to be helped to first develop knowledge needed for entry into advanced and abstract mathematical work. He concluded that delaying a course in Algebra until basis arithmetic skills are mastered might be necessary.

Supporting or challenging Loveless’ conclusion is not of particular concern to our inquiry; neither is it central to the discourse that concerns what mathematics might be of value to children in middle grades or what students might gain from a formal course in Algebra. Several questions persist: Would courses in Algebra then be beneficial if students have indeed mastered the basic computational skills? What do middle grade children gain from a course in Algebra I after completing the course with honorable grades and suitable ranking on the standardized achievement exams? Would these students be able to access their knowledge of algebra when solving problems? The need to address these questions motivated our study.

In this work, we hoped to document how a group of successful 8th graders performed on problem solving tasks that drew on central concepts from Algebra. In particular, we sought to seek evidence of whether efficiency of algebraic techniques was internalized by the participants as demonstrated in their work. Our goal was not to record gaps in computational skills but to identify ways in which they solved problems.

**Setting**

The study reported here is a part of a longitudinal research project in which we trace development of mathematical thinking and problem solving of approximately 80 middle grades children as the result of exposure to an after school mathematics enrichment program. Participants are of minority heritage and come from various urban schools and communities. The enrichment program provides opportunities for students to work on authentic tasks and explorations using technology and inquiry methods. The current study was conducted as an effort to document algebraic and problem solving skills of 8th graders at the time of their entry.
into the enrichment program with the intent to develop appropriate curricular materials that could enhance their existing knowledge.

Participants and Methods

The sample for the study consisted of 30 8th graders from urban communities. Three of the participants were of Hispanic, two of Caucasian and all others of African American heritage. All children had earned or maintaining either a letter Grade of A or A- in their Algebra I class.

At the time of data collection eighteen of the children were enrolled in either a regular or an Honors Geometry course, having completed an Algebra I course in 7th grade. Among this group 12 reported having been studying trigonometry in school at the time of data collection. The remaining six were studying either similarity and congruence criteria (proving triangles being similar using two column proofs) or constructions using compass and straight edge. The twelve students enrolled in Algebra I were studying either FOIL method or solving system of linear equations.

Data collection and analysis

All children initially completed a Personal Inventory Survey (PIS) consisting of 12 questions. The survey consisted of three parts. On the first part of the survey the children reported their feeling towards mathematics; and ranked their ability to make sense of mathematical ideas as well as their confidence in their ability to think mathematically. On the second part of the survey the children identified mathematical areas in which they felt most and least successful. The last portion of the survey elicited information from children on two issues: (1) what they considered to be features of a person with a mathematical mind and; (2) skills they felt were needed to be successful in mathematics. The last portion of survey asked students to state what they believed the study of Algebra was about and its major ideas and concepts.

Upon completion of PIS, all children were administered a test of mathematical problem solving consisting of four questions (See table 1). The questions could be solved using a variety of different approaches and techniques and concerned topics traditionally covered in Algebra I curriculum. Selection of problems was guided by both theoretical and practical considerations. On a theoretical level, in line with Schoenfeld’s (1994) characterization of mathematical thinking, we opted to use tasks that provided opportunities for children to show their competence in solving novel problems. Additionally, we aimed to use contexts that allowed children to use

the tools of the trade (Schoenfeld, 1994) with which they felt most comfortable (including algebraic tools) and using them to solve problems. Further, in line with Cobb et al.’s perspective (1991) we agreed that the purpose for engaging in problem solving is not just to solve specific problems using pre-defined tools, but to encourage and elicit the interiorization and reorganization of the schemes as a result of the activity. The test items were piloted among children in grades 5 through 7 in the previous to assure various approaches could be used to solve them. The items did not restrict students to the use of specific Algebraic tools. Therefore, they had the potential to elicit “natural” mathematical behaviors on the part of learners. On a practical level, in choosing specific content pieces to be addressed in the test, we focused on linear relationships since mastery of this topic is the central goal of Algebra I curriculum. Students were asked to solve each of the problems using any method they wished. They were also asked to explain why they felt their answer was correct in each case.

1. Consider the two pay options: $300 a week or $7.50 an hour. A) What factors will affect you’re your choice of option to take. (B) Draw a graph that compares the two pay options, allowing the reader to determine which option might be best for them to take.
2. Water lilies are growing on a lake. The water lilies grow rapidly, so that the amount of water surface covered by lilies doubles every 24 hours. On the first day of summer, there was just one water lily. On the 90th day of summer, the lake was entirely covered. On what day was the lake half covered?
3. Karim lends $104 to 3 friends. He gives the second one twice as much as the first one and the third friend 5 times as much as the first one, how much did he give to each friend?
4. In a crowd of horses and people we see 18 heads and 52 legs. How many humans and how many horses were in the crowd?

Data analysis followed two stages. At the first level, students’ responses were analyzed along four criteria: (a) Appropriate representation of the problem, (b) appropriate implementation of procedure for solving the problem, (c) completion of response and, (d) adequacy of justification. Each question was scored on a scale of 0-2 (0=No/wrong response; 1= some error; 2=complete response). Descriptive data was compiled for each item for the group. T-tests were conducted to see whether significant differences existed among the group according to the course in which they were enrolled at the time of data collection.

Second, reviewing students’ responses to each question, we identified and tallied the various problem solving heuristics children had used on each problem. Common difficulties children had seemingly encountered on each task were also recorded. In particular, we noted where students had used Algebraic techniques for solving problems and whether they were successful in their effort. Inferences concerning ways in which Algebra could have enhanced or impeded students problem solving were then made.

Results

The participants’ responses were analyzed using both qualitative and quantitative means. Each response was scored on a scale of 0 to 2. A score of 2 was assigned to a response where correct procedure was used and correct answer was obtained. A score of 1 was assigned to each response when either an incorrect answer was obtained using a correct procedure, or a correct answer was reported without showing work. A score of zero was assigned with either no response was provided or the answer was incorrect or irrelevant to the question. A second
review of each item was completed with attention focused on the justifications provided on each response by the participants.

**Overall results according to different groups**

Table 1 summarizes the performance of children on each task. Note that while some differences existed among the overall scores of each group on items 1b, 2, and 3, the only statistically significant difference appeared on the second problem.

**Common Approaches to tasks**

**Graphing.** Drawing and interpreting graphs, representing data graphically, and communicating information and relationships using graphs are among the most important skills children are expected to develop in Algebra I curriculum (NCTM 2000). In response to part a of problem 1 all students successfully identified that the number of hours worked per week should influence the choice of job option, indicating an understanding of dependent and independent variables (Note that three students also identified location of the job and health benefits as critical considerations when deciding on a job). Part b of the problem asked students to illustrate the relationship between two job options graphically, capturing all necessary data that could assist an individual make a decision regarding each option. Among 30 students only one student successfully produced a “Pay vs. Hours Worked” graph for the two options, highlighting “40” as the point of intersection of the two lines. Other responses produced fell under four different categories: (1) documentation of instances of pay vs. hours without realization of a need for continuity in representation; (2) Separate graphs representing a cumulative count of pay for different weeks; (3) Two distinct bar graphs representing each of the options using different scales for amount of pay in each case, and (4) Cumulative “Pay vs Week” graphs of options with (0,0) as the common point (point of intersection of the two lines).

**Water Lily problem.** The water Lilly problem was designed and used so to determine children’s facility with the use of working backward heuristic. The problem highlighted the negative influence of algebra on students’ problem solving process. All but one of the participants approached solving the task by setting up a table of values, assuming 1 water lily on day one and doubling the value each time (representing growth in days). Among the 29 who used this approach, 12 students seemingly stopped computations after approximately 10 levels and wrote 45 (90/2) as the answer. Five of the students crossed out the table they had set initially and reported 89 as the answer. Neither one of these groups students explained how they had reached the final solution or whether they were certain of the accuracy of their answer. Five students noted 30 as the answer, stating that 30 was the square root of 90. Only one student had tried to represent the problem pictorially (See Figure WL1). This approach did not lead to an answer.

![Figure WL1. Drawing a picture](image-url)
Lending Money problem. The lending money problem is arguably the most typical of problems used in Algebra I curriculum. As such, we had hypothesized that a majority of the students would use an algebraic approach for solving the problem. However, only three students attempted to represent the relationships algebraically and only one of them was successful in establishing a formula to solve the problem. Figure LM1 is illustrative of the unsuccessful efforts used by children to solve the problem algebraically. Among the remaining 27 students, 15 first attempted to equalize the amount among the three individuals and used the established initial value as a way to determine the amount of money borrowed by each of the three friends. These individuals reached incorrect answers by rounding up and rounding down answers (see Figure LM2) without attention to the context. No student in this group attempted to check the results for accuracy. Twelve students used a guess and check strategy with an equal number of students using either systemic (educated first guesses and refining the guess to reach the final answer) (See Figure LM3) or un-systemic approach (beginning randomly with one extremely low or extremely high initial guess) (See Figure LM4). Five of the 6 students who used a systemic approach for solving the problem answered the question correctly. Among those who had used an un-systemic guess and check approach, four abandoned the problem after 10 numerical trials. Only one student in this group correctly answered the question.

Horses and People problem. Figures HP1-3 illustrate the most commonly used problem solving strategies by children when solving Horses and People problem. Among the thirty participants only two of them used algebraic techniques (solving the problem using a system of linear equations). In case of one of these students, due to an un-noticed arithmetic error, an
incorrect answer was obtained. Other approaches used by children included: drawing a picture (n=12) (See Figure HP1), guess and check (n=10) (See Figure HP2), and repeated subtraction (n=5) (See Figure HP3).

**Discussion**

Algebra for All is certainly an honorable educational goal. Requiring Algebra in middle grades, however, may not be wise if a serious consideration is not given to how and what children are taught in previous years. Increasing participation in advanced mathematical coursework is a major concern to the discipline. However, success in such courses rests on students’ ability to reason, think mathematically, use mathematical tools to solve problems, and communicate ideas in writing. Our data indicate that an early course in Algebra did not appear to have led to development of either efficient problem solving skills or algebraic approaches among the participants. Indeed, among the thirty participants only 3 tried to solve problems using algebra. More importantly, only one of these individuals was successful in this effort. Problem solving heuristics used by children included the use of guess and check and setting up table of values without evidence of thoughtful consideration of efficiency of the methods they used. Considering that the thirty participants in this study were from 24 different classrooms in 10 different schools, the results are of particular importance.

Success in advanced mathematical coursework and continued participation in pursuing such courses beyond high school depend largely on the ability to think mathematically. Thinking mathematically has more to do with using the tools of trade to solve problems (Schoenfeld,
1994) and less with the ability to recall or accumulate these tools. Algebra courses in their current form and content share several major shortcomings. First, they focus on mastery of a narrow range of skills for solving equations and inequalities, graphing, and simplifying expressions. As such, they remove context from learning and emphasize manipulation of symbols to the point of hindering the development of algebraic reasoning and mathematical thinking skills among children. Second, they tend to be prescriptive in terms of what students are expected to do as they complete exercises and tasks. An early emphasis on Algebra courses that focuses on mechanical mastery neglect the importance of helping children develop an understanding of Algebra as a language for communication and prediction. Children need to learn to answer questions about quantitative patterns and relationship and should be provided a chance to realize how algebra may empower them to engage in such activities. There is consensus that mathematical power consists of the ability to work with mathematics flexibly and in different contexts. There is also consensus that a major educational goal for all children is to assist the development of their mathematical power. We argue, based on the data we presented in this paper, that requiring a formal course in Algebra may not be an appropriate pathway towards reaching the goal of making mathematics children.

In this paper, we examine classroom norms and teacher moves that support the equitable participation and growth of all students in a third-grade inclusion classroom during a routine focusing on relational thinking. Analysis of classroom video supports findings that a highly conceptual approach like relational thinking can be used successfully with an inclusion classroom.

Introduction

In this study, we focus on one teacher’s implementation of an algebraic routine in a third-grade inclusion classroom. Student participation is an issue of equity and achievement; students who participate more generally learn more from the lesson, and low rates of participation can predict low achievement in the early grades (Cohen, 1984; Finn & Cox, 1992). The paper speaks directly to the conference theme of Optimizing Student Understanding in Mathematics, as we examine how establishing classroom norms and assigning competence to low-status students promoted the participation of all students, including those students with Individual Education Plans (IEPs).

Theoretical Perspectives

The work of Carpenter, Franke, and Levi (2003) around relational thinking examines the use of number sentences (equations) designed to develop concepts of equality and relational thinking. These include two types of number sentences. One type is complete number sentences about which the question is asked as to whether they are true or false. Examples of these are: 2=2; 3+0=3; 5=1+4. These number sentences are used to challenge children’s notions of the meaning of the equal sign. As Carpenter and colleagues (2003) note, children often reject the previous three examples (and others) as being equal because respectively (a) there is no operation; (b) adding zero is not really adding anything so it isn’t allowed; and (c) the order is wrong. A second type of number sentence is one where an unknown is present such as 3+10=7. Children who believe the equal sign indicates that the answer comes next will predict that 13 is the correct response for the unknown (Falkner, Levi, & Carpenter, 1999). Challenging children’s naïve or emergent understanding of the equal sign is one aspect of supporting them in developing relational (or algebraic) reasoning.

A second aspect of supporting children is developing the capacity to use relational strategies instead of computational strategies when solving for an unknown (Carpenter et al., 2003). Through working on series of number sentences containing unknowns and carefully selected values for the given numbers, children begin to see that it can be easier NOT to compute to find an unknown value. For example, in the case of judging the truth or falseness of the number sentence 27+37=25+39, instead of computing to find that the value for each side of the equation is 64, children will begin to use relational strategies to determine whether the expression is true. The will, for example decompose 27 into 25+2 and 39 into 37+2 resulting in an expression that now is clearly equal: 25+2+37=25+2+37.

In order to understand the teacher moves that supported the achievement of all the students, we situate the discussion of mathematical content and strategies within a larger sociocultural framework, in which the co-constructed norms of a classroom community shape the learning of the students (Yackel & Cobb, 1996). Establishing norms such as the necessity of (a) explaining one’s thinking around a solution to a problem, and (b) carefully attending to the presentation of thinking by classmates, helps to create an atmosphere in the classroom where everyone is expected to engage in and explain substantive mathematical thinking and everyone is respected for his or her contribution. We analyze these norms developed over time in this classroom, through particular teacher moves in interaction with students. In other words, this teacher invested in creating norms that would support learning, including the learning of students with IEPs.

Next, we draw on the work of Cohen and her colleagues (Cohen, 1997; Cohen & Lotan, 1995; Cohen, Lotan, Scarloss, & Arellano, 1999) around complex instruction in heterogenous classrooms. Among other things such as using rich and worthwhile mathematical tasks, complex instruction involves teachers explicitly assigning competence to low-status students by making comments that are public, specific to mathematics, and valid. It is this aspect of complex instruction that we focus on in this study. Children with low-status (social and academic) are often reluctant to participate in mathematical discussions and thus defer to their higher status classmates. Assigning competence by explicitly noticing and calling public attention to work of lower status students challenges the notion that students have that there are those who are good and competent with mathematics and others who are not.

As we are particularly concerned with the inclusion of low-achieving students in conceptual mathematical practices such as the relational thinking routine, we also draw on Empson (2003), who specifically analyzes the mathematical participation of low-achieving students in a discussion based classroom. Research has documented the unequal participation of low achieving students in discussion-based classrooms, including lack of participation and less mathematical contributions than their high performing peers (Baxter, Woodward & Olsen, 2001). Empson (2003) found many different strategies used by low-achieving students, such as reading teacher cues and attempting to avoid work. After days, months and years of limited participation, low achieving students are less likely to take up opportunities to learn, such as making presentations in class. Our study analyzes how one teacher sought to interrupt this cycle. Empson (2003) uses socio-interactional linguistics to determine participant frameworks, or a unit of activity in which relationships, roles, and domain-specific content affect classroom interactions (Goffman, 1981). These frameworks are particularly useful to understand the relationship between the learners, teacher, and the mathematical content as it is constructed within classroom discussion. In our study, we focus on the whole group discussion of relational thinking problems, as individual student present their solutions. We look, then, to see how the participants, especially low-achieving students, are positioned into particular roles.

In order to understand the representations that students used to solve problems like the ones described above, we draw on earlier work of Carpenter and colleagues (Carpenter, Fennema, Franke, Levi, & Empson, 1999). We extend a framework (direct modeling, counting, and numeric strategies) previously used to analyze solution paths to contextualized problems to work done around relational thinking. Direct modeling involves modeling each value in a problem with concrete materials. In the original framework for example, a child might use direct modeling with cubes or other manipulatives to solve the following problem: I have 3 pencils. I pick up 4 more pencils from the classroom floor. How many pencils do I now have? Following
the action of the problem, the child might lay out three cubes, representing the initial number of pencils, add four more cubes to represent the pencils found on the floor, and then count the entire number of cubes to find the solution of seven pencils. A child using a counting strategy might solve by counting on from four, saying 4, 5, 6, 7 to arrive at the solution. A child using a numeric strategy might know the math fact 4+3=7 or might derive the fact thinking: I know 3+3=6 and so one more will be 7. This framework supports our analysis that children with poor numeric strategies (often in our case, children with IEPs) were able to display relational thinking through the use of concrete materials.

For a final note, we are taking a social constructivist view of competence and disability in this paper. Within this study we are considering the label of students with IEPs, not as an inherent and static determinant of individual ability, but as a school-based designation which reflects and recreates differential ability within the classroom (Dudley-Marling, 2004; McDermott, Goldman & Varenne, 2006). Because of the importance of this designation in the culture of schools, we choose to use this classification to focus attention on how the teacher successfully managed a discussion-based classroom that included all students.

**Research Question**

The goals of the research reported in this paper were to examine the teacher moves and classroom norms that supported the development of relational thinking (Carpenter et al., 2003) with particular attention to the participation of students with IEPs. Our data collection and analysis processes were guided by one question: What are the norms and teacher moves that support the equitable participation and growth of all students in an inclusion classroom during a routine focusing on relational thinking?

**Methodology**

During the course of one school year, a teacher in a third grade inclusion classroom employed a weekly routine focused on developing children's competency with relational thinking (Carpenter et al., 2003). Once a week for approximately 30-45 minutes, the teacher presented the class with number sentences to solve. These were either (a) complete number sentences to be judged true or false, or (b) number sentences that had to be solved for an unknown. Number sentences had already been written on the board when the children entered the classroom. They were encouraged to get to work quickly on solving the problems. After 20-30 minutes of independent work, students were asked to present their thinking to the class. It was these presentations that were video-taped. A total of 25 of the presentation portions of these weekly sessions were video-taped and comprise the data set.

There were 12 participants, seven boys and five girls. Seven students were African American, five were White. Four students had IEPs; all of these were African American. These 12 participants are the students who were enrolled in this class for the majority of the school year and who participated in the routine; there was one student with Downs Syndrome who was in the class for the entire year but did not participate in the routine.

For analysis, the video was segmented by student presentation so that one student presenting his/her solution path to a given problem on a given day constituted one unit. For each unit, a detailed narrative description of the student solution path, including interactions with the teacher, was constructed. These solution paths were then coded for relational or computational thinking (Carpenter et al., 2003). Following this initial coding, a second pass was taken through the data. At this time the solution paths were coded as to what type of representation was used: direct
modeling, counting, or numeric (Carpenter et al., 1999). For each unit, teacher moves were then identified. In addition we cataloged which participants presented their thinking at each session so as to examine to what extent all students (particularly those with IEPs) were supported in participating in this portion of the activity.

**Results**

The teacher was able to create a classroom in which students with IEPs were not isolated, but were contributing, developing members of the classroom mathematics community. She did this in two ways: (a) by developing and consistently employing classroom norms that applied to all students and (b) by using several strategies for assigning competence to students with IEPs (Cohen & Lotan, 1997). After discussing the classroom norms that the teacher established, we turn to an extended example of the work of one student with an IEP, although this student is not an isolated example. By the end of the year, there was significantly greater participation in the routine by students with IEPs.

**Classroom Norms**

From our analysis of the data, it seems clear that the teacher created a supportive environment for all students to learn complex concepts. While at the beginning of the year, higher-achieving students were the ones that presented their thinking most often, by the middle of the year, students with and without IEPs made presentations of their thinking and contributed to the ensuing discussions a similar percentage of time. Some of the norms that supported student success included:

- Every student was expected to explain his/her thinking out loud at the board.
- Students were allowed to use notebooks to scaffold their presentation without loss of status.
- Every student was expected to attend carefully to the presentations, and encouraged to compare the strategies that they used and the strategies of the presenter.
- Emerging strategies were named after children who used them; this was as likely to be a student with as a student without an IEP.
- When a student struggled to present his/her ideas, the teacher asked questions and re-voiced statements, but only after allowing considerable wait time, often at several points throughout the student’s presentation.
- Students were encouraged to use manipulatives to solve problems without loss of status.
- Teacher focused attention on thinking, not on correctness of answer.
- Teacher had high expectations that all students would move from computational to relational thinking strategies.

Most of these norms were enacted in a strikingly consistent way for all students. This consistency, along with the continually high expectations that the teacher held for all students, were key factors in creating a supportive environment for all students including those with IEPs and others who struggled to think relationally. In what follows, we present an example that demonstrates the development of one student (with an IEP) over the course of the school year with respect to the enactment of several of these norms. In the example, this includes (a) the student explaining his thinking, (b) the use of teacher scaffolding, (c) the use of manipulatives for direct modeling, and (d) movement from computational to relational thinking. The example
of this one student is meant to be indicative more generally of the ways in which the teacher managed the classroom to support the mathematical performance and participation of all students.

In one exchange, early in the fall, the teacher asked Caleb, a student with an IEP (all names are pseudonyms), to present his solution for the problem: 8+7=15+1, True or False? The teacher began the exchange by attempting to relate his presentation to the strategies of other students, “Do you want to do it the way Jacob did it or Serena did it or Karen or Jessica? Is there something about what they did that you would like to try?” Caleb did not answer, instead he turned to the board and wrote 15 under 8+7, then wrote 16 under 15+1, and circled false. Although correct, the teacher did not accept this work as sufficient. She asked:

Teacher: Tell us in words what you were thinking please?
Caleb: (No response, looks down)
Teacher: How did you know that this was a false equation, a false number sentence?
Caleb: (Looks down)
Teacher: Look at the board please.
Caleb: (He turns and looks at the board.)
Teacher: What is 8+7 equal to?
Caleb: 15
Teacher: What is 15 + 1 equal to?
Caleb: 16
Teacher: Is 15 equal to 16?
Caleb: (Under his breath, he repeats the question to himself.) No.
Teacher: No, so false is the correct answer.

The next time that Caleb presented a solution, for the problem 19+3=0+9+3, both teacher and student had a different strategy. Caleb used a direct modeling strategy to solve the problem and his teacher validated this strategy, simultaneously scaffolding his presentation. Caleb brought connecting cubes to the board and began his presentation by meticulously arranging his cubes into stacks of 10, 9, 3 and then 9 and 3.

Teacher: What number of cubes do you have, Caleb?
Caleb: (He doesn’t answer, but continues arranging his cubes.)
Teacher: Look. Here you’ve got 10 and 9 and 3. And here I see 9 and 3. (Teacher looks into his notebook). Well what did you do on this side, Caleb? (Indicating the 19 and 3.)
Caleb: I made 19 and 3.
Teacher: You started with the 10 . . .
Caleb: And then I put the 9.
Teacher: And that made how much?
Caleb: 19
Teacher: You’ve got the 19+3 on this side (showing his cube representation). What about this side of the equal sign?
Caleb: On this side I had 9 and 3.
Teacher: So what was missing here?
Caleb: The ten (showing his separated stack of ten cubes).
In a final example, in the spring of the year, Caleb was called on to quickly present a solution from his seat. Here he did not need additional teacher scaffolding, and was able to present a purely verbal solution. The teacher, focused on interrogating student understanding of the nature of the “answer” in these problems, asked Caleb what the answer was in the problem 5+1+1=8. When Caleb answered “False”, she responded with “Because why?”

Caleb: False, because this (referring to the 5) would have to be a 6.
Teacher: What is the answer?
Caleb: False.

Discussion

In this classroom, the teacher positions all students as problem solvers and solution reporters (Empson, 2003). Students with IEPs in mathematics are expected to present, just as high-achieving students are. These roles, problem solver and solution reporter, were not immediately taken on by Caleb or by other students with IEPs in the classroom. In fact, the teacher invested considerable resources of time and scaffolding in students with IEPs so that these students became full participants in the classroom routine. The first exchange in the above example lasted seven minutes, the second 11 minutes. Clearly, the amount of time invested in this student during these class sessions is significant.

The consistent application of a set of classroom norms resulted in a classroom that supported the participation of all students. The remarkably consistent expectations of this teacher, resulted in a classroom that allowed all students to participate equitably. Mathematics classrooms are too often focused on a single ability: executing procedures correctly (Boaler, 2006). One important strategy used by this teacher in creating an equitable classroom was de-emphasizing procedures and correct answers. Instead, as our example shows, the teacher consistently focused on student thinking. In the first exchange, we can see the teacher attempted to position Caleb as a competent solution reporter, even though he seemed to need considerable verbal scaffolding to present his solution. Many teachers may have accepted Caleb’s initial non-verbal presentation. This teacher consistently expected all students to provide both a visual and a verbal explanation of their solution. She did not let Caleb off the hook- and chose rather through direct questioning to introduce language for a simple proof. We would argue that this approach allowed students to feel safe taking risks, whether that attempt was at presenting an idea to the class or in trying the strategy of another student.

As the results indicate, the teacher used several strategies for assigning competence to this student with an IEP: valuing his problem solving methods; holding high expectations of the justification in his presentations; and making positive comments that were specific and valid about his thinking. Another critical aspect of teacher practice in promoting equity was allowing solutions using direct modeling, or manipulatives, to have equal status with numerical solutions. Most of the students who were struggling (those with IEPs) often used direct modeling with linking cubes to arrive at their solutions. As we saw in the extended example, the teacher encouraged the students to share this strategy during presentations, even asking them to demonstrate how they used cubes to find the answer. In the second exchange, the teacher continued to expect that Caleb would present his work both visually and verbally. Caleb needed fewer prompts to explain his thinking than he had in the first exchange. The concrete manipulatives supported both his thinking, and the presentation of his strategy. The cubes

allowed him to demonstrate the decomposition of 19 into 10 and 9, which was central to his thinking relationally about the problem. The teacher attached status to the connecting cubes as a strategy, here, by choosing Caleb to demonstrate this strategy. As the results demonstrate, students who struggled significantly with computation were able to think relationally and demonstrate this thinking using direct modeling.

More generally, the level of scaffolding provided by the teacher was based on whether or not a student was stalled in his or her presentation, not on his or her status within the classroom. Thus, although in this case, we see the teacher scaffolding a student with an IEP, both high and low-status students gave presentations where the teacher provided significant scaffolding. In this way, variations in scaffolding were evenly applied across all students regardless of classroom status.

Our results show a student who began the year using computational strategies to solve problems and who was a reluctant participant. By the end of the year, this student was more confident in his participation as the last student-teacher exchange demonstrates. By the end of the year, not only he, but most students, including those with IEPs, were solving problems relationally a great majority of the time.

**Conclusion**

Through the analysis of Caleb’s participation in the classroom routine, we can see a development of his algebraic thinking from computational to relational. This thinking was scaffolded by his use of direct modeling to solve the problems. In addition, we can see the development of his class participation in the community, from a student who was reluctant to speak (first exchange), to a student who confidently engaged in the discussion from his seat (final exchange). This work, including and engaging the students with an IEP in mathematical thinking, is hard work. It would be easier to let a shy, reluctant student like Caleb get away with limited participation. Instead, this teacher made participation a requirement, and supported Caleb through encouraging alternative strategies for solving problems that had equal status in the classroom, in this case direct modeling with connecting cubes.

In our work with teachers and students, we are frequently asked how to include all students in high-level mathematical thinking. Teachers, faced with low-achieving students who may not often participate in whole group discussion, assume that this kind of instruction is not for “them.” As Empson (2003) suggests, teachers want to help students save face, and not to embarrass those who are struggling. This classroom presents an equitable resolution to this conflict. Through high expectations of participation, and a supportive community, all students were able to present relational thinking to their classmates. We believe that the results of this study are significant, as they demonstrate that a teacher can successfully use a highly conceptual approach like relational thinking with an inclusion classroom.

This paper compares the nature of the transformational algebraic activities addressed in four beginning algebra classes that used the same innovative algebra curriculum materials. Two classes were taught by one teacher; the other two by another teacher. We developed categories of transformation-related ideas and used them to analyze the transformational activities enacted in each class. The analysis reveals that some ideas were addressed in all classes, whereas others were addressed in only some of the classes. Moreover, in the case of one teacher, transformation-related ideas were addressed similarly in her two classes, whereas major differences were found between the two classes of the other teacher. The findings suggest that the differences found between teachers and between classes of the same teacher are related to complex interactions among the teachers, the curriculum, and the classes.

Introduction

By and large, meaning-making work in algebra has been mostly associated with generational algebraic activities, i.e., with developing meaning for the objects of school algebra: expressions and equations (Kieran, 2004). However, the construction of meaning in algebra need not be related solely to generational activities, since constructing meaning for the concept of equivalence and for using properties and axioms in the manipulative processes occurs within transformational algebraic activities (Ibid). Kieran (2007) pointed out a recent change in research in the area of transformational algebraic activity, from emphasis on the manipulative processes used in simplifying expressions and in solving equations, to attention to the theoretical foundations of students' manipulative work. Thus, in recent years attention has been given to studying the processes of learning the concept of equivalence and using meaningfully properties and axioms in the manipulative processes. Similarly, in recent years a major change has occurred in the way transformational activity is treated in algebra curriculum materials. Algebra textbooks have traditionally centered on the transformational aspects of algebraic activity, emphasizing rule following and rote symbol manipulation, often without attention to conceptual understanding and meaning (Kieran, 2004). However, innovative algebra curricula developed in recent years (e.g., Everybody Learns Mathematics in Israel; Connected Mathematics Project (CMP) in the USA) often emphasize conceptual understanding of algebraic processes, and developing meaning for equivalence, and for the use of properties and axioms in the manipulative processes, thus, giving meaning to algebraic manipulative processes.

Obviously, students that use different curriculum materials may be exposed in class to different natures of transformational activity. For example, studying from a textbook that focuses primarily on rule following and symbol manipulation would probably result in more emphasis on rote transformational activities than in the case of using a textbook that focuses on conceptual understanding and construction of meaning. But do students that use the same curriculum materials experience the same nature of transformational activity? Accumulating research suggests that the enacted curriculum is not identical to the written curriculum (e.g., Remillard et al., 2009), and that different teachers use the same curriculum materials differently.

(Manouchehri & Goodman, 2000; Tirosh, Even & Robinson, 1998). Studying the same teacher teaching in different classrooms has also recently begun to be the focus of research (e.g., Herbel-Eisenmann, Lubienski, & Id-Deen, 2006). Still, seldom did the teacher in such studies use the same curriculum materials in different classrooms. Furthermore, these studies focused mostly on pedagogy – rarely did they examine the enacted mathematics.

Recently, as part of the Same Teacher – Different Classes research program (Even, 2008), Eisenmann and Even (2009, in press) examined the enactment of the same algebra curriculum materials in four classes that used the same innovative algebra curriculum materials. Two classes were taught by one teacher; the other two by another teacher. Eisenmann and Even’s study, which employed quantitative analysis that compared the distributions of three types of algebraic activity – generational, transformational, and global/meta-level – revealed statistically significant differences between the written and the enacted curricula, between the two participating teachers, and between the two classes of each teacher. Our study builds on these quantitative findings. Its aim is to compare, this time using qualitative methods, the nature of the transformational algebraic activities addressed in Eisenmann and Even’s four classes, between the two participating teachers, and between the two classes of each teacher.

**Methodology**

Two teachers and four 7th grade classes – all using the same innovative algebra curriculum materials – participated in this study. Each teacher taught in two classes, each from a different school. Sarah taught classes S1 and S2; Rebecca taught classes R1 and R2. Interviews with the teachers revealed that each perceived one class (S2 and R2) as encountering more difficulties in engaging in mathematics. The curriculum materials that Sarah and Rebecca used in their classes were part of the Everybody Learns Mathematics program, one of the innovative 7th grade curriculum programs developed in Israel in the 1990s. The curriculum materials include suggestions on enactment, including detailed lesson plans. Sarah followed rather closely the written lesson plans whereas Rebecca did not. Rebecca also was more attentive and responsive to students’ mathematical behavior and performance (Eisenmann & Even, 2009, in press).

The main data source included video- and audio-tapes of the teaching of a whole learning unit that introduced the topic equivalent algebraic expressions (intended for 15 lessons in the curriculum materials) in each of the four classes (a total of 67 lessons). Our analysis centered only on whole-class work. First, we analyzed the nature of each transformational activity in the written curriculum materials, using open coding. We then used the categories generated to analyze the enacted transformational activities in each of the four classrooms. Activities that the teachers used that were not from the curriculum materials were also categorized. We constantly compared the categories with new data from the videotapes and refined them. The occurrence, explicitness, and inter-connections of various central ideas embedded in the transformational activities were also analyzed, as well as the contribution of both the teacher and the students to the progression and implementation of the activities.

**Transformation-related Ideas Addressed in Class**

Analysis of the whole class work in the four classes revealed the following, more or less chronological, 12 categories; each linked to a different transformation-related idea. The first six categories, briefly listed below, represent ideas addressed in the written materials:
Chapter 2: Algebraic Thinking and Reasoning

(1) Substitution of numerical values into expressions to show that an expression does not represent a generalization of a given pattern.

(2) Substitution of numerical values into expressions to develop a sense of the behavior of expressions.

(3) Substitution of numerical values into expressions to show non-equivalence.

(4) Substitution of numerical values into expressions is not an appropriate means to show equivalence.

(5) Expanding and simplifying expressions to maintain/show equivalence.

(6) Expanding and simplifying expressions as a means of engineering expressions for a desired purpose.

The upper row in Figure 1 illustrates the teaching sequence of the above six ideas as addressed during the suggested whole class work of the 15 units in the written materials.

The next five ideas (#7–#11) were not offered in the written materials, but were addressed in at least one of the classes:

(7) Substitution of numerical values into expressions as a means to show that an expression represents a generalization of a given pattern (mathematically invalid).

(8) Substitution of numerical values into expressions to examine the potential of equivalence.

(9) Substitution of all numerical values into expressions as a means to show equivalence.

(10) Substitution of numerical values into expressions as a means to show equivalence (mathematically invalid).

(11) Expanding and simplifying expressions to show non-equivalence.

Another transformational activity addressed in class was:

(12) The technical practice of simplifying expressions and substituting numbers in expressions.

Note that technical practice was not recommended in the written materials as part of whole class work; therefore, it is not included in the list of categories generated by analyzing the written curriculum materials. Yet, it was suggested in the written curriculum materials as individual work or homework.

The above 12 categories can be divided into three conceptually different types: (a) ideas related to developing an understanding of generational activity (#1, 2, 6, 7), (b) ideas related to developing an understanding of equivalence of expressions (#3, 4, 5, 8, 9, 10, 11), and (c) technical practice with no attention to meaning and understanding (#12).

Similarities and Differences between Teachers and between Classes of the Same Teacher Sarah, S1 and S2

Sarah taught the topic equivalent algebraic expressions in both S1 and S2 using the same curriculum materials, covering by and large the same written units. She followed rather closely the suggested lesson plans outlined in the curriculum materials. As can be seen in the second and third rows of Figure 1, all six transformation-related ideas suggested in the written materials were enacted in S1 and S2 – and they were enacted similarly by means of proportion, order, and distribution, as well as with respect to the written materials. Moreover, transformation-related ideas that were not offered in the curriculum were rarely addressed in her classes (only ideas #10 and 11).
In both classes Sarah tended to make clear presentations of the above-mentioned ideas and to lead students to applying them in the different assignments. For example, when working on unit #6, students in both classes were presented five pairs of expressions and were asked to substitute several numeral values in the given pairs of expressions, compare the results, and cross out the non-equivalent pairs. Eventually, two pairs of expressions were left not crossed-out on the board. In both classes, Sarah stated that substitution could not be used to prove that two given expressions are equivalent (#4). She explicitly incorporated in her presentation of this idea its underlying justification: that there might exist a number that was not yet substituted, but its substitution in the two given expressions would result in different values. Sarah presented this idea as a motivation for finding a method to show equivalence, and immediately proceeded to work on using properties in the manipulative processes as a means to prove equivalence (#5):

We substituted two numbers, and it was the same... And then the third number gave something else. Who says that these expressions (points to one pair), if we substitute more numbers, there wouldn’t suddenly be a number that will give a different result? Therefore, it isn’t enough; substitution isn’t enough in order to know that expressions are equivalent. What do we need to do in order to know that expressions are equivalent? We need to use properties.

Rebecca, R1 and R2

Rebecca used in both R1 and R2 the same teaching sequence that Sarah used. However, unlike in Sarah's case, major differences were found in the transformation-related ideas between the written materials and Rebecca’s classes. As can be seen in the fourth and fifth rows of Figure 1, in both R1 and R2 a central idea suggested in the written materials was not addressed at all (#6). Also, compared with Sarah's classes, in R1 and R2 considerably more ideas that were not suggested in the written materials were addressed in class (#7-#12). Moreover, ideas that were not suggested in the written materials took a great deal more class time in Rebecca’s classes than in Sarah's classes. In addition, in both R1 and R2 Rebecca assigned technical practice, with no attention to conceptual understanding and meaning (#12); this activity was not recommended in the written materials for whole class work, nor was it addressed in Sarah's classes.

Unlike Sarah’s case, major differences were found in the transformation-related ideas addressed between R1 and R2, both regarding ideas suggested in the written materials and ideas not suggested in the written materials. For example, in R2 significantly less time was devoted to working on the central idea of expanding and simplifying expressions as a means to maintain/show equivalence (#5) than the time devoted to it in R1. Moreover, the idea that substitution is not an appropriate means to show equivalence (#4) was addressed only in R1. In addition, only in R2 were ideas suggested in class (by students) (#7, 10), which are mathematically invalid. Finally, the last units enacted in R2 centered on technical practice (#12), devoting significantly more time to it than in R1.

Unlike Sarah, who tended to make explicit presentations of main ideas, Rebecca attempted to draw ideas from her students and to follow students’ suggestions. For example, when working on unit #6, Rebecca also presented students with the problem of deciding which of five given pairs of expressions are equivalent. Similarly to the activity in Sarah’s classes, after substituting several numeral values in the given pairs of expressions and crossing out non-equivalent pairs, three pairs of expressions were left not crossed-out on the board. In contrast with Sarah, who suggested herself the use of properties as a method to show equivalence, in both R1 and R2,
Rebecca pressed her students to find a method that works, and different scenarios developed in the classes, as is illustrated in Figure 1, unit #6. In R1, the class concluded that the remaining pairs appeared to be equivalent but that it was impossible to know for certain. Following students’ proposal, the discussion centered on the possibility of proving equivalence by substituting all numbers or by substituting representative numbers:

Rebecca: When will I be sure that these three [she points to the pairs not crossed-out on the board] are indeed equivalent? That each pair is equivalent? When will I be sure?
Student1: When you check all the numbers.

…

Student2: There is an infinite number of numbers so you will never finish.
Rebecca: So I am not going to substitute infinite numbers. I need to find some other trick.
Student3: Substitute different kinds of numbers… Negative, positive…

After the class discussed the ideas suggested by students and eventually rejected them, Rebecca changed the focus of the activity to looking for a connection between pairs of expressions. The class quickly embraced the discovery that by using properties, it was possible to move from one expression to another and to show equivalence.

In contrast with R1, R2 embraced the idea that many successful substitutions are a valid means for determining equivalence of expressions. For example,

Rebecca: Why are they equivalent? Why do I say that these are equivalent?
Student1: Because we checked at least thirty [numbers].
Rebecca: We didn’t check thirty, but I am asking: Why are these equivalent, in your opinion?

…

Student2: Because we checked.
Rebecca: Because you checked, but we said that maybe there is one number that you did not check.
Student3: But we checked almost all the [inaudible].

Rebecca then asked the class to find new expressions that would be equivalent to the given ones. Eventually, R2 embraced the idea that equivalence can be determined by manipulating the form of expressions, using properties of real numbers.
Chapter 2: Algebraic Thinking and Reasoning

Figure 1: Teaching sequences of transformation-related ideas, addressed during whole class work, in the written materials and in the classes.
Discussion

Sarah and Rebecca taught the topic *equivalent algebraic expressions* using the same curriculum materials and a similar teaching sequence. However, differences were found between the two teachers in the ways transformation-related ideas were addressed in class. All transformation-related ideas suggested in the written materials were addressed in Sarah’s classes, whereas not all were addressed in Rebecca’s classes. Moreover, compared with Sarah's classes, a relatively large number of ideas that were not suggested in the written materials were addressed in Rebecca’s classes – some of which were not mathematically valid. Thus, eventually, Sarah’s students and Rebecca’s students were introduced to some extent to different mathematical ideas when the 15 units were taught. These differences between the two teachers regarding the mathematics that was offered to students in class appeared to be linked to their teaching approaches. Sarah chose to follow rather closely the suggested written lesson plans with only minute deviations, and stated explicitly the main ideas. In contrast, Rebecca used the suggested written lesson plans in a flexible way, was attentive and responsive to students’ mathematical behavior and performance, and spent time probing students, expecting them to suggest and explicate important ideas. Naturally, Rebecca enabled various scenarios to develop in her classes, and innovative ideas to emerge – some mathematically invalid – that were not addressed in the written materials. Yet, at times, depending on students’ contributions, important ideas were not made explicit.

Teaching approaches also appeared to be linked to the similarity or differences found between the two classes of the same teacher. Whereas there was a similarity between Sarah’s classes, major differences were found between Rebecca's classes. In the case of Sarah, who followed rather closely the lesson plans in the curriculum program, and who made explicit the main ideas, the same transformation-related ideas suggested throughout the 15 units in the written materials were addressed in both classes, and they were addressed similarly. Likewise, transformation-related ideas not offered in the curriculum materials were rarely addressed in her classes. In contrast, in the case of Rebecca, who did not follow the lesson plans so strictly, and who was attentive and responsive to students’ suggestions, and who seldom stated in her own words the main ideas, major differences were found in the transformation-related ideas offered to students in her two classes. For example, ideas related to proving equivalence, such as that substitution may not be an adequate means to show equivalence of given expressions (#4), and that the use of properties of real numbers is an adequate means to show equivalence (#5) – known to be problematic for students (e.g., Mariotti & Cerulli, 2001) – were addressed in R1, but were never made explicit, or were relatively briefly addressed in R2. In addition, because of the difficulties that R2 students encountered, Rebecca chose to assign in this class, but not in R1, extensive technical practice, skipping assignments related to developing understanding.

The significance of this study is twofold. First, is its contribution to the development of conceptual frameworks for analyzing the nature of school-level algebraic activities. Refining Kieran’s (2004) model, focusing on the algebraic meanings and ideas associated with transformational activities, we identified several ideas addressed in beginning algebra teaching, related to three conceptual types: (a) developing understanding of generational activity, (b) developing understanding of equivalence of expressions, and (c) technical practice. Another significant contribution of this study lies not in evaluating the mathematics learning opportunities offered to students in one class or another. It is rather in showing how transformation-related ideas may be addressed differently, even in classes taught by the same teacher using the same written materials, and in pointing out links between the differences found and teaching
There is a broad agreement today that teachers are key to students' opportunities to learn mathematics. We agree with that. Yet this study points to complex dynamic interactions among teachers, curriculum, and classrooms, the nature of which remains to be further explored.

ALGEBRA AND NO CHILD LEFT BEHIND: STANDARDIZED TESTS AND ALGEBRAIC COMPLEXITY

Caroline C. Williams
University of Wisconsin – Madison
cwilliams3@wisc.edu

As No Child Left Behind (NCLB) places increasing emphasis upon high-stakes standardized tests, the phenomena of teaching to the test becomes of paramount concern to the education field. Given the role of algebra as a gatekeeper to advanced mathematics and STEM fields, I examine the algebra items that appear on NCLB-mandated tests with two cognitive complexity frameworks. With an understanding of the importance of algebra and the impact of NCLB on states, teachers, and what is being taught in the classroom, this research project explores the mathematical complexity of items found in the tests from 40 states, and discusses the far-ranging impact of the findings.

Introduction

Algebra holds a place of great importance in mathematics learning, due both to its common usage in the workplace and its status as a gatekeeper in the mathematical education community (e.g., Moses & Cobb, 2001; National Research Council [NRC], 1989; National Council of Teachers of Mathematics [NCTM], 2000). Consequently, a considerable amount of attention has been paid to improving the currently dismal situation surrounding algebra (Steen, 1992) by exploring ways to consistently allow students access to the necessary algebraic concepts (e.g., Knuth, Stephens, McNeil, & Alibali, 2006; Knuth, Alibali, McNeil, Weinberg, & Stephens, 2005; Moses & Cobb, 2001; Stephens, 2005; Nathan & Koedinger, 2000). As the call to focus more on the importance of algebra in the K-12 curriculum came from mathematicians and educators alike, another widely reaching shift occurred in the US educational system: the No Child Left Behind Act (NCLB) passed in 2001.1 NCLB's emphasis on school accountability for student performance requires all states to individually develop standardized tests that satisfies NCLB requirements, as a method for assessing which schools provide adequate educations. Although the language of NCLB emphasizes challenging all students, there is concern that—given the pressure to perform well—schools are "teaching to the test" (e.g., Center on Education Policy [CEP], 2007; Apple, 2007; the Commission on No Child Left Behind, 2007), in which case standardized tests may guide the mathematics undertaken in the classroom, instead of instruction focusing on conceptual and coherent understanding or mathematical skills applicable beyond these test items.

A wide variety of research geared towards unpacking the impact of standardized tests on teaching has revealed powerful and complex effects that include "teaching to the test." Wilson (2007) notes that "high-stakes testing in mathematics…can affect teaching practices, curricular decisions, and the decisions made about schools or individual students" or individual teachers (p. 1107). The National Mathematics Advisory Panel (NMAP; 2008) states flatly that tests "can drive instruction" (p. 57), and Taylor, Shepard, Kinner and Rosenthal found that teachers reported a considerable impact upon their classroom time and instruction due to high-stakes testing (2003). "Teaching to the test" is not a new NCLB-linked phenomenon, but rather a situation present pre-NCLB (see Resnick & Resnick, 1992; NRC, 1989) that is increasing as all states increase the number and importance of standardized tests as mandated by NCLB.

The scenario of "teaching to the test" becomes particularly problematic when considering the results of Hyde, Lindberg, Linn, Ellis, and Williams (2008): they analyzed a number of mathematics items from NCLB-mandated standardized assessments in order to compare the performance of males and females. While examining various grade levels and NCTM strands of mathematics, they found very few high cognitive demand items according to Webb's Depth of Knowledge (DOK) framework (one of the frameworks used in this paper). Given evidence that standardized assessments may at times guide mathematics in the nation's classrooms, Hyde et al.'s findings stimulate the research question: What difficulty level of algebra content are NCLB-mandated standardized tests measuring?

The exploration undertaken here is devoted specifically to determining which algebra items are present on standardized tests, and what level of cognitive complexity they represent according to two different and well-respected frameworks: Webb's DOK for mathematics (2002) and the National Assessment of Educational Progress' (NAEP) Levels of Mathematical Complexity (NAGB, 2004). With an understanding of the importance of algebra and the acknowledgement of the impact of NCLB on states, teachers, and what is being taught in the classroom, this analysis explores the mathematical complexity of items found in the mandated tests from 40 states, and discusses the far-ranging impact of the findings.

**Motivation For Analysis**

**No Child Left Behind**

The 1983 release of *A Nation at Risk* (National Commission on Excellence in Education) directed the public's attention to the state of public education (Bullough, Clark, & Patterson, 2003), and in the following decades the public's demand for accountability increased. A reauthorization and drastic overhaul of the Elementary and Secondary Education Act from 1965, NCLB was a comprehensive response to the call for accountability, requiring various demonstrations of achievement from schools in order to avoid sanctions or receive rewards. Signed into law in 2002, schools were given until 2014 to fully achieve NCLB's requirements of 100% proficient students. Now, eight years after being signed into law, as NCLB is being re-examined and revised by a new administration, it is a topic of conversation that inevitably engenders controversy. In this research project, the 2001 bill is the one under discussion due to both the incomplete status of the Act II version and the fact that the original bill has dramatically shaped what standardized assessments written for fulfillment of NCLB look like now and in the future.

NCLB specifically indicates mathematics and language arts (reading) as the two topics of the greatest importance, emphasizing the need for "challenging" curriculum and content in these areas and others. NCLB requires tests that are developed and designed by each individual state which are used to provide yearly "report cards" that are used to make decisions at a variety of policy levels. Failure or success is measured by what student percentage achieves "proficiency" on the tests, and each year's percentile benchmark is defined by each state under the guidance of NCLB's Adequate Yearly Progress (AYP) requirements.

AYP is defined individually by state, with a number of guiding points designed for flexibility so that each state can implement the policy as it sees fit. For example, NCLB mandates that the calculation of AYP be based primarily upon the standardized assessments, but that graduation and attendance rates must also be a factor of importance. Exactly how graduation and attendance rates are weighted in respect to the test scores is up to individual states, so long as their formula meets those NCLB requirements. To add another layer of flexibility, each state was permitted to...

---

determine which scores count as "proficient." This was, naturally, taken up differently by different states (Fuller, Wright, Gesicki, & Kang, 2007).

As the assessment scores carry a considerable amount of weight in determining whether a school is identified as failing to meet AYP or not, the standardized tests are high-stakes for individual schools, districts, and states. And as Wilson (2007) notes, although these tests were designed to provide aggregate results, in some cases the test scores are used to make decisions at the individual student or classroom level. The design and annual administration is thus of considerable importance to all educational stakeholders.

Algebra

As NCTM is an authority that is not bound up tightly in the content standards of a specific state, using NCTM's algebra standards allows for a more comprehensive picture than what would be available by choosing a single state's standards. NCTM's (2000) summary of algebra is that it "emphasizes relationships among quantities, including functions, ways of representing mathematical relationships, and the analysis of change" (p. 37). The Principles and Standards then reminds us that "algebra is more than moving symbols around": "Students need to understand the concepts of algebra, the structures and principles that govern the manipulation of the symbols, and how the symbols themselves can be used for recording ideas and gaining insights into situations" (p. 37). NCTM continues beyond this definition to provide examples of algebraic concepts that are appropriate and important for every grade from pre-K to 12th, noting that "a strong foundation in algebra should be in place by the end of eighth grade" (n.p.).

Their call for a "strong foundation" has been echoed recently NMAP, who go even further than NCTM by recommending an increase in the number of students taking algebra by the end of middle school: "All school districts should ensure that all prepared students have access to an authentic algebra course—and should prepare more students than at present to enroll in such a course by Grade 8" (2008, p. xviii). Finally, the increasing trend across the country is to provide algebra as an 8th grade subject, and one state, California, has even gone so far as to require algebra for all 8th graders (see California Department of Education, 2009, for more information about this edict). This decision has spawned a plethora of discussions by scholars and the popular press (Cavanaugh, 2008), and the Association of California School Administrators (ACSA) has filed a temporary restraining order to prevent the implementation of the new law (2008).

NCTM, NMAP, and others are rightly concerned about access to algebra, as the subject is widely considered to be a gatekeeper to success in future mathematics classes, in college, and Science, Technology, Engineering, and Mathematics (STEM) fields (Moses & Cobb, 2001; Stinson, 2004). Algebra provides the needed foundation for abstract and advanced mathematics, and lack of access to algebra concepts limits access to mathematics classes, college options, and career choices. Furthermore, NMAP notes that "a strong grounding in high school mathematics through Algebra II or higher correlates powerfully with access to college, graduation from college, and earning in the top quartile of income from employment" (2008, p. xii). The powerful impact of algebraic understanding on future opportunities for students mandates that we make algebra a priority for all, whether that includes offering algebra at lower grade levels or weaving key algebra elements throughout elementary and middle-school classes. The quality of teaching, curriculum, and equitable student access are of considerable importance in this goal, as are the high-stakes standardized tests that concretize the requirements for algebra learning.

Teaching to the Test

Everybody Counts (1989) declares, "What is tested is what gets taught. Tests must measure what is most important" (p. 69). This concern over the connection between standardized tests and the shape and content of classroom teaching has continued to be an urgent topic of discussion in classrooms across the country, in the educational research field (CEP, 2007), and even in presidential speeches (Obama, 2009). Apple (2007) notes that NCLB could be considered "a situation in which 'the tail of the test wags the dog of the teacher'" (p. 109). Taylor et al. (2003) found that teachers reported an impact on classroom instruction due to high-stakes tests, and noted that teachers viewed some of these changes positively and others negatively. For example, some teachers added mathematical content to their classes in order to prepare their students more fully for the test, while other teachers bemoaned the considerable amount of classroom time they spent on sample test items in order to prepare the students for the test format.

"Teaching to the test" is not inherently bad or inappropriate; rather, "teaching to the test" makes it even more important that standardized tests are designed carefully and thoughtfully so that they can serve as curricular guidelines. The controversy over "teaching to the test" indicates that standardized tests are designed to be assessments of student achievement, and are not universally accepted as impacting classroom level instruction. Given considerable evidence of the effect of high-stakes tests on mathematics instruction, a careful examination of the content and quality of the tests themselves becomes of paramount importance. Asking What mathematical content do these tests contain? becomes the same as asking What mathematical content are teachers being guided to emphasize in their classrooms?, and we must begin looking at tests and test items with such a question in mind.

Research Methods

First, the data collection process is described, and the examination that each data point went through. More specifically, each data point was examined individually for algebra content, then all algebra problems were coded for problem format, DOK level, and LMC level (the problem format coding is not discussed here for lack of space). The author's coding was compared with each state's coding wherever possible in order to provide an ad hoc inter-rater reliability.

Data

As discussed previously, algebra begins to take a more prominent role in middle and high school, with many students taking Algebra I in 8th or 9th grade. Given this fact, the standardized tests at these two grades were deemed most appropriate and most likely to provide a sufficient number of algebra-coded items. Each of the states with NCLB-mandated test items available contributed items from 8th grade tests, and 7 of those states also contributed items from voluntary (non-NCLB mandated) 9th-grade tests. I chose not to include 10th grade tests because there are few tests designed for 10th grade, and those that are administered in 10th grade are very likely to be end-of-class tests or preparation tests for graduation exams. In total, the initial data set contained 1729 items from 40 states.

Released and sample items from states were found on state education websites or received through personal communiqué. When multiple years were available from a single state, the most recent two years of items were used; and when a state had both released and sample items available, released items were given preference. A number of states released items that were considered representative of their mathematical strand in the assessments, but did not release the
complete exams. Thus, data collection was conducted with an eye towards acquiring as many items as possible, and not towards accurately reproducing actual assessments.

**Coding Algebra**

The framework for determining what qualifies as "algebra" comes from NCTM's outline of thorough content standards for grades K to 12 (2000). As discussed in the Algebra section, NCTM's status as one of the foremost leaders in the field of mathematics education makes this an appropriate choice, especially given the widely disparate state of mathematics education in the US. The nature of decentralized educational practices and state-specific policies results in very different definitions of "algebra" across the country, but NCTM provides a common ground for analysis that does not privilege any particular state.

The first round of analysis used NCTM's standards to the purpose of examining the complete data set in order to determine which of the 1729 problems were algebraic in nature. In total, 421 of those items were classified as primarily Algebra. Of the 40 states that contributed items to this analysis, 24 provided standards information of their own, with a total of 847 items coded independently by states. Of the items coded Algebra by these states or the author, there were 58 irreconcilable coding disagreements, which is a 93.15% agreement of codes. The majority of these disagreements were occasioned by states coding items "Algebra" instead of "Measurement" or "Number and Operations," apparently because of the presence of a variable.

**Coding Webb's DOK**

When Webb's DOK levels were provided for individual items by the states themselves, they were used as an ad hoc inter-rater reliability test. When differing codes were encountered, the author's codes trumped the state's unless the author's original code was on the cusp between levels, in which case it was changed to the state's code (items can fall between two of the four DOK levels, see the methodology used by Webb in a similar situation, 2008). The state-provided DOK levels were taken with a grain of salt, as Webb was not explicitly cited in all of the resources. A total of 56 problems from 4 states (Mississippi, Nevada, Oklahoma, and the New England Common Assessment Program) provided DOK levels, there were 36 agreements between the author and the state, and 20 disagreements.

**Coding NAEP's LMC**

When NAEP's levels were provided for individual items by the states themselves, they were used as an ad hoc inter-rater reliability test that gave feedback regarding accuracy to the author. However, only 19 of the 421 items provided used a Low/Moderate/High framework, and of those 10 were agreements between the author and the state, and 9 were disagreements.

**Results**

According to Webb's DOK, a total of 11 of the 421 problems were rated level 3 (2.61%) by Webb's framework, and 0 problems were ranked 4. The rating of 1 was applied to 177 (42.04%), and the remaining 233 problems were ranked 2 (55.34%) (see Table 1). Note the asymmetric distribution, with the majority of the problems Level 2, and the remaining problems distributed primarily towards Level 1, with fewer Level 3.

According to Webb's DOK framework, the majority of the items (55.34%) fall in the Level 2 range, which is not problematic. What is problematic, however, is the skewed distribution of the remaining items, the majority (42.04%) of which are Level 1, leaving a small number (2.61%)
ranked Level 3 and absolutely zero problems ranked Level 4. This finding duplicates the unexpected results published by Hyde et al. (2008), and brings to the forefront the fact that our nation's assessments are failing to assess truly complex algebraic and mathematical thinking. The amount of time required by Level 4 problems may explain in part their lack of presence in standardized assessments, but the combination of few Level 3 and absolutely no Level 4 items clearly indicates that our algebra items are measuring only mathematical thinking that is not particularly complex, according to this framework.

According to NAEP's LMC, a total of 23 items were ranked High (5.46% of the total), 102 were ranked Moderate (24.23%), and the remaining 296 were ranked Low (70.31%) (see Table 2). Note that the distribution is positively skewed, with the majority of items ranked Low, then a smaller number of Moderate and a still smaller number of High rankings. Note that the vast majority (70.31%) of these items were of Low complexity, considerably more than the DOK percentage at the least complex level. Fuller et al. (2007) have noted that NAEP assessments tend to be more difficult than the individual state assessments, which may explain this distribution of rankings. However, these results serve to underscore the DOK framework results: our NCLB-mandated tests tend towards the less complex in their algebraic items, and include very few cognitively complex items.

**Conclusion**

The NCLB-mandated state tests are undoubtedly impacting teachers and their classroom practices, as they strive to tailor their instruction and content to the test. Given the status of algebra as a gatekeeper, we as a field want students to develop deep conceptual understandings of the subject. Sadly, the cognitive complexity of the nation's algebra items tend strongly to the simplistic and the rote, instead of providing truly challenging problems that measure the level of abstraction and sophistication of our students. By designing such assessments, states are supporting a situation in which teachers may be teaching to a mediocre (in terms of algebraic content) test.

Despite the bleak outlook, there is a remedy for this situation. Stakeholders must require that the designers of each state's standardized tests begin to examine the impact of their standardized tests, and strive to design the tests in such a way that they support complex algebraic thinking in the classroom. In order to inform and assist those involved in creating these assessments,
additional research must be conducted on the relationship between tests and classrooms. A nuanced understanding of the long-term and far-reaching effects of NCLB-mandated tests on curricula, teachers, and students must be achieved before we can design assessments that steer us to the more complex algebraic understanding that our students need to achieve.

Endnotes

1. All information regarding NCLB was retrieved from http://www.ed.gov/nclb.
2. Special thanks to Janet S. Hyde, Sara M. Lindberg, Marcia C. Linn, & Amy B. Ellis for sharing standardized assessment items previously collected.
3. The New England Common Assessment Program (NECAP) is composed of three states: Rhode Island, New Hampshire, and Vermont. Given that the items provided by each state were identical, NECAP is being counted only once for the purpose of analysis of items.
4. This paper reports the study and analysis from Williams (2010), an unpublished master's thesis.

AN EXAMINATION OF ALGEBRAIC REASONING: ELEMENTARY AND MIDDLE SCHOOL STUDENTS’ ANALYSES OF PICTORIAL GROWTH PATTERNS

Temple A. Walkowiak
North Carolina State University
temple_walkowiak@ncsu.edu

One approach to help children develop algebraic reasoning is the examination of pictorial growth patterns. The purpose of this study was to explore and compare how elementary and middle school students analyzed pictorial patterns, with a focus on figural and numerical reasoning. Task-based interviews were conducted with a second, fifth, and eighth grader in which they were asked to describe, extend, and generalize a pattern. A cross-case analysis showed figural reasoning was more evident with the younger students, but all students did not exclusively use figural or numerical reasoning. The students’ generalizations included informal notation, descriptive words, and formal notation.

Introduction

Over the past twenty years, the focus on algebra in school curricula and state standards has shifted from less to more emphasis as a primary content strand across K-12 mathematics. Traditionally, algebra has been considered a formal course students take in eighth, ninth, or maybe tenth grade. As recent as the late 1980s, algebra was a course deemed abstract in nature and only appropriate for college-bound students who were developmentally ready. Proportionally, African-American, Hispanic, and White working-class students were underrepresented in formal courses in algebra (Gamoran, 1987). In today’s global economy, algebra is considered the “gatekeeper” course to higher level mathematics and in turn, a college education (Moses and Cobb, 2002; RAND Mathematics Study Panel, 2003). Increasingly, algebra is becoming the focus of policymakers, researchers, and practitioners with a movement towards all students taking a formal course in algebra in eighth grade.

Regardless of when students take algebra, students need opportunities throughout their elementary and middle school years to develop their algebraic thinking. When students analyze pictorial or geometric patterns, they use algebraic reasoning. Further, the patterns serve as a rich context for exploring generalization, a major part of algebraic thinking (Kaput, 1999). The purpose of this study was to explore and compare how elementary and middle school students analyze pictorial patterns.

Theoretical Perspective

The release of the Curriculum and Evaluation Standards for School Mathematics (1989) and the Principles and Standards for School Mathematics (2000) by the National Council of Teachers of Mathematics (NCTM) called for new thoughts about algebraic thinking being integrated into work in elementary school mathematics. Furthermore, the Standards propose integrating algebraic thinking early and throughout elementary school to promote students’ abilities to make generalizations. The idea of early algebra “encompasses algebraic reasoning and algebra-related instruction among young learners – from approximately 6 to 12 years of age” (Carraher & Schliemann, 2007, p. 670).

Since there is a push to integrate algebraic reasoning across the grade levels in K-12 mathematics, describing algebra and defining algebraic reasoning are necessary. First, algebra...
includes generalized arithmetic, a problem-solving tool, the study of functions, and modeling (Benarz, Kieran, & Lee, 1996). Carraher & Schliemann (2007) define algebraic reasoning as “psychological processes involved in solving problems that mathematicians can easily express using algebraic notation” (p. 670). Algebra is typically thought of as a study of symbol systems while algebraic thinking is often used to “indicate the kinds of generalizing that precede or accompany the use of algebra” (Smith, 2003, p. 138). NCTM’s Principles and Standards (2000) explain that algebraic thinking focuses on analyzing change, generalizing relationships among quantities, and representing these mathematical relationships in various ways.

One of many approaches to help young children generalize about patterns is through the examination of geometric or pictorial growth patterns (Ferrini-Mundy, Lappan, and Phillips, 1997; Orton, Orton, & Roper, 1999). A pictorial growth pattern is a “sequence of figures in which the objects in the figure change from one term to the next, usually in a predictable way” (Billings, 2008, p. 280). When using pictorial growth patterns, the goal is for students to analyze, describe, and extend the pattern and ultimately, generalize about relationships in the patterns. Pictorial growth patterns provide a context for students to make generalizations about what they notice. Further, the nature of the pattern tasks allows for a variety of approaches to making generalizations.

Two modes of reasoning are often used when analyzing pictorial growth patterns, figural and numerical. “A numerical mode of inductive reasoning uses algebraic concepts and operations (such as finite differences), whereas a figural mode relies on relationships that could be drawn visually from a given set of particular instances” (Rivera & Becker, 2005, p. 199). When analyzing pictorial growth patterns, children often use a “covariation analysis of the pattern” (Smith, 2003) in which they focus on the changes from one figure in the pattern to the next. They use the previous figure to build up to a new figure and identify what stays the same and what changes in the pattern. This can also be called recursive induction. When asked to generalize to figures later in the sequence, children may switch to a “correspondence analysis” (Smith, 2003) in which they are able to describe the relationship between the figure number and the changing aspect of the dependent variable. Further, they generalize about what any figure in the pattern will look like. When generalizing about any figure in a sequence, students are sometimes able to provide a closed or explicit formula.

Becker and Rivera (2005) conducted a five-year study in a school district assessing ninth graders’ abilities to analyze patterns and functions. Over the period of five years, they assessed close to 60,000 students. They used pictorial growth patterns and found that 70 percent of the participants could extend patterns one at a time, but only 15 percent could develop a closed, explicit formula through generalizing algebraically. To follow up this study, Rivera (2007) conducted interviews of 22 ninth graders in which he asked them to analyze pictorial growth patterns. He analyzed the strategies of the students to find that most students who used only numerical reasoning and developed a closed formula were not able to explain their formulas.

In their work with second and fourth graders, Moss et al. (2006) worked with students on integrating figural and numerical patterns. They facilitated a series of lessons to promote students translating between the two representations of patterns. After the treatment, they found students who participated in the lessons were stronger on number knowledge and on making generalizations with explicit reasoning than students who did not receive the lesson instruction. Students who used both numerical and figural reasoning were better able to make generalizations, develop closed formulas, and make connections to what the terms in the formula mean.
Research Questions

The purpose of this study was to explore how students of various ages and grade levels engage in algebraic reasoning when presented with pictorial growth patterns, through a qualitative research design. Specifically, there were three research questions. First, what are the processes and strategies a second grader, fifth grader, and eighth grader utilize to describe and extend a pictorial growth pattern? Second, what are the processes and strategies the three students utilize to generalize about a pictorial growth pattern? Finally, what are the similarities and differences in the employed strategies of the three students in their analyses of pictorial growth patterns?

Methodology

Participants

The participants in this study were a second-grader, a fifth-grader, and an eighth-grader. I refer to the participants as Dara, Jenny, and David, respectively.

Dara, a second grader at an elementary school in a suburban area of a southeastern state, said her teacher “makes stuff fun” in math. Dara’s parents expressed that Dara does not exhibit the same high level of confidence in mathematics as she does in reading and writing. Despite this lower level of confidence, she has been successful in school mathematics.

Jenny, a fifth grader at an elementary school located in a rural area of a mid-Atlantic state, was enrolled in an advanced mathematics class in which she learned sixth grade concepts as outlined by state standards. She described her sixth grade math as mostly review with only some “new things”. Her teacher usually says, “what we’re going to learn about and he explains it. And, then we take notes, and he helps us on worksheets and stuff”.

David attended eighth grade at the only middle school in the same rural district as the elementary school that Jenny attended. David was enrolled in Geometry, the high school course, as an eighth-grader. He completed Algebra I when he was in the seventh grade. David expressed that he likes math. He shared, “a typical day is taking notes with examples that look a lot like what we’re doing on our homework and then we do our homework”.

Data Collection: Task-Based Interviews

The participants engaged in a task-based interview for approximately thirty minutes. The interviews occurred at a site convenient for the participants. During this time, the participants were asked to analyze two pictorial growth patterns (Smith, Silver, & Stein, 2005). The first of these patterns is examined in this paper and shown in Figure 1.

Figure 1. Pictorial Growth Pattern

The task-based interviews were semi-structured. Participants were presented with one picture in the pattern at a time and were first asked to describe the picture. Next, they had Figure 1 to explain the next picture in the pattern, reason about later entries in the pattern (e.g., picture #20, picture #100), and generalize about any entry in the pattern. During the interviews, participants had access to plain white paper, pencils, the papers with the pictorial growth pattern, and square tiles. The interviews were videotaped with the camera focused on their workspace as they described their thinking.

Data Analysis and Reporting

Miles and Huberman’s (1994) systematic data analysis was used to obtain descriptions from and relationships among the data. The three components to this type of data analysis are: data reduction, data display, and conclusion drawing and verifying. The data is reported through individual case studies followed by a comparative, cross-case analysis. Comparisons are made between the three students as to the type(s) of reasoning each used, figural or numerical. Validity for systematic data analysis is attained through checking for representativeness, checking for researcher effects, triangulating across data sources, and weighing the evidence.

Results

Dara

When Dara, a second grader, was presented with picture #1 and asked to describe what she sees, she immediately said, “3, 6, 9, 12.” When asked to elaborate, she circled four groups of three (see Figure 2), double circling the corner squares. Subsequently, when she was asked to compare picture #1 to #2, she said, “I can say they can still be in the same way.” Dara proceeded to circle four groups of four and said, “4, 8, whatever.”

![Figure 2. Dara circled four groups of three to explain her “3, 6, 9, 12”](image)

When presented with picture #3, Dara says she noticed how this could be a tool for helping students with counting and says, “5, 10, 15, 20.” Again, she circled the four groups of five like she did on picture #1. When asked what picture #4 would look like, Dara said “probably sixes” and draws the correct picture. Next, I asked Dara to predict what picture #10 would look like.

She drew a large square made up of twelve smaller squares on each side. Dara proceeded to explain the relationship between picture #10 having 12 squares “in each row”. She says 12 represents the “number in each row” and 10 represents the “picture”. She explained her numerical notation (see figure 3) by saying “you start with picture 1, you skip a number, and you come up to 3.” Similarly, she used the same notation to describe pictures #2, #4, and #5.

Next, I asked Dara to predict picture #25. Dara applied the same strategy as illustrated in Figure 3. She started at 25, skipped 26, and said there would be 27 squares in each row of the square. In reference to the squares in the corner, she recognizes they overlap. She says, “even these that overlap, it doesn’t matter. It’s still a row.” She knows she is double counting the corner squares, but she recognizes this does not change the description of her pattern. When asked to consider picture #100, Dara immediately applies the same strategy. She says there will be 102 squares in each row.

I asked Dara to describe her strategy for finding picture #100, and she started to generalize on her own using invented symbolic notation. She said, “start, to skip, to answer”. Her symbol for “start” was a circle with a vertical line. For “skip”, she used a backwards “C”. For “answer”, she sketched a circle with a horizontal line (see Figure 4).

She explained her rationale for having notation by saying, “if you have like one hundred, um, one thousand, four hundred, ninety-three, I don’t think you could just pop that out of your mind, the next number and the next number after that, if you’re in second grade. So, it’s easier to do that (referring to her notation and strategy). All you have to do is skipcount. Once you do it, poof, you know it.”

Jenny

Jenny, a fifth grader, described picture #1 as squares making up a square. When asked to compare picture #2 to picture #1, she noticed there are three squares in the base and height in picture #1 versus four squares in the base and height for picture #2. When asked to predict what picture #4 would look like, Jenny said, “it’s going to be a six height and a six base because it gets bigger by one.” When asked to determine picture #10, Jenny says there will be twelve squares on each side “because there are six numbers in between ten and four. And, on picture #4, there are six and there’s six in between so you do six plus six and you get twelve.”

Next, Jenny described picture #25. After doing some work (see Figure 5), she explained, “I just subtracted twenty-five minus four to find out how many numbers are in between four and twenty-five. It would be twenty-seven squares because I found out there were twenty-one numbers in between. So, it would be six plus twenty-one, and I get twenty-seven. The six comes from six squares in that (points to the bottom row of picture #4).”
Jenny’s strategy for generalizing was not dependent on the picture number given. Instead, she used information about the largest picture she had (#4) to determine any other picture in the pattern. For picture #100, Jenny thought quietly, then wrote $96 + 6$ on her paper to determine 102. She said, “102 squares on the bottom, on the height, on the top, and on the other side because I subtracted 100 minus 4 and got 96 so there are 96 numbers in between. Then, you already have 6, so you plus 6 plus 96 and you get 102.” When asked about any picture in the pattern, she said, “draw it out?” When asked again for any number in the pattern such as 144, she included 144 in her description. She said, “you take the number and subtract it from the highest picture you have, like 144 minus 4. Then, you add that to six in this case, so 146.”

David

When David was asked to describe picture #1 in the first task, he said, “it’s made up of eight tiles, it’s a square, it forms a perimeter instead of an area, it’s not like a filled-in figure.” His prediction of picture #4 was: “A square that only forms a border made up of 6, 6, 4, and 4, made up of 20 tiles.” He drew picture #4 and explained how he divided the tiles into groups of six, six, four, and four (six on the vertical sides of the square and four on the horizontal sides).

As we moved to picture #5, David said, “I’m noticing a pattern that it’s four more tiles each time.” To move beyond consecutive pictures, I asked David about picture #10. David said, “It would be the tenth picture in the sequence. The first one was eight. So, it would be eight plus four for every picture after that. So, you could come up with a formula.” David proceeded to write the formula (see Figure 6). His description of his formula follows: “the number of tiles, t, equals eight plus four times the number there is minus one.”

$$t = 8 + 4(n-1)$$

Cross-Case Analysis

The analysis of these three cases resulted in two interrelating themes. The two themes are: an intersection between figural and numerical reasoning and making generalizations using symbols and/or words.

The intersection between figural and numerical reasoning. The three students in the study did not use one type of reasoning exclusively. By combining figural and numerical reasons, the students were able to make generalizations about the pictorial growth patterns. The participants would not have made generalizations without examining the spatial features of the pictures and applying their knowledge of number relationships. Dara’s reasoning was primarily based on figural reasoning. She focused on how many squares are “in each row.” To relate the picture number to the number of squares in each row, she used her ability to reason numerically to describe her skip counting technique. Jenny’s strategy for describing the first pattern was based...
on the figure as she notes the number of squares in the base and the height of each square. When asked to extend and generalize about the pattern, Jenny drew more on her numerical reasoning than figural reasoning. David’s strategy for describing the first pattern was focused on the figural characteristics of the pattern. When he moves to extending, he primarily used numerical reasoning as his explanations centered on the increase of four tiles from one picture to the next.

Making generalizations using notation and/or descriptive words. Making generalizations using notation and/or descriptive words was common among the three case studies. The types of generalizations the students used were descriptive words or notation. The notation was invented or formal in nature. Dara used descriptive words to describe how she determined how many square tiles are in each row. She explained her “start, skip, answer” strategy as starting with the picture number, skipping the next number, and the answer is the next number. As she described her generalization, she used invented notation for the start number, skip number, and answer. Jenny used descriptive words to describe her generalization of the pattern focusing on the distance between picture numbers, but she did not use notation for her generalization. David used formal, algebraic notation to write a closed, explicit formula. David was able to explain in words why his formula worked. David was able to generalize with a formula, explain his formula, and describe how any picture in the pattern would look.

Discussion

There are three primary findings from this study. First, students did not use figural or numerical reasoning exclusively. The pictures appeared to promote both types of reasoning as the students described, extended, and generalized the patterns. This supports the work of former researchers who found students use a combination of numerical and figural reasoning, although one type may be the dominant choice for a student (Becker and Rivera, 2005; Moss et al., 2006).

Second, the younger students are more apt to rely more heavily on figural reasoning when analyzing pictorial growth patterns. Both Dara and Jenny used some level of figural reasoning for every stage (describe, extend, generalize). This is developmentally appropriate in a learning trajectory of algebraic reasoning. While David used figural reasoning, he was very focused on the number of tiles in both tasks. This raises the need to incorporate pictorial growth patterns of various levels of challenge for students. For these students, their choice of reasoning (figural, numerical, or both) is likely affected by their experiences in their mathematics classrooms.

Third, students will generalize using various ways to communicate – informal notation, language, and formal notation. Dara created her own notation system to describe how to determine the number of squares on each side of the first pictorial pattern. Jenny used language as she generalized about the pattern. David used formal algebraic notation. Developmentally, the progression of generalizations among students is expected, although oral language may precede informal notation for younger students.

This study suggests pictorial patterns would serve as valuable tools in elementary and middle school classrooms to promote algebraic reasoning. When students make sense of their generalizations in terms of a pictorial context, students will likely be able to describe mathematical relationships, the heart of algebraic thinking. Presumably, then, they would be able to make meaning of formulas rather than just manipulating numbers. Generalizing the patterns can potentially connect to their understanding of the constant and slope in linear equations. As evident in the findings, providing picture patterns also seems to elicit several different ideas about the same pattern.
In summary, incorporating the analyses of pictorial growth patterns into elementary and middle school mathematics promotes the use of figural and numerical reasoning together. Most importantly, students use algebraic thinking to generalize about the relationships, a critical factor to prepare students for success in their formal algebra courses.

ASSESSING ELEMENTARY STUDENTS’ FUNCTIONAL THINKING SKILLS: THE CASE OF FUNCTION TABLES

Katherine L. McEldoon
Vanderbilt University
katherine.l.mceldoon@vanderbilt.edu

Bethany Rittle-Johnson
Vanderbilt University
bethany.rittle-johnson@vanderbilt.edu

Functional thinking is an appropriate way to introduce algebraic concepts in elementary school. We have developed a framework for assessing and interpreting students’ level of understanding of functional thinking using a construct modeling approach. An assessment was administered to 231 second- through sixth-grade students. We then developed a progression of functional thinking knowledge. This investigation elucidates the sequence of acquisition of functional thinking skills. This study also highlights the utility of a construct modeling approach, which was used to create criterion-referenced and ability-leveled assessment. This measure is particularly suited to measuring knowledge change and to evaluating instructional interventions.

Introduction
Research into the effectiveness of teaching and learning interventions has become increasingly more mainstream, particularly as the call for evidence-based research grows louder. Unfortunately, instruments that measure learning outcomes from focused interventions are often researcher-created and are not tested for reliability and validity. This makes it difficult to compare research results and generalize findings into instructional recommendations. The goal of this project is twofold. The first is to develop an assessment of elementary-school student’s functional thinking abilities, with a specific focus on students’ ability to find a rule of correspondence within a function table. The second is to develop a model of knowledge progression of elementary-level functional thinking skills. We identified a set of skills important for elementary-level functional thinking, designed an assessment which tapped these skills, administered the assessment to students in Grades 2 to 6, and used a construct modeling approach (Wilson, 2005) to developed a construct map, or model of knowledge progression, based on the student performance data. The findings provide insight into the typical sequence in which learners acquire functional thinking skills. This proposed sequence of functional thinking skills, and the assessment, are useful tools for measuring student knowledge. Eventually, the assessment can be used to measure learning gains after instructional interventions.

Theoretical Perspective
The transition to algebra is a notoriously difficult one for many students. Our students must be better prepared in order to take on the challenges of an increasingly technical and complex world. Traditional mathematics instruction, which focuses on teaching arithmetic procedures, followed by a similarly procedure-based algebra instruction in middle and upper grades, has not been successful in supporting student learning (Blanton, 2005).

One way to overcome this difficulty is to inculcate appropriate forms of algebraic reasoning into early math instruction. Algebraic reasoning is defined as a type of reasoning in which students generalize mathematical ideas from a set of particular instances, establish those generalizations through the discourse of argumentation, and express them in increasingly formal and age-appropriate ways (Kaput, 1999).
Functional Thinking

Functional thinking is a particular kind of generalized thinking that lends directly to the development of algebraic thinking. It is a type of representational thinking that focuses on the relation between two varying quantities (Smith, 2008). Functional thinking is one of the core strands of Kaput’s (2008) framework of algebraic reasoning and a core expectation for mathematics curriculum. For grades 3 through 5, students are expected to “describe, extend, and make generalizations about geometric and numeric patterns; represent and analyze patterns and functions, using words, tables, and graphs” (NCTM, 2008). At the heart of functional thinking is a relationship between two particular quantities; this can be referred to as a rule of correspondence (Blanton, 2005). This relationship can be used to find other sets of particular quantities that adhere to the same rule. The functional relationship binds together the set of numbers to which it applies.

Elementary-school students often focus on particular numbers as outcomes. In order to think in an algebraic way, and in a way which allows for generalization, one must understand that there are many possible outcome values. Finding a functional relationship between two sets of numbers is a way to jump from thinking of particulars to sets (Carrahar et al., 2008). This is an accessible way to get students thinking about numbers in a general way, and in a way which eases their transition to algebra. Thinking about functional relationships makes explicit the fact that many sets of values are possible for a given constraint (i.e., the rule) (Carrahar et al., 2008).

Children’s Functional Thinking Abilities

Exploring ways to support early functional thinking has been the focus of several recent teaching experiments, and commonalities across these studies indicate particular abilities that can be cultivated in elementary school.

Evidence from teaching experiments have shown that elementary-school students have the ability to understand the functional relation between X and Y values (Carraher, Schliemann, & Brizuela, 2003; Carraher, Martinez, & Schliemann, 2008), identify the rule or pattern (Carraher et al., 2003), use it to predict new values (Carraher et al., 2003, Carraher et al., 2008), and articulate the general rule verbally (Carraher et al., 2008; Cooper & Warren, 2008; Warren & Cooper, 2005; Warren & Cooper, 2006) and symbolically (Carraher et al., 2003; Carraher et al., 2008; Carraher & Earnest, 2003; Cooper & Warren, 2008; Warren & Cooper, 2006). In the teaching experiments, researchers typically use geometric or numeric patterns and introduce function tables as a representation for capturing functional relations. However, researchers have used their own assessments of student thinking and have not provided evidence for the validity of their assessments. In addition, little is known about the emergence of these skills in students in typical classrooms. In the current study, we focused on assessing students’ knowledge of function tables, working with students in classrooms not receiving special interventions.

Assessment Development

We chose to focus on numeric patterns presented in function tables because they are a common and foundational component of functional thinking (Schliemann, Carraher & Brizuela, 2001). In an informal review of textbooks and national and state tests, we found function tables to be the most common problem format used at the elementary level. In particular, we focused on
students’ ability to identify rules of correspondence in function tables and use the rule to predict new instances.

A review of existing test items as well as a task analysis suggested at least 6 skills related to understanding function tables. (1) A precursor skill is to apply a given rule. When presented with a table with X and Y values, and a verbal or symbolic rule which describes how to compute the Y value from an X value, students should be able to use that rule to compute a Y value given a particular X value. (2) Students should also be able to recognize a function rule out of a selection of possible rules for a given table. In this case, students can test the rule against values in the table, rather than needing to generate the rule. (3) Students should be able to determine the next instance in a function table. However, students may be able to predict the next instance without thinking about the relation between the X and Y values (Schliemann et al., 2001). (4) Students should be able to extrapolate the function rule and articulate the function rule for a table in words. (5) Students should be able to predict a variety of instances in a function table, particularly instances that require identifying the function rule to make the prediction (e.g., predicting the 100th instance). (6) Students eventually learn to articulate the rule in the function table symbolically (Schliemann et al., 2001). Although there is a logical ordering of the relative difficulty of some of these skills (e.g., skill 1 is easier than skill 6), the relative difficulty of some skills could not be determined from previous research, and exploring the relative difficulty was one goal of the current research.

With these skills in mind, we created an assessment meant to tap each skill for working with functions presented in function tables. The functions were additive, multiplicative and two-operator functions. After data collection, we evaluated the progression of mastery of these skills, and used the data to inform the creation of a construct map (Wilson, 2005) of the development of functional thinking.

**Methodology**

The assessment was administered to a wide range of grade levels, as we expected differential performance and an increase in functional thinking skill through the grade levels. Participants were 231 2nd - 6th grade students attending two suburban schools. There were 52 second graders (24 girls), 50 third graders (30 girls), 25 fourth graders (15 girls), 60 fifth graders (28 girls), and 44 sixth graders (16 girls). Approximately 3% of the students were from minority groups. About 27% of students at the schools were eligible for free or reduced lunch.

The assessment contained 11 items, and was divided into three parts. Some of the items were broken into sub-items. The first section (one item) asked students to identify the number of eyes that a certain number of dogs would have, and to articulate the rule. It was designed to see to what extent students could engage in functional thinking given a supportive and grounded context without scaffolding from the problem formats that follow. The second section (six items) asked students to apply (two items) and recognize (four items) function rules. Of these four items, the function rules were presented as verbal statements (two items), and as algebraic equations (two items). The third section (four items) contained two problem types. Three of the items were function table problems, which required students to determine missing entries in the table, and then formulate both a verbal and symbolic rule. There was also a multiple-choice item asking students to identify the next value in a sequential numeric pattern.

The assessment was administered during a single class period. A member of the research team read the directions for each section, answered any questions, and enforced a time limit for

---

each section. For 2nd and 3rd graders, each item was read aloud to reduce the reading demands. If a student had a question, the researcher would provide a helping prompt from a script.

All items were coded as correct or incorrect. A few items had open ended responses, and these were also coded as correct or incorrect according to a strict coding rubric. Each item or sub-item in the assessment only assessed one isolated skill.

**Results**

We used student accuracy on each item, in conjunction with other findings in the functional thinking literature, to place the skills into hierarchy and develop a construct map. A construct map is a representation of the continuum of knowledge that people are thought to progress through for the target construct (Wilson, 2005). Our preliminary construct map is presented in Table 1, with lower level skills at the bottom of the table. Student accuracy at each level of the construct map is presented in Table 2.

![Table 1. Elementary Function Skill Construct Map](image)

**Level One: Apply Rule**

The easiest items were the application of a given function rule items (85% correct). This ability level included items that asked students to apply a rule to determine missing values in a
table. This application of an explicit rule is level one of our construct map. These items required that students understood enough about a relationship between X and Y values in a table that they could determine new Y values when the rule is provided. To complete items like these, computational skill is required, but not yet any deep understanding of a functional relationship.

**Level Two: Recognize Rule**

Level two of our construct map is Recognize Rule. Within this level are two of our original skills: recognizing a rule, and determining the next Y value. Performance on items at this level was at 61%. Recognizing a rule for a table from a number of other options is presumed to be a skill children acquire before they can generate a rule on their own, and our data bear this out. This level also includes determining the next sequential Y value in a function table. This is different than determining other missing values in a function table, as the next value can be determined by extending the pattern in the Y values, if the table is ordered sequentially.

**Level Three: Generate & Use Verbal Rule**

Level three in our construct map incorporates the main set of skills students must have in order to have a grasp of function table problems. The skills included within this level are determining further missing values in a table and generating a verbal rule. The ability to generate a correct rule for a table coincided with the ability to determine the missing values. This should not be so surprising, as one would have to determine the rule to find the missing values. Performance on items that utilized these skills was at 40%.

**Level Four: Generate Symbolic Rule**

The fourth and final level in our construct map is Generate a Symbolic Rule. These items entailed writing the rule using algebraic notation, such a Y = X + 4. This was more difficult for students, presumably not only because of the use of variables, but because of the generality that variables imply. Performance on Symbolic Rule items was at 28%.

**Assessment and Construct Map Evaluation**

To further evaluate the assessment and refine the construct map, classical test and item response methodologies were used. The alignment of the relative difficulty of the items and the leveled construct map was considered. An item-respondent map (i.e., a Wright map) generated by a Rasch model (a type of item response model) was used in this evaluation. The left column of a Wright map is the respondent, or participant, column. Respondents with the most estimated ability are placed near the top of the column, and those with the least estimated ability are on the lower end. In the right column, the most difficult items are listed at the top, and the easier items

---

are at the bottom of the column. This Wright map allows for a visual evaluation of construct map.

The purposed levels roughly clump together in the Wright map (Figure 1). There are some issues with Level 3 items overlapping with Level 2 and 4 items. The fact that there are different arithmetic operations in the underlying functional relationships in the items was the suspected cause for this overlap. Specifically, some items have an underlying functional relationship that involve addition (i.e., \( y = x + 2 \)), some multiplication (i.e., \( y = 2x \)), and others, a combination of both (i.e., \( y = 2x + 2 \)). Students in grades two through six have different proficiencies with these arithmetic skills, and so it is reasonable that this would affect item difficulty. When the items were separated by operation of underlying function, the Wright maps have good grouping of items by level, and good separation between levels (Figures 2-4). There is some compression of levels 3 and 4 in the combination-only Wright map. This is likely due to the difficulty of the items; if a student is of high enough ability to do the level 3 combination items, they are also likely to be of high enough ability for the level 4 combination items. Viewing the Wright maps separately by underlying function type, or operation, seems to be quite useful for delineating and clarifying the underlying functional thinking ability progression. Now the levels have much more separation, and the item difficulties are no longer confounded by arithmetic difficulty. This multidimensional model, with operational difficulty considered as a separate factor, is a much clearer way of tracking the progression of early functional thinking knowledge. This model will be developed further in future work.

Several analyses were performed to evaluate the validity and reliability of the assessment. To evaluate validity from measures of internal structure, the expected rank order of difficulty from the construct map was compared to the empirical rank order difficulty from the Wright map analysis \( (r_s = 0.916) \). An item-mean location analysis was performed to determine if getting an item correct implicated a greater ability level on the part of the respondent than getting it incorrect would. All items behaved appropriately according to this metric. Internal consistency of the assessment was high. The classical test index of internal consistency for binary data (the Kuder-Richardson 20) was quite high, indicating that 93% of the variance was accounted for by the model. The analogous measure from item response methodology, the separation reliability index, was at 0.99. These measures can be thought of as similar to Cronbach’s alpha. Additionally, several other analyses from item response methodology were employed, and all metrics of item analyses and person and item fit indicated that the assessment functions well.

**Discussion**

Functional thinking has been argued to be a useful way to introduce young students to fundamental algebraic concepts. Several teaching experiments have suggested instructional techniques for bringing functional thinking to elementary classrooms. As this topic becomes a focus of more research studies, it becomes increasingly important to have a reliable and valid measure that can be used to capture knowledge change and to have a well defined knowledge construct, so that general claims can be made across studies. In this project, we have identified key skills that are important for elementary-level functional thinking, with a focus on function table problems. These skills were then incorporated into an assessment, which was given to 231 2\textsuperscript{nd} through 6\textsuperscript{th} grade students. Student performance data was used to develop a construct map, or proposed knowledge progression, of elementary-level functional thinking skills. The resulting construct map provided insight into the acquisition of functional thinking knowledge in elementary-school students, and can be used to guide future research.
Benefits of a Construct Modeling Approach

This approach to measurement development, based on Wilson’s construct modeling approach (2005), was useful for several reasons. First, it elucidated the relative difficulty of functional thinking skills, and at times this was not in line with our predictions. Second, the resulting assessment is a criterion referenced measure which is particularly appropriate for assessing the affects of an intervention on individuals (Wilson, 2005).

In regard to relative skill difficulty, skills fell together in ways which we did not predict. For instance, Level 2 includes the ability to recognize a rule, as well as determine the next sequential Y value. Based on our literature review and intuitions, we predicted that determining the next Y value would be the easier skill. Also, Level 3 includes the skills of completing a function table and generating a verbal rule. We had predicted that there would be a gap in students’ ability to master these two skills. This construct modeling approach allowed us to see that these skills were of the same difficulty, as they could be completed by students of the same ability level. Another aspect we did not predict to play such a large role was the arithmetic operation of the underlying function. We initially predicted that functional thinking skill would function somewhat independently of operation type, but the data indicated that operation profoundly effects students’ ability to successfully complete a function table problem. As such, operation type must be given attention in future functional thinking research. We are working to more formally incorporate arithmetic operation of the underlying function into our model.

Future Directions and Conclusions

Our elementary-level functional thinking assessment and construct map are important first steps, but they could each be further refined. Based on the construct map, we can now edit the assessment to more evenly include items at the different skill levels. Additionally, since it is now clear that the operation in the underlying function is a highly important factor, we will include more items so that there are items of each difficulty using each operation type. This revised assessment will then be used in a new iteration of this project. We hope to develop a multidimensional item response model that incorporates both functional thinking and operational skill level. This will allow us to more accurately measure change in students’ knowledge.

Knowledge of mathematical equivalence is a foundational concept in algebra. We developed an assessment of equivalence knowledge using a construct modeling approach. Second through sixth graders (N = 174) completed a written assessment of equivalence knowledge on two occasions, two weeks apart. The assessment was both reliable and valid along a number of dimensions. The relative difficulty of items was consistent with the predictions from our construct map and accuracy increased with grade level. This study provides insights into the order in which students typically learn different aspects of equivalence knowledge and illustrates a powerful, but under-utilized, approach to measurement development.

Introduction

To increase students’ success in algebra, there is an emerging consensus that educators must re-conceptualize the nature of algebra as a continuous strand of reasoning throughout school rather than a course saved for middle or high school (National Council of Teachers of Mathematics, 2000). Part of this effort entails assessing children’s early algebraic thinking. In the current paper, we describe development of an assessment of one component of early algebraic thinking – knowledge of mathematical equivalence. Mathematical equivalence is the principle that two sides of an equation represent the same value. We employed a construct modeling approach (Wilson, 2003, 2005) and developed a construct map (i.e., a proposed continuum of knowledge progression) for students’ knowledge of mathematical equivalence. We used the construct map to develop a comprehensive assessment, administered the assessment to students in Grades 2 to 6, and then used the data to evaluate and revise the construct map and the assessment. The findings provide insights into the typical sequence in which learners acquire equivalence knowledge. The study also illustrates an approach to measurement development that is particularly useful for detecting changes in knowledge over time or after intervention.

Theoretical Perspective

Too often, researchers in education and psychology use measures that have not gone through a rigorous measurement development process, a process that is needed to provide evidence for the validity of the measures (AERA/APA/NCME, 1999). For example, Hill and Shih (2009) found that less than 20% of studies published in the Journal for Research in Mathematics Education over the past 10 years had reported on the validity of the measures. Without this information, we cannot know if measures assess what they intended or if conclusions based on them are warranted.

A construct modeling approach to measurement development is a particularly powerful approach for researchers interested in understanding knowledge progression. The core idea is to...
develop and test a *construct map*, which is a representation of the continuum of knowledge that people are thought to progress through for the target construct. Although Mark Wilson has written an authoritative text on the topic (Wilson, 2005), there are only a handful of examples of using a construct modeling approach in the empirical research literature (e.g., Claesgens, Scalise, Wilson, & Stacy, 2009; Wilson & Sloane, 2000). We illustrate how this approach was used to develop a reliable and valid measure of mathematical equivalence knowledge.

Although few previous studies have paid careful attention to measurement issues, a large number of studies have assessed children’s knowledge of mathematical equivalence (sometimes called mathematical equality). Understanding mathematical equivalence is a critical prerequisite for understanding higher-level algebra (e.g., Kieran, 1992; MacGregor & Stacey, 1997). Given the importance of mathematical equivalence, it is concerning that students often fail to understand it. Many view the equal sign *operationally*, as a command to carry out arithmetic operations, rather than *relationally*, as an indicator of equivalence (e.g., Jacobs, Franke, Carpenter, Levi, & Battey, 2007; Kieran, 1981; McNeil & Alibali, 2005). Evidence for this has primarily come from three types of tasks: (1) solving open equations, such as $8 + 4 = \square + 5$, (2) evaluating the structure of equations, such as deciding if $3 + 5 = 5 + 3$ is true or false, and (3) defining the equal sign (Baroody & Ginsburg, 1983; Behr, Erlwanger, & Nichols, 1980; e.g., Carpenter, Franke, & Levi, 2003; Li, Ding, Capraro, & Capraro, 2008; Seo & Ginsburg, 2003). The primary source of U.S. children’s difficulty understanding mathematical equivalence is thought to be their prior experiences with the equal sign (e.g., Baroody & Ginsburg, 1983; Carpenter et al., 2003). What is less clear is how a correct understanding of mathematical equivalence develops without specialized interventions.

<table>
<thead>
<tr>
<th>Level 4: Comparative</th>
<th>Compare the expressions on the two sides of the equal sign, including recognizing that doing the same thing to both sides maintains equivalence. Relational definition considered the best definition.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Level 3: Relational</td>
<td>Accept and solve equations with operations on both sides and recognize and generate a relational definition of the equal sign (although it co-exists with an operational definition).</td>
</tr>
<tr>
<td>Level 2: Flexible Operational</td>
<td>Accept and solve equations not in operations-equals-answer format that do not directly contradict an operational view of the equal sign, such as equations with operations on the right or with no operations. Continue to think of equal sign operationally, or in other non-relational ways.</td>
</tr>
<tr>
<td>Level 1: Rigid Operational</td>
<td>Only accept and solve equations in operations-equals-answer format correctly; define the equal sign operationally (e.g., it means “get the answer”).</td>
</tr>
</tbody>
</table>

The primary goal of the current study was to develop an assessment that could detect systematic changes in children’s knowledge of equivalence across elementary-school grades (2nd through 6th). To accomplish this, we utilized Mark Wilson’s Construct Modeling approach to measurement development (Wilson, 2003, 2005). The core idea is to develop and test a *construct map*, which is a representation of the continuum of knowledge that people are thought to progress through for the target construct. Our construct map for mathematical equivalence is presented in Table 1. We hypothesized that there would be a transition phase between a rigid operational view and a relational view of equivalence, which we labeled *Level 2: Flexible*.
operational view. We also included a fourth level of understanding to capture a more flexible and sophisticated relational understanding of equivalence – comparing the expressions on the two sides of the equal sign.

**Method**

We used our construct map to guide creation of an assessment of mathematical equivalence knowledge, with items chosen to tap knowledge at each level of the construct map using a variety of problem formats. We developed a pool of possible assessment items from the past research and selected and modified items so that there were at least two per construct map level for each of the three common item types identified in the literature review - solving equations, evaluating the structure of equations, and defining the equal sign.

We administered an initial long version of the assessment to 174 children in grades 2 through 6. Analyses of these results and input of a domain expert informed the creation of two shorter, comparable forms of a revised assessment, which were administered to the same students two weeks later.

**Results**

In presenting our results, we focus on the revised forms of the assessment, with data from the initial assessment used as supporting evidence when appropriate.

**Evidence for Reliability**

Internal consistency, as assessed by Cronbach’s $\alpha$, was high for both of the revised assessments (Form 1 = .94; Form 2 = .95). Performance on the assessment was also very stable between testing times. There was a high test-retest correlation overall for both Form 1, $r(26) = .94$, and for Form 2, $r(26) = .95$.

**Evidence for Validity**

First, experts’ ratings of items provided evidence in support of the face validity of the test content. Four experts in mathematics education rated most of the test items to be important (rating of 3) to essential (rating of 5) items for tapping knowledge of equivalence, with a mean rating of 4.1.

Next, we confirmed that we could equate scores across the two forms. Our forms were administered to equivalent groups, demonstrated similar statistical properties, and received similar difficulty estimates for most paired items. Having met these criteria, it is reasonable to use a random groups design in IRT to calibrate the scores from the two forms, placing all item difficulties and student abilities on the same scale.

To evaluate the internal structure of the assessment, we evaluated whether the a priori predictions of our construct map about the relative difficulty of items were correct (Wilson, 2005). An item-respondent map (i.e., a Wright map) generated by the Rasch model was used to evaluate our construct map. In brief, a Wright map consists of two columns, one for respondents and one for items. On the left column, respondents (i.e., participants) with the highest estimated ability on the construct dimension are located near the top of the map, while those with the least ability are located near the bottom. On the right column, the items of greatest difficulty are located near the top of the map and those of least difficulty are located near the bottom of the map. The Wright map seen in Figure 1 allows for quick visual inspection of whether our construct map correctly predicted relative item difficulties.

---

Figure 1. Wright Map for the Mathematical Equivalence Assessment. Easiest items are at the bottom of the map (L1, L2, L3 & L4 indicate which Level the items was expected to be at). Each X represents one person.
As seen in Figure 1, the items we had categorized as Level 4 items were indeed the most difficult items (clustered near the top with difficulty scores greater than 1), the items we had categorized as Levels 1 and 2 items were indeed fairly easy items (clustered near the bottom with difficulty scores less than -1), and Level 3 items fell in between as predicted. Overall, the Wright map supports our hypothesized levels of knowledge, progressing in difficulty from a rigid operational view at Level 1 to a comparative view at Level 4. This was confirmed by Spearman’s rank order correlation between hypothesized difficulty level and empirically derived item difficulty, \( \rho(62) = .84 \), \( p < .01 \). Additional evidence for the validity of the assessment is that ability estimates should increase with grade level. Ability estimates can be thought of as students’ predicted success on the equivalence assessment. As expected, mean ability estimates progressively increased as grade level increased, \( \rho(173) = .76 \), \( p < .01 \).

To gather evidence based on relation to other variables, we examined the correlation between students’ standardized math scores on the Iowa Test of Basic Skills (ITBS) and their estimated ability on our equivalence assessment. As expected, there was a significant positive correlation between students’ scores on the equivalence assessment and their grade equivalent scores on the ITBS for mathematics (\( r(86) = .85 \) and \( r(83) = .87 \), \( p’s < .01 \), for Forms 1 and 2 respectively), even after controlling for their reading score on the ITBS (\( r(86) = .79 \) and \( r(83) = .80 \), \( p’s < .01 \), for Forms 1 and 2 respectively). This was true within each grade level as well. This positive correlation between our assessment and a general standardized math assessment provides some evidence of convergent validity.

**Characterizing Students’ Knowledge Levels**

Much of the power of IRT results from the fact that it models participants’ responses at the item level, as opposed to classical test models which are modeled on responses at the level of test scores. Thus, with IRT, we can use participant ability and item difficulty estimates to glean specific information about individual student knowledge and about the relative skill levels of cross-sections of students. For summary purposes, we can partition students into groups according to knowledge levels of our construct map. Students can be classified as working on developing knowledge at a particular level based on their ability estimate. The distribution of ability levels by grade is listed in Table 2.

<table>

</tbody>
</table>

In second grade, almost all students were at Level 2, or a flexible operational view, meaning they were in the process of gaining a more flexible, operational view of equivalence. In third
grade, a majority of the students had gained a flexible, operational view and were working on a relational view of equivalence (Level 3) or had advanced to beginning to compare the two sides of an equation (Level 4). From fourth to sixth grade, an increasing number of students were advancing to Level 4, with all of the sixth graders reaching Level 4. Note that classification at a particular level indicates that students are working on learning this knowledge, not that they have mastered it.

**Discussion**

Numerous past studies have pointed to the difficulties elementary-school children have understanding equivalence (e.g., Behr et al., 1980; Carpenter et al., 2003), underscoring the need for systematic study of elementary students’ developing knowledge of the concept. We used a construct modeling approach to develop and validate an assessment of mathematical equivalence knowledge. We proposed a construct map that specified a continuum of knowledge progression from a rigid operational view to a comparative view. We created an assessment targeted at measuring the latent construct laid out by our map and used performance data from an initial round of data collection to screen-out weak items and to create two alternate forms of the assessment. The two forms of the revised assessment were shown to be reliable and valid along a number of dimensions, including good internal consistency, test-retest reliability, test content, and internal structure. In addition, our construct map was largely supported. Below, we discuss possible sources of increasing equivalence knowledge, benefits of a construct modeling approach to measurement development, and future directions.

**Developing Knowledge of Equivalence**

Our construct map specified a continuum of knowledge progression from a viewing the equal sign operationally to comparing the two sides of an equation. Inspection of the Wright map (see Figure 1) indicated that items of a given level clustered together. There did appear to be a transition level between a rigid operational view and a relational view. In particular, items with operations on the right or without operations were easier than items with operations on both sides. In addition, some students in elementary school were advancing beyond a basic relational view (Level 3) and were comparing the relations between the two sides of an equation (Level 4). By fifth and sixth grade, a majority of students were successful on Level 3 and some Level 4 items. A comprehensive assessment of children’s knowledge of mathematical equivalence requires items detecting transitional knowledge as well as items detecting more advanced relational thinking.

We have also analyzed the use of the equal sign in the textbooks used at the participating school and gathered teacher reports of student exposure to equations in different formats. Both analyses suggest that mere exposure to the equal sign is not the primary driver of knowledge change. Rather than simple exposure, explicit attention to ideas of equivalence in classroom discussion, with attention to the equal sign as a relational symbol, may promote knowledge growth, even in typical classrooms. This is in line with teaching experiments conducted by Carpenter and colleagues on the effectiveness of classroom discussions of non-standard equations and what the equal sign means (Jacobs et al., 2007).

**Benefits of a Construct Modeling Approach to Measurement Development**

A construct modeling approach to measurement development is a particularly powerful one for researchers interested in understanding knowledge progression, as opposed to ranking
students according to performance. We found construct modeling to be very insightful and hope this article will inspire other educational and developmental psychologists to use the approach. This measurement development process incorporates four phases that occur iteratively: 1) propose a construct map based on the existing literature and a task analysis, 2) generate potential test items that correspond to the construct map and systematically create an assessment designed to tap each knowledge level in the construct map, 3) create a scoring guide that links responses to items to the construct map, and 4) after administering the assessment, use the measurement model, in particular Rasch analysis and Wright maps, to evaluate and revise the construct map and assessment (Wilson, 2005). The assessment is then progressively refined by iteratively looping through these phases. Overall, repeatedly evaluating our theory against performance on individual items helped us to evaluate our commonsense assumptions that otherwise would have gone unquestioned.

Another benefit of a construct modeling approach is that it produces a criterion-referenced measure that is particularly appropriate for assessing the effects of an intervention on individuals (Wilson, 2005). We developed two versions of our equivalence assessment so that different versions could be used at different assessment points in future intervention or longitudinal research. Our equivalence assessment could also help educators modify and differentiate their instruction to meet individual student needs.

Conclusions

Although we have made an important first step in validating a measure of equivalence knowledge, much still needs to be done. A critical next step is to provide evidence for the validity of the measure with a larger and more diverse sample; a task we are currently undertaking. Further, we need to know the predictive validity of the measure – for example, does the measure help predict which students need additional math resources or who are ready for algebra in middle school?

In conclusion, our assessment and accompanying construct map for developing knowledge of mathematical equivalence are quite promising. The construct map provides a means for tracking students’ developing knowledge of equivalence across elementary school and a construct modeling approach provides a criterion-referenced analysis of performance. Multiple measures of reliability and validity support the promise of our measure. In the future, this measure should be a valuable tool for researchers who are evaluating the effectiveness of different educational interventions and for teachers who want to differentiate their instruction.

BEHIND AND BELOW ZERO: SIXTH GRADE STUDENTS USE LINEAR GRAPHS TO EXPLORE NEGATIVE NUMBERS

Ruth Beatty
Lakehead University
rbeatty@lakeheadu.ca

Ten sixth grade students utilized their understanding of creating graphs for linear rules to explore negative numbers, and mathematical operations with negative numbers. Students extended the axes of their graphs (the first quadrant) to include numbers “below” zero on the vertical axis, and “behind” zero on the horizontal axis. They then created graphs for linear rules with either a negative constant ($y=mx-b$) or a negative multiplier ($y=(-m)x+b$). Results indicate that constructing linear graphs supported students in developing both a unary and binary understanding of negativity. In addition, working within the four quadrants of the graph, and the process of plotting trend lines for linear rules may also have supported a multiplicative understanding of negativity.

Introduction

The purpose of this study was to determine whether Grade 6 students’ previous work with linear growing patterns, and graphical representations of linear growing patterns, could support their understanding of negative numbers and operations with negative numbers. Three lessons were developed as a way of extending students’ understanding of graphical representations of linear rules that contained only positive numbers to incorporate negative numbers. Activities included extending the boundaries of the graphing space from the first quadrant to include all four quadrants, and working with linear rules with a negative constant ($y=mx-b$) or a negative multiplier ($y=(-m)x+b$).

Theoretical Framework

When coming to understand negative numbers, students must develop an integrated understanding that the minus sign performs several roles, which then leads to an overall understanding of ‘negativity’ (Vlassis, 2004). Two roles are particularly pertinent when beginning to think of ‘negativity’ (Gallardo & Rojano, 1993) – the first is the unary role of the minus sign that acts as a structural signifier to indicate that an integer is negative. The second is a binary role of the minus sign that is an operational signifier, that is, the sign is an indication of the operation of subtraction. Studies have shown that students do not consider that the minus sign could have a double status, that is, have either a unary or binary function and instead tend to have a rigid idea of a minus sign as indicating subtraction (Carraher, 1990). Other studies have outlined the deep-rooted and widely held misconceptions students have about signed numbers and the kinds of operations that can be performed on them (Vlassis, 2002, 2004; Gallardo, 2002; Gallardo & Romero, 1999).

Past studies have looked at two general types of models for teaching negative numbers. One model is based on the embodiment of negative numbers in practical situations – for instance, a witch’s pot where hot cubes are positive and cold cubes are negative, with the goal of achieving equilibrium through the addition or subtraction of negative or positive cubes (Kemme, 1990, as cited in Streefland, 1996). Research suggests that these kinds of models are not beneficial (Streefland, 1996) primarily because students have difficulty understanding the connection.
between the magnitude of number (in terms of its proximity to zero) and the temperature of an object.

Researchers have demonstrated that when teaching negative numbers, a more successful model is a number line, which has been shown to be a more intuitive representation for students (Bruno & Martinon, 1999; Streefland, 1996; Hativa & Cohen, 1995). Hativa and Cohen (1995) conducted a study with Grade Four students, and demonstrated that younger students can develop an understanding of negative numbers by extending their understanding of the positive number system. By situating students’ problem solving on a number line, students learned how to locate numbers on a number line (either side of 0), compare the magnitude of two numbers, and estimate the distance between two numbers. This in turn enabled them to perform some simple addition and subtraction \((a+b, a-b, -a+b, -a-b)\). The researchers found that students did have an intuitive sense of negative numbers even at this young age, but that operations with signed numbers were still problematic. Similar results have been reported in studies with older children, for whom the operations with two negative numbers were found to be difficult (Bruno & Martinon, 1999). Other researchers (Streefland, 1996) have explored children’s conceptions of negative numbers as being the mirror opposites of positive numbers on the number line with 0 playing a prominent role in the approach to distinguishing between positive and negative integers.

There have been no studies to date that have specifically looked at how children’s intuitions about negative numbers on the number line can be incorporated into their understanding of linear graphs and linear rules, and how this in turn can support their conceptions of negative numbers. Graphs offer an opportunity to visually represent both the location of negative numbers in 2-dimensional space, and the outcome of operations with negative numbers, for instance, the fact that multiplication does not always result in a greater number if the number being multiplied is less than 0 (Greer, 1992). When plotting points for linear rules students can explore how a negative multiplier \((y=(-m)x+b)\) or a negative constant \((y=mx-b)\) or a negative x-value \((y=m(-x)+b)\) affect the value of \(y\).

**Methods**

This study is part of a larger three-year study using design research methodology to develop and assess new learning situations that support students’ understanding of linear relationships. In year 1 of the study, students developed an understanding of the covariation of two sets of data, position cards and numbers of tiles in growing patterns, and expressed this as a pattern rule, for example “total tiles = position number x 2 + 3.” In the second year of the study, the instruction was extended to include graphical representations of linear relationships. Results indicated students developed an initial understanding of the connections among growing patterns, pattern rules, and graphs (for example, author, 20xx). These results formed the basis for the instructional design of the present study.

As outlined in the research literature, the number line can be a powerful support for learning negative numbers with 0 playing a prominent role in distinguishing between negative and positive integers. In this study the learning of negative numbers was integrated into students’ developing understanding of linear graphs, thus allowing them to work in a Cartesian graphing space bounded by both a vertical and a horizontal number line that intersect at 0 (the origin). Three lessons were developed for this study. The instruction centered the inclusion of negative numbers in linear rules \(y=mx+b\) and the effect on graphical representations, both in terms of the
trend lines of the pattern rules themselves, and how negative numbers are represented in the graphing space.

Lesson 1. The goal of this lesson was to have students think about extending the graphing space they had been working in (the first quadrant) in order to think about where on the graph negative numbers could be represented. Initially students were asked to brainstorm about where they had seen negative numbers in order to see what metaphors the students used when thinking about negative numbers, with the goal of establishing two models of negative values – a horizontal number line and a vertical number line. This was so that students could think about how both the vertical and horizontal dimensions of negative numbers could be used to extend the two axes of the first quadrant graph that they were familiar with.

Lesson 2. In this lesson, students were shown the rule “y = 4x-2.” Students were asked how they would graph the rule. I was interested to see whether they would utilize a previous heuristic, “the constant part of the rule is responsible for where the line “starts” on a graph at the y-intercept.” The goal was to determine how the students would carry out calculations with negative numbers, and whether the graph supported this.

Lesson 3. The students were asked to create graphical representations for rules with negative multipliers, such as y = (-4)x + 20.

Teaching Intervention

The three research lessons were delivered during 6 class lessons over the course of three weeks, and were alternated with the classroom teacher’s math lessons that covered other strands of the curriculum. The lessons were taught during the students’ regular math classes. The lessons were taught by the classroom teaching intern, who was in her second year of a two year Master of Arts degree in teaching, child development and education.

Participants

This study included one grade six class of 10 students (5 boys and 5 girls). They came from a class of 22 students, 11 of whom were in grade 5. One grade six male student did not wish to participate in the study. This was an opportunistic sample of students who had participated in the previous 2 years of the larger 3-year study. The students were from a University Laboratory School, and had been taught mathematics using reform-based teaching approaches with an emphasis on inquiry-based tasks, use of manipulatives, and mathematical discussion. The Laboratory School was chosen (rather than one of the classrooms in the public school system that had participated in the previous two years’ research) primarily because of their mandate to “provide an environment that fosters research and professional inquiry and involvement in supporting new ideas related to improving education.” This allowed for the content of the lessons to include material that went beyond the expectations set out in the provincial curriculum documents for grade 6.

Data Collected

The primary forms of data collected were comprised of videotaped observations of classroom lessons and transcripts of those videotapes. Videotape included observations of classroom whole group discussions, with a particular focus on capturing student-student interactions.

During classroom sessions, students were also interviewed as they engaged in individual or small group work. Other supporting data included all student artifacts and field notes.
Data Analyses

Video data and transcripts were viewed and coded, and codes were used to merge categories together to establish trajectories of understanding. These trajectories underwent both a descriptive analysis in order to identify the elements of the trajectory, and a theoretical analysis as a means to identify the theoretical constructs of the understanding of negativity. Cross-referencing of trajectories from the codes identified in transcripts to other sources of data (particularly field notes and student work) was undertaken for the purpose of complementarity (Greene et. al., 1993).

Results

Extending the Graphing Space

When discussing their experiences with negative numbers, the students introduced several metaphors including typical examples such as debt and temperature, and a less typical example of a timeline. By using these commonly understood metaphors, the values along the number lines were imbued with meaning. Temperature became the basis for a vertical model of negative numbers, representing negative (cold) and positive (warm) values. The concept of the timeline underpinned the horizontal model, with years BCE representing negative values and years CE representing positive. In both cases the students were familiar with how to represent negative values, “below zero” starting with negative 1 and numbering down on the vertical model, and “behind zero” starting with negative 1 and extending left on the horizontal model. Zero was used as the division between positive and negative numbers, with the two (positive and negative) number lines mirroring each other on either side. The students knew that the farther away from zero, the larger the numeral (signed or unsigned) became.

Students used three distinct ways to extend their first quadrant graphs to include the three other quadrants. One approach was to start with the vertical number line in the middle of the grid, and the horizontal line along the bottom. Both lines had zero in the middle. The vertical axis was labeled with positive and negative values – the negative values from -1 to -10 but after -10 came the 0 of the horizontal axis. One student explained the problem with this initial representation:

I realized that on the thermometer line it didn’t make sense to count down from -1 to -10 and then have 0 again. So I decided to lift the bottom number line up to the middle and kind of overlap the zeros [gesture lifting the horizontal line from the bottom of the page and placing it in the middle of the page]. That way there was room for negative numbers to go behind the zero and to go below the zero.

Another way was to extend the vertical axis down “below zero” and the horizontal axis left “behind zero.”
We put the 0 in the centre of the page. We went down like this (extending down from the origin to extend the vertical axis) and across like this (extending horizontally to the left of the origin).

A third approach was to reconfigure the numbering of the existing horizontal and vertical axes along the bottom and left-hand side of the page. The fact that the two number lines “ran into each other” in the lower left corner did not seem to bother the students.

I did my numbers along the side and bottom, like we usually do. Then I colour-coded it, to make it easier for me visually. So, the bottom half of the graph is red and that’s all the negative numbers, because it’s under the line...the zero line (the horizontal axis) and then these are all the positive numbers above the zero line. And here, this half (the left half) is all green, and the green is all the negative numbers that are behind zero (the vertical axis). And these (to the right) are all the positive numbers in front of zero. When you look at where the zero lines intersect, that’s the ultimate zero.

Plotting a Rule with a Negative Constant

These students had previous experience creating graphs for rules with a positive constant. In order to plot points, the students knew that the y-intercept represents the value of the constant in a pattern rule. They plotted points by carrying out the operation of the rule with each x-value, which meant multiplying the x-value by the multiplier and then adding the constant.

The students were introduced to a negative constant both as a signed number and as representing the operation of subtraction. The negative constant meant that the y-intercept was a point at a negative value on the y-axis. The negative constant also meant that a constant amount had to be subtracted as each point was plotted. For example, Jack created a graph of a rule with a negative constant by calculating the rule at successive x-values and subtracting the constant amount instead of adding. The physical plotting of points, and the contrast of counting down for a negative constant (subtracting a constant amount from each point) reinforced the notion of directionality of negative and positive numbers, in this case oriented to the vertical axis as the number line. Jack demonstrated how to plot the points for the first few x-values.

The first x-value is times 4, so 1 times 4 equals 4 and then you do minus 2, which equals 2 [plots point on the graph at (1,2)]. Two times 4 equals 8 and then you subtract 2, which is 6 [plots point at (2,6)]. Three times 4 is 12 minus 2 is 10.

Elsie started by plotting the y-intercept. “Now, the rule is 0 times 6 minus 3 so 0 times 6 is 0 minus 3 is
negative 3.” This is a blending of the understanding of both meanings of negative (subtraction and negative integer). She continued calculating the rule for each positive x-value. She then calculated the rule for an x-value of negative 1. “Negative 1 times 6 is negative 6, minus 3 is negative 9.” She plotted a point at (-1,-9). I asked her if she thought that was the correct answer. She confidently replied it was, “Because it makes a straight line. It’s a nice way to visually check and see if I’m doing it right.” Elsie used the trajectory of the trend line to check the correctness of her calculations.

**Plotting a Rule with a Negative Multiplier**

In the final activity, students were asked to construct graphs for rules with a negative multiplier and a positive constant. The students used two strategies to plot the trend line for the linear rule with a negative multiplier.

Students used a strategy based on the functional relationship between the x-value and y-value, carrying out the calculations with the x-value to find the value of y for the first two or three points. They then relied on a recursive strategy, which involved subtracting the amount of the multiplier from the previous y-number (from left to right in the upper right quadrant) so that the negative multiplier represented the successive subtraction of 2. When plotting points for negative x-values all students relied on a recursive approach of adding the value of the negative multiplier to previous y-numbers, or “going up 2 each time” from right to left. The trend line of the graph in the upper left quadrant was a tool for checking their calculations, and the correct placement of the points. The students developed the understanding that multiplying positive x-values with negative multipliers resulted in smaller values, and that as the value of x increased, the resulting value of y decreased. They then related this to the slope of the trend line on the graph.

The numbers (y-axis numbers) if you start at the zero position (y-intercept) and keep going, the numbers got smaller. So instead of getting bigger and the line going like this [shows angle positive slope with forearm] they just went like that [angled arm downward]. The slope was going down instead of up.

However the students noticed that the opposite was true for negative x-values.

Ya, what’s weird is if you have a negative multiplier and a negative x-number it gets higher (the trend line in the upper left quadrant), cause usually you’d think a negative multiplier and a negative x-number must be getting lower, because negatives are lower, but it keeps getting higher in the positives (y-values) when you go into negative x-values.
It's really cool. This can help you think about why a negative times a negative is a positive.

Discussion

The purpose of this study was to examine how building on students’ work with graphical representations of linear relationships could support their understanding of negative numbers. During the course of the study, we identified that students were able to use their intuitions about vertical (thermometer) and horizontal (timeline) number lines to develop an understanding of the numeric values represented in the four quadrants of the Cartesian plane. Although the students utilized three different strategies to create their four quadrant graphs, all of the students were successfully able to extend their graphing space by integrating a vertical and horizontal model of negative numbers to include numbers “below zero” on the vertical axis, and “behind zero” on the horizontal axis.

Once they had meaningfully created spaces “below” and “behind” zero the students were able to then apply their understanding of working with linear rules to incorporate negative numbers. They included negative numbers as the constant or the multiplier of the pattern rules, and calculated points for negative x-values. Students were able to make connections between the pattern rules and the resulting trend lines on the graph – including developing an understanding that pattern rules with a negative constant would have a y-intercept below 0, and pattern rules with a negative multiplier would have a trend line that sloped downward. All students were able to carry out addition and subtraction with negative numbers, including subtracting a number from a negative number, or -a-b, which has been shown to be problematic (Streefland, 1996). In this case, the students were able to utilize the trend line as a way of checking the “correctness” of their answers, since they understood that linear trend lines are straight, and so calculating linear rules with x-values (positive or negative) had to result in a value somewhere along the trend line.

As previously outlined, there are two kinds of negativity that are important to develop when considering negative numbers. The first is unary understanding, an understanding of negativity as a point on the number line. The second is binary understanding, negativity as indicating movement along a number line that corresponds with the operation of subtraction. When considered on a horizontal number line, positive and negative integers allow two directions to be used – to the right of 0 (positive) and to the left of 0 (negative). In this study the integration of two number lines introduced two more directions, above 0 or up (positive) and below 0 or down (negative). Just as number lines are defined by two directions, positive or negative, the four areas of the graph allowed for 4 different combinations of values represented by points in each of the four quadrants: positive/positive (PP), negative positive (NP), positive negative (PN) and negative, negative (NN). The four quadrants as area models of positive and negative values supported students in their ability to identify the position of negative numbers in the Cartesian graphing space. Creating graphs for linear rules that had either negative constants, or negative multipliers allowed students to develop an understanding of carrying out arithmetic operations with negative numbers. Plotting points allowed students to reason about adding and subtracting with negative values, with the added support of the trend line to determine if their results were correct by viewing whether the resulting point on the graph was in line with other points.

Students in this study seemed to also develop a multiplicative understanding of negativity, in addition to a unary and binary understanding. Multiplicative negativity is the understanding that the product of multiplying negative or positive x-values with negative or positive multipliers results in a product that is represented by a point in one of the four quadrants of the graph.

four quadrants acted as area models of positive and negative values, which supported students in their ability to think multiplicatively about negative values. When multiplying positive or negative multipliers with positive or negative x-values, the resulting point on the graph expressed the sign of the x-value, and the sign of the y-value based on the influence of the sign of the multiplier. The resulting points could be above or below the x-axis, and in front of or behind the y-axis in different combinations of positive and negative space. All of the students began to identify points within the four quadrants of the graph as representing the relationship between positive and negative multipliers and positive and negative x-values. However, this was a limited study (3 lessons with 10 students), and further research is required.

FOURTH GRADE STUDENT CONCEPTIONS OF PIECEWISE LINEAR POSITION FUNCTIONS

James P. Burke
University of Massachusetts Dartmouth
james.burke@umassd.edu

This study examined fourth grade student concepts of graph shapes in piecewise linear position functions and their relationship to the motion of an animated runner by focusing on the student predictions of the runner’s motion. Descriptions from six students reveal interpretations of the graph and strategies used to answer questions related to rate of speed. Two conceptions are identified as being common to all the students. When students considered graph shape they usually exhibited an iconic interpretation. Alternately, students read values from the axes and apply those in coming to a prediction story.

Introduction

What students can understand about piecewise-defined linear position functions necessarily begins with what they do understand – what their conceptions are about graphs. Discovering students’ interpretations of piecewise-defined linear position functions graphically represented is a step in understanding how to communicate expert conceptions of linear position graphs. DiSessa (1991) speaks of “conceptual expertise” (p. 152) being present in students. These conceptions are how students make sense of graphs, and the point of view through which they will interpret graphs. Specifically, DiSessa (1991) discusses speed as a “principal and direct resource in students’ thinking about motion” (p. 153). Would this accessibility be present in early grade students, and would it be available to them as they thought about the shape of graphs?

Theoretical Framework

Algebra is a vital component of mathematics education, included as its own thread in the standards of the United States’ National Council of Teachers of Mathematics (2004). One skill targeted in these standards is the ability to relate change in one variable to changes in other variables, even in the early grades. However, this is not associated with graph representations until much later in the strand.

Students can grasp algebraic concepts at much earlier ages than is suggested by the current curriculum, even in the early grades (Carraher, Schliemann, & Brizuela, 2000). Kaput (1999, p. 136) has described a number of forms of algebraic thinking including algebra as the ability to generalize and formalize patterns and constraints. These patterns may be shapes that students recognize in graphs, for example. Students can engage in these sorts of activities and this sort of mathematical thinking in the early grades, “making qualitative interpretations of symbolic but situated representations” (Tierney & Monk, 2008, p. 199).

Among graphical representations which carry mathematical meaning, the notion of the slope of a linear graph is an important subdomain, giving students access to algebraic notions of joint variation of quantities (Kaput & Blanton, 2001; Kaput, 2000). Students have an ability to talk about the rate of change of a variable over time by looking at slope, even at the 4th grade level (Tierney & Monk, 2008).
Smith, diSessa, and Roschelle (1993) have described certain student conceptions as being based on prior knowledge, but having been extended in a faulty way. Student conceptions of slope which are often labeled “misconceptions” can tell us something about student prior knowledge upon which algebra concepts can be built. While work is being done to examine some of these conceptions (Zahner, Moschkovich, & Ball, 2008), much of it is focused on the late middle grades. My approach to learning about conceptions follows from an assumption that knowledge construction is “mediated by symbol systems including language” (Moschkovich, 1988, p. 212). Student stories and descriptions, predicting how a character is going to move based on their examination of a graph, tell us more than their conclusions; they reveal some of the processes students use to make sense of what they see.

**Research Questions**

This study aimed to answer three questions:

1. How will students describe the motion defined by a plot of a simple (single piece) linear function on a position graph?
2. How will students describe a slightly more complicated 2-piece function plot involving two positive rate pieces?
3. Given a race which includes positive, zero and negative slopes, how will students describe that motion?

**Method**

The teacher of a Massachusetts fourth-grade mathematics classroom allowed me to work with students in the back of a classroom while class was in session. This presented some technical limitations, but it provided a comfortable, familiar setting for the students.

Following some initial start-up experiences, I collected data from six students for approximately 20-minutes per each session, returning over a number of days to work within the time constraints of the hour-long class.

For the purpose of being able to present students with a number of piecewise-defined position functions, I used SimCalc MathWorlds software (Hegedus & Dalton, 2006). The software has the ability to display editable piecewise position graphs, and to animate a runner character according to the motion defined by the graph (see Figure 1).

This software was developed at the University of Massachusetts Dartmouth as part of the SimCalc project in the Kaput Center for Research and Innovation in STEM Education. The software provides a number of representations related to joint variation of quantities using a motion context. The graphs are dynamically, graphically editable. An executable representation is provided in the form of animated runners on a soccer field. Once the graphs are edited into a desired configuration, running the animation activates the executable representation. The runners move according to the position graphs and a number of other visual cues represent the passage of time, and highlight the current time on the graph.

The software is designed to be used with a curriculum targeted at middle grade and high school students; it is used here without its curriculum, merely as a delivery platform for the graphs. However, students did observe graph editing and participate in graph editing during the sessions.

**Activity**

Sessions with the students would roughly follow the following pattern:
1. I would briefly describe the software interface.
2. I would explain the association between the graphs and the runners (“the blue graph is describing the motion of the blue runner.”)
3. I would ask the student to make a prediction about what the red runner was going to do when the animation is allowed to run. (“Does the red graph tell you anything about what the red runner is going to do when the race is run?”)
4. I would allow student to describe prediction/story.
5. I would run the animation.

Figure 1. SimCalc MathWorlds Software
This pattern would then repeat with a slightly more complex graph containing two positive-slope pieces for the blue runner, reaching the same position at the same time as the red runner at the end of the race.

For the third iteration I allowed the student to build a graph and then tell me a story about what sort of a race that graph would cause the blue runner to run (see Figure 2). (“Tell me a story about the race you’ve created.”)

Finally, I would sometimes explore further by creating a graph with features that had been neglected in the earlier iterations. For instance, I would introduce zero or negative slope pieces if they had not been introduced by the student.

I asked questions throughout the session comparing the runners to get the students to elaborate about their conceptions (“Which runner is running faster at the beginning of the race?”).

The data gathered was on discussions that each student participant had with the interviewer through each approximately 20 minute session; these discussions took place before and after the executable representation was allowed to run. However, the bulk of the discussion took place in the form of predictive stories that students told before they witnessed the executable representation of the piecewise-defined position function.

Analysis

After transcribing the student sessions, I decided to focus on the language that students used before they saw any animation of the graph under discussion. Seeing the animation often changed a student’s description of the “race.” Post-animation discussions were characterized by students discussing what they had observed the runner doing, or attempts at reconciling their conception of the graph with the runner’s apparent motion. By focusing on the pre-animation discussion, the data pertained to student’s understanding of the race based solely on the static aspects of the software – primarily the graphs.

I coded the language for a number of identifiable patterns in the descriptions that appeared to be references to graph shape, or relating graph shape to motion, or relating some other aspect of the graph to the motion. Two conceptions dominated the students’ language, appearing in every one of the students stories. I called these conceptions “direct reading” and “graph as path.”

Direct reading

Direct reading occurred when students read the quantities which were directly represented by the graph. In this case, they were reading position and time from the axes. Every student was comfortable doing this when there was a question of one runner’s position in the animation world, or the relative positions of the runners.

For example, for the single-piece graph representing a motion going from 0 to 20 in 10 seconds, this typical exchange occurred:

Interviewer: Can you tell me by looking at the graph what you think the red line is telling us about how the red runner is going to run?
John: Uh he’s gonna run 20 feet in 10 seconds?
Interviewer: OK and how do you know that?
John: Because the line ends. When you go across it ends on the 20 and go straight down it ends on 10 seconds.

This sort of direct reading also occurred in more complicated graphs. Direct reading is usually characterized by using numbers to talk about the graph, or relationships between two numbers. Usually this discussion took place without any mention of graph shape.

**Graph as path**

Graph as path has also been called “graph as picture” (Mokros & Tinker, 1987) and iconic interpretation (Leinhardt et al., 1990); it happens when students take the graph shape to directly represent some other type of object the student is familiar with. The student may take the graph to be like the path on a map. The consequence of this is that students describe the motion as if it is in two dimensions rather than the one-dimensional motion that the runners are limited to in their animation world. For example, if a student knows that the two runners will end the race in the same place at the same time, but one runner has a single, straight piece from beginning to end (20 feet over 10 seconds) and the other runner has two pieces of different slope, the latter graph appears to be a longer “path.” To meet someone at the same place and time yet take a longer path means you must have gone faster, since you covered a greater distance in the same time. This is the sort of conclusion that students come to using graph-as-path. Here is a specific instance:

<table>
<thead>
<tr>
<th>Interviewer:</th>
<th>Ok, so can you tell me anything about who’s running faster in this race?</th>
</tr>
</thead>
<tbody>
<tr>
<td>Issac:</td>
<td>Um, I mean he’s going to make it to 20 in that time. Running faster?</td>
</tr>
<tr>
<td>Interviewer:</td>
<td>Yup.</td>
</tr>
<tr>
<td>Issac:</td>
<td>Blue, ‘cause he’s going kinda fa—’cause he’s and take—it’s like taking 2 routes and they make it to the same place</td>
</tr>
</tbody>
</table>

There is only one route in the animation world; the runners are sharing a road. The student has concluded here that the two graphs represent different actual paths, each with their own independent total distance. These iconic representations dominate the shape descriptions that the students used. None of the students escaped some form of this conception, in which the graph stood in for a picture of something else.

**Collapsing representations**

My other codes attempted to describe other conceptions the students had. “Flat is stopped” was identified when a student described a zero slope as a lack of motion. “Down slope is slower” was identified when a student described a negative slope as slowing down. “Bend as stop” appeared when a student described a bend in the graph as a moment when the runner stopped.

Many of these other codes for language used in predictions were only related to graph shape because of my own efforts to identify them; students’ actual spontaneous references to graph shape were more rare. Often these codes could be collapsed to either direct reading or graph as path. For example, here is a description of backwards motion which appears to be related to graph shape at first, but as the student elaborates, it appears that she has reached her conclusion by reading position off the graph. The student’s description is of a negative slope section:

| Interviewer: | And what’s he doing there? |

---

Gloria: He’s running back because the line... the line goes down.
Interviewer: OK.
Gloria: Um, which means, um, that like he’s not going as many yards as he was. This would be… 16 yards? and this would be… can I just say less than 16 yards?

Similarly, one student, Fred, repeatedly described steeper slopes as being slower motions. Steep downward slopes appeared to him to be going faster. In this case, the graph is not a path for him, but I suspect his iconic conception of the graph is more like the runner having to negotiate a hilly terrain. So, “steeper is slower” collapses to my iconic representation code.

At times, an iconic interpretation of the graph conflicted with what a student was able to read off the graph. This was apparent in some halting descriptions. For example, here a student is trying to describe a zero slope segment of the graph:
Interviewer: Ok, and how does he move after that?
Helen: Straight—well, uh. [pause] He stays there.
Helen’s initial answer is an interpretation of a straight, flat line as representing motion. However, she corrects herself when she realizes that the runner is at the same place at the beginning of the segment and at the end. She doesn’t say the runner has stopped, she says “he stays there” choosing to describe the motion in terms of position.

Another Common Conception

Another conception was present in half of the six students. Students resisted describing changes in speed as instantaneous, even though they were represented that way on the graphs. Issac stated that the runner would “start getting faster” after a slope change. While this does not directly relate to slope, it does represent a description or prediction of the motion that is not based on what the student is seeing in the graph and may be an assumption carried in from experience in the world that change in speed is not a naturally instantaneous phenomenon.

Conclusion

I have identified two very strong student conceptions that were apparent in the work of students who participated in the study. Direct reading off the graph was a familiar conception and students relied on it comfortably. The iconic conception of the graph was also common among all students, and resulted in shapes being interpreted as paths, hills, or other familiar objects. This conception resulted in inaccurate student predictions.

Direct reading of position was a skill that students utilized often when they were asked about velocity—a quantity that they did not appear to see represented directly on the graph. When they turned to direct reading, students were often forced to describe motion in terms of position.

Graph as picture is different in that it includes awareness that the shape of the graph has some meaning that can be understood by shape alone. Students working on an unfamiliar question about a secondary characteristic of the graph extend some conception from their prior knowledge to this situation. Students using the direct reading method sometimes came to conclusions similar to what you might get from an understanding of slope; they read quantities off the graph and used a procedure to combine them in an effort to build on their prior conception in order to come up with an answer about rate of speed. However, the students did not associate this with the shape of the graph; they had not generalized a pattern of slope as it relates to rate.

The common ability to read position quickly off the graph implies that if they were given some instruction on slope, they could verify it for themselves with their skills of reading position off the graph. By this verification process, perhaps they could convince themselves that the direction of slope or relative degree of slope between two graphs has meaning.

During the initial stages of reading/transforming the statement of a word problem, one must necessarily undertake what we call the logico-semiotic outline, which includes processes of analysis and synthesis, and not just the recognition of a previously learned solution scheme. Outcomes from analyzing solution protocols of students in a pre-service mathematics teachers program, suggest that as of the stage of the logico-semiotic outline, it is feasible to anticipate whether the solvers will use the algebra sign system or not, and this wields an influence on the algebraic –or arithmetic- nature of the remainder stages of the entire problem solution process.

Introduction

In the Cartesian method symbolic algebra operates as the linguistic vehicle that makes it possible to detach oneself from the meanings referred to in the text of the problem, and thus reach the solution by way of transformations -at the syntactic level of algebra- of the equation or equations that represent(s) the situation described in natural language. This is what gives the Cartesian method its algebraic nature. One of the goals most sought after in secondary school is for students to master that method. Yet sundry studies have documented a marked preference for non-algebraic methods, both informal (such as trial and error) and school-based methods (such as arithmetic solutions) within this population of students (e.g. Bednarz & Janvier, 1996; Stacey & MacGregor, 1999; Lins, 1992). The foregoing has lead several authors to attempt to decipher the arithmetic-algebraic nature of the problems themselves (e.g. Puig & Cerdán, 1990), trying to see what response could be given to the question raised by Wagner & Kieran (1989, p. 226) “Are there word problems that are intrinsically algebraic rather than arithmetic?”

Other studies that have focused on analyzing the solution processes used by students at varying school levels reveal that in many cases, from the problem reading, interpretation and analysis stage, it is possible to identify whether the predominant nature of the strategy adopted is arithmetic or algebraic (Rubio, 1990; Filloy, Rojano & Rubio, 2001). In this article we broach the topic of the nature of the “structure of the problem” (a priori theoretical analysis) and of the resolution processes utilized (empirical data) jointly. From a theoretical standpoint that emphasizes interaction of the sign system of algebra with natural language and with other sign systems, such as that of arithmetic, we analyze episodes of the solution processes involving a problem “with an algebraic structure”, carried out by two pairs of students in a pre-service mathematics teachers program.

Solving methods and the logico-semiotic outline

In addition to the already mentioned preference of secondary school students for non-algebraic methods of solving word problems, documentation exists to specifically support that together with strictly arithmetic strategies junior secondary school and middle school students show that they are inclined to use number substitutions in representations of the relations present in the problem (Filloy & Rubio, 1991; Kutscher & Linchevski, 1997; Malara, 1999; Filloy, Rojano & Rubio, 2001). Based on the previous studies, one can say that the non-algebraic
methods most used can be grouped into two general methods, as follows: the arithmetic method and the exploration by number substitution method. The Cartesian method, on the other hand, consists of translating the problem statement into algebraic code and of finding the solution by solving an equation or system of equations in the field of algebra. It is important to note here that the arithmetic method, a method that shall be known here as the *successive analytical inferences method*, differs from the Cartesian method in that in it one does not anticipate the formulation of an equation, rather that the statement of the problem is conceived of as the description of “possible states of the world” and that text is transformed by analytical phrases, using “facts” that are valid in “any possible world”. These analytical sentences constitute logical inferences that act as logical descriptions of transformations of “possible situations”, until such time as the solver arrives at one that he/she recognizes as the solution to the problem (Filloy, Rojano, Puig, 2008, p. 217).

Analyzing the statement of a problem enables one to reduce that wording down to a set of relations among quantities; during this process some contextual elements become no longer relevant for the solver. Said relations may be represented by means of a graph in which the vertices correspond to quantities and the edges to the relations among quantities. In these graphs, which we have adapted from those formulated by Fridman in his work “Trinomial graphs as meta-language of problems” (Fridman, 1990), one can show the network of relations that exist among quantities that have been established in the analysis of the statement and the known quantities or data of the problem appear as black vertices, while the unknown quantities of the problem (including auxiliary unknowns) appear as unfilled boxes. The criterion for establishing the arithmetic-algebraic nature of the solution consists of whether the relations among quantities, that is to say the operations that must be carried out in order to reach the solution, involve operating with the unknown, with what one is searching for, or not. Figure 1 portrays the *hay problem* (taken from Kalmykova, 1975, p. 90, and slightly modified) and the corresponding graph from an analysis of the statement. The graph shows that any solution that uses that particular network of relations necessarily means having to operate with the unknown because there is no edge in which there is only an unknown quantity. In the cases to be discussed here, we have used the same type of graph to represent and analyze the reading and interpretation of the text of the *hay problem* made by participant pre-service teachers who had received instruction on general practices applied to solve problems in mathematics. However prior to going on to discuss the cases chosen, we will introduce several theoretical elements that will enable us to refer to such cases in terms of the sign systems involved in that reading process.

The *hay problem*
Some farmers stored hay for 57 days, but since the quality of the hay was better than they initially thought, they saved 13 kilos per day, as a result of which they had hay for 73 days. How many kilos of hay did they store?

![Figure 1](hayproblem.png)

The studies “Heuristic tools, plausible patterns and management in problem solving”
This article reports some of the findings of the series of studies entitled “Heuristic tools, plausible patterns and management in the process of solving problems”. The main objective of the portion of the work reported here is to study the influence on student actions of explicitly teaching problem solving management and process control. In more particular terms, we report

---

two of the study’s cases that correspond to solution of arithmetic-algebraic word problems. The students -around 18 years of age- were studying in a teacher training school and had sufficient knowledge of the mathematics contents involved in the problems they were given. They had particularly received prior instruction on algebraic solution of problems, but it was the first time they had received instruction on general issues related to problem solving. The instruction was given to a natural group made up of 34 students, to whom a test was applied both before and after receiving the instruction. The objective, *inter alia*, of said tests was to select the students who would be observed in the clinical study. The data reported here are derived from the clinical study which was undertaken by video-taping the students as they solved problems in groups of two with no intervention by the researcher.

In our work, we have used the idea of Mathematical Sign System (MSS) in order to describe the phenomena of teaching, learning and using symbolic algebra (Filloy, Rojano & Puig, 2008). In addition, given that the mathematical texts include signs of natural language as well as mathematical signs, and that in no case do the signs appear in isolation in the texts, we speak of a mathematical system of signs and not of a system of mathematical signs. In other words, the adjective “mathematical” is qualifying the system in its entirety and not just the signs (Puig, 2003). By the same token we conceive of MSSs from the standpoint of semiotics (basing ourselves on the semiotics of Pierce, 1982-) in which it is the processes rather than the very signs that are emphasized (Hoopes, 1991). And the processes we are interested in studying are those of the reading/ transformation of a text through which sense is produced (Filloy, Rojano, Solares, 2010) (in our case, the initial text is a word problem). Those processes involve the mathematical sign systems of algebra and of arithmetic, which is why we have abbreviated them as AlSS and ArSS, respectively.

During the initial stages of reading/transforming the statement of a problem, one must necessarily undertake what we have denominated here as the logico-semiotic outline, which includes processes of analysis and synthesis, and not just the recognition of a previously learned solution scheme (Filloy, Rojano & Puig, 2008, p. 35). That is to say that the outline includes, among other things, a mental representation of the problem that contains the basic information concerning the problematic situation and that identifies the relations that are central to the possibility of implementing any sort of solution strategy—or method—(Filloy, Rojano & Puig, 2008, p. 250). In the analysis—carried out using graphs—of the hay problem solution protocols undertaken by two pairs of students in the afore-mentioned clinical study, one can observe that as of the stage of the logico-semiotic outline in these cases it is feasible to anticipate whether the solvers will use the AlSS or not, and this determines to a great extent the algebraic—or arithmetic— nature of the remainder of the stages and of the entire solution process. The foregoing is regardless of the result of an *a priori* analysis using graphs, of the nature of the problem or of implementation by the solvers of practices learned that were incorporated into the solution process (such as, for instance, systematic review of the expressions that are used and of the actions carried out at each step). The section below consists of a presentation and discussion of the cases referred to above.

*The protocol of student pair A & J*

Pair A & J ends up solving the problem by translating the statement into the equation

\[ x = \left( \frac{x}{57} - 113 \right) 73 \]

and solving it. Yet they had previously written other erroneous algebraic expressions, which they corrected as a result of the fact that their process management is
effective enough that it enables them to detect mistakes. In successive analytical readings they extracted, either explicitly or implicitly, the following quantities and relations from the statement:

Quantities: days planned ($D_p$), actual days ($D_a$), additional days ($D_m$), planned consumption of hay ($C_p$), actual consumption of hay ($C_a$), daily reduction in consumption of hay ($C_r$), consumption on the additional days ($C_{Dm}$), consumption on the actual days ($C_{Da}$), consumption on the planned days ($C_{Dp}$), total saving ($S_t$), hay stockpiled ($T$).

Relations: $D_p + D_m = D_a$, $C_a + C_r = C_p$, $C_{Dp} + C_{Dm} = C_{Da}$, $D_p \times C_p = T$, $D_p \times C_a = C_{Dp}$, $D_p \times C_r = S_t$, $D_a \times C_a = T$, $D_m \times C_a = C_{Dm}$, $C_{Dm} = S_t$, $C_{Da} = T$.

This network of quantities and relations can be represented in the graph depicted in Figure 2, which shows the space of quantities and relations within which the solvers have moved during the overall solution process.

In the final correct solution they have only used the quantities and relations indicated in bold in the graph. These are the quantities and relations that serve to build the equation

$$x = \left( \frac{x}{57} - 113 \right) \times 73,$$

as can be seen in the graph in Figure 3.

The previous erroneous attempts are always guided by the logico-semiotic outline that pertains to the Cartesian method. From the very first, they anticipated operating with the unknown in the same way as with known quantities. Their plan of action can be described as a version of the Cartesian method, made up of three steps as follows: a) call the unknown $x$; b) examine quantities that appear in the story narrated in the statement of the problem and calculate them numerically or write them down by way of algebraic expressions that solely involve the letter that refers to the unknown, until an equation is obtained; and c) solve the equation.

The errors originate with the lack of analysis or bad analysis of the relations that exist among quantities, which leads the students to make calculations or write algebraic expressions that fail to respond to the correct relations among quantities, responding rather to incorrect quantity relations.

The first attempt, after calling the unknown in the problem $x$, consists of calculating the total hay saved by using the mistaken relation $S_t = C_r \times D_a$ (they write “hay saving = 113 \times 73”). The calculation is then cast aside because of J’s doubt “…it is per day, for each of the days for which there was a planned consumption of hay”, which implies the correct relation $S_t = C_r \times D_p$. The graph in Figure 4 shows the erroneous relation used with a dotted line.
In the second attempt, they begin by correctly calculating the planned consumption of hay. A says “So every day they planned to consume …”, writes “x/57 every day initially” and adds “this is what they had initially planned”.

Once the quantity $Ca$ had been correctly analyzed, and the corresponding algebraic expressions had been written, A proposes to continue the analysis using quantity $Cp$: “So then, what they actually consume is …” However to do this he does not appear to analyze the quantity, rather he combines the unknown and the data in some way: “every day they consume $x$ minus 113 divided by… And so, what do we divide it by?”

Not having analyzed the relations leads to writing an algebraic expression that is void of meaning, $\frac{x-113}{73}$, and in which the erroneous relations used are those represented in the graph depicted in Figure 5.

The discussion between A & J leads them to examine the meaning of the expression they have written because J maintains that they must divide by 57. Their collaborative management work means that A must reanalyze the quantities and relations, and discover that the algebraic expression is mistaken: “not 113 either, 113 daily … Well this is wrong.”

During the third attempt the expression they write for $Ca$ is $\frac{x-113 \times 57}{73}$ adding the multiplication times 57 in the numerator of the foregoing expression.

The discussion between A and J is once again a source of process management since it forces them to discuss the meaning of the expressions written. J ascribes an erroneous meaning to the numerator (“this would be the amount of hay that you would have left”), while A does not see it the same way. Since they are unable to find a meaning for the expression that they can both

---

agree to, J decides that “This is wrong”, and deletes the numerator. In Figure 6, we have shown in a graph just how the expression on the numerator could have been imbued with sense, but with the division taken from an erroneous relation.

The definitive and correct attempt is unleashed thanks to a discussion that enable them to make sense of the correct algebraic expression for \( Ca \left( \frac{x}{57} - 113 \right) \), by calling the relation “consume every day saving”. That denomination in daily language contains what they had previously called “consume every day initially” \((x/57)\) and the subtraction in the verbal form “saving”, which represents the action of saving every day 113 applied to \(x/57\). As a result they are able to conclude their analysis by building the following equation: “Anyway it’s the initial hay. They consume this every day, they do so over 73 days, and then during that entire time what they consume is the initial quantity, which is the \(x\).”

In short the solution process used by A & J is therefore algebraic from the very beginning, and they do not depart from that process to fall into arithmetic or trial and error strategies in spite of discovering their errors. Finding and correcting the errors was possible because of their process management. The students have been given instruction on review and control of the expressions they write. Control is undertaken by resorting to an examination of the very meaning of the expression and to a description that uses a vernacular name to express that meaning. By working together and in collaboration, the students are compelled to arrive at a shared meaning, thus preventing them from working in a syntactically senseless manner.

The protocol of student pair M & H

During the entire solution process M & H move within the field of arithmetic solution: calculating solely with the data. And this is the case as of the initial analysis (M: “And what other data do we have?”) and the first actions that deal with the data and are aimed at obtaining further data (J: “Look, every one of the 57 days, every day they saved 113 kilos, let’s see how many kilos they saved.”). Once they had correctly calculated the total saving \((57 \times 113 = 6441)\), they continue analyzing the statement in search of relations among the data (J: “And the kilos they saved are the ones that allowed them to have 16 more days of hay”), and by transforming that assertion into a hypothetical relation (J: “if they were able to make it through 16 days with the kilos that they planned..., stored to make it through the 57 days … I don’t know if it’s 57 or 73”). The proportion is set erroneously because the option of 57 or 73, that is opting between the days planned and the actual days, is discussed without examining the arithmetic meaning of the relation, in other words the ratio involved in that proportion. Instead of examining the arithmetic meaning, they –mistakenly- examine the meaning in the story that is narrated in the wording “it is 57 days because those are the days they had calculated that they had to store for, not the time they were able to withstand; that came later because of the fact that they had saved.”

Not having taken into consideration that ratio \( C_{Dm}:Dm \) is \( Ca \) and that ratio \( C_{Dp}:Dp \) is \( Cp \) led them to establishing the erroneous proportion of \( C_{Dm}:Dm::C_{Dp}:Dp \), rather than the correct proportion of \( C_{Dm}:Dm::C_{Da}:Dr \). M & H express the foregoing mistaken proportion by way of the scheme of the rule of three, which also provides them with an algorithm for obtaining the result.

The quantities and relations used in the solution have been represented in Figure 7. The figure shows that, with the reading given the problem has an arithmetic solution because it can be run through without the need to work with unknowns. (In the graph the erroneous proportionality relation is represented by way of a dotted edge that has four vertices.)
After obtaining the result (erroneous) M & H go through a very long series of verifications that we shall not go into in detail here. The number of times they verify the mistaken result is indeed high: seven. On each of those occasions, their verification is based on a correct analysis of the relations among quantities and, consequently, ends up contradicting the initial result. Yet M & H have greater faith in their initial result than in their verifications. Hence upon completion of each verification, they do not decide that their initial result is incorrect but rather search for a different verification. It is only their persistence to continue verifying that leads them, on their seventh attempt, to a reflection that is absolutely crucial. M says: “What is truly clear is that if we have formulated a verification strategy, that is the way to solve the problem; it’s another path, sure let’s see if it’s the right path, since we know…”

The solution that they then derive from that “verification strategy” is also arithmetic and is based on calculation of the ratio that they had alluded to in their incorrect initial solution when they used the rule of three algorithm. Consideration that the ratio of the proportionality relation is $Ca$ corrects the initial error and leads to the solution depicted in the graph shown in Figure 8, which is once again arithmetic.

**On the nature of solution strategies: Final remarks**

The objective of incorporating into school training the teaching of general review and monitoring strategies or practices that enable students to look at their own actions as they carry out the steps needed to solve problems is that of allowing the students to become competent problem-solvers, who are even able to change their solution strategy or method when their monitoring efforts throughout the process show them that their efforts are not being met with success. In the cases of student pairs A & J and M & H, one can see that despite having systematically undertaken reviews and corrections of their steps, both pairs of students remain on the solution path that each pair had chosen from the very start.

A & J decide to use the AISS and as of the graphs that correspond to the episodes analyzed, one can see the algebraic nature (Cartesian) of their approach to the problem. That is to say, the algebraic nature of the solution is not solely derived from their choice of the AISS to represent the relations found in the logico-semiotic outline, but also from the nature of the network of those relations, in which operations on unknown quantities also appear. In this case the corrections are made to the equation that A & J were first able to produce, but this does not only happen in the AISS. The back and forth between this sign system and the elements of the problem in its verbal form also involves, at the very least, natural language. In these processes of reading/transformation of the algebraic text initially produced and in those that involve elements of the statement, sense is produced and that sense guides the correction actions. One could say
that in this case the algebraic nature of the logico-semiotic outline permeates the entire solution path.

Student pair M & H resort to data calculations and to proportional reasoning as of the logical outline stage, and remain in the field of arithmetic throughout all of the verifications that they carry out on the result they obtained initially, despite the fact that those verifications contradicted the initial result time and again. The text of the problem statement is subject time after time to readings/ transformation, generating quantities and relations. Yet at no time do they calculate with an unknown quantity. Only reflection on the verification process enables them to carry out the final correction, without ever leaving arithmetical reasoning behind.

The foregoing cases demonstrate just how the algebraic or arithmetic nature of solution strategies for a word problem are intimately related both to the sign system chosen to express the network of relations among quantities –determined as of an interpretation of the statement- and to the fact of whether or not that network includes operating with the unknown quantity (ies) of the problem. Analysis of the succession of reading/transformation actions of the text of a problem by the problem solvers suggests that the logico-semiotic outline stage significantly influences the choice of mathematical sign system and, consequently, also yields an influence on the nature of the solution strategy.

RATIO AND PROPORTION: HOW PROSPECTIVE TEACHERS RESPOND TO
STUDENT ERRORS IN SIMILAR RECTANGLES

Ji-won Son
University of Tennessee
sonjiwon@utk.edu

The idea of interpreting and responding to student thinking is one of the central tasks of reform-minded mathematics teaching. This study examined elementary and secondary prospective teachers’ interpretations of and responses to a student’s errors involving finding a missing length in similar rectangles. Analysis results revealed that although the student’s errors came from conceptual aspects of similarity, a majority of prospective teachers identified the student’s errors from procedural aspects of similarity. They tried to cope with the student’s errors by invoking procedural knowledge. This study also revealed the two different forms of address by prospective teachers to student errors.

Introduction

Ratio and proportion are a core topics in elementary as well as secondary mathematics education (NCTM, 1989, 2000; Kilpatrick, Swafford & Findell, 2001). The NCTM document (1989) describes proportionality to be “of such great importance that it merits whatever time and effort that must be expended to assure its careful development” (p.82). Very often multiplication and division tasks in the lower grades are presented in unit-rate form, which is a special form of ratio and proportion. In the middle grades, word problems involving equivalent fractions and fraction comparisons can also be thought of as ratio and proportion situations (NCTM, 2000).

The ability to recognize structural similarity and multiplicative comparisons illustrated in such proportional reasoning processes are the cornerstone of algebra and more advanced mathematics (Kilpatrick, Swafford & Findell, 2001). Nevertheless, research has consistently shown that many students have difficulty with developing proportional reasoning. Hart (1984), for example, reported that less than 42% of students in grade 7 succeeded in solving simple problems of enlargement, a most common error is additive reasoning (Lamon, 2007). According to these studies, students tend to focus on the difference between the given quantities rather than proportionality illustrated in given contexts. What instructional support do teachers need to provide? How do teachers need to use student errors in instruction?

In this study I set out to investigate prospective elementary and secondary teachers’ reasoning, their responses to student errors on the topic of ratio and proportion, and the relationship between their knowledge and approaches. I used aforementioned student error in exploring prospective teachers’ reasoning and approaches. I was curious about how prospective teachers would interpret and respond to student errors in finding a missing length in similar rectangles, and how their approaches related to their mathematical knowledge. Although a growing body of research has focused on teachers’ treatment of student errors (e.g., Schleppenbach, Flevares, Sims, & Perry, 2007; Stevenson & Stigler, 1992), prospective teachers’ responses and their strategies have received limited attention in the research literature. If teachers are called to use student errors as springboards for inquiry into mathematical concepts, it is important to explore prospective teachers’ responses and strategies to student errors, and prepare them to make better use of student errors through teacher education programs. The purpose of this study is not to add to the collection of studies documenting

Chapter 2: Algebraic Thinking and Reasoning

Prospective teacher weakness, but rather to inform the design of teacher education in this area. Exploration of prospective teachers’ interpretations of and responses to student ideas and, in particular, student errors will help enrich a dialogue among reformers, teacher educators, and professional developers in ways they could help prospective teachers learn to teach math to promote student understanding. More specifically, the research questions guiding the study included:

1. How do prospective teachers understand ratio and proportion problems?
2. How do prospective teachers interpret and respond to student errors on ratio and proportion in similar rectangles?

Conceptual Framework

Teacher Knowledge, Approaches and its Relationship

Although many researchers have devoted considerable attention over the last two decades to what teachers should know and be able to do, there are still large gaps in this research, in particular, research studies on teachers’ knowledge of ratio and proportion. Fisher (1998), for example, investigated secondary mathematics teachers’ understanding and strategy usage in ratio and proportion problems. He used word problems involving direct proportional reasoning and inverse proportional reasoning. He reported that, overall, teachers were more successful with direct proportional reasoning problems (i.e., \( y=kx \)) than with inverse proportional problems (i.e., \( xy=k \)). However, the strategy chosen by teachers varied with the type of problem. In terms of teaching approaches, he reported that most teachers said they would use the same strategies they used while teaching the problems tested. Lim (2009) investigated twenty-eight preservice teachers with four types of invariance in miss-value problems: ratio, sum, product, and difference. He found that preservice teachers had different levels of understanding depending on the type of problems. While prospective teachers had less difficulty with the first and second problems (ratio and sum), they showed greater difficulty with a missing value task involving product and difference. In particular, he reported that preservice teachers generally do not pay close attention to the meaning of ratios when they set up a proportion to solve a missing value problem, indicating that prospective teachers tend to use the same approach for a missing value problem regardless of different contexts. Although the findings from these studies help us understand prospective teachers’ understanding and strategies, there remains a need for research to unfold how the teachers’ own understandings impact their interpretations of the students’ misconceptions. An investigation of this important topic is described here.

Strategies in Ratio and Proportion problems

In analyzing prospective teachers’ knowledge, interpretation, and approaches to student error(s), I was guided by the studies of Rittle-Johnson and Alibali (1999), who distinguished between the use of procedural and conceptual knowledge. I also referred to the studies of Fisher (1999) and Lamon (2007), who articulated different levels of understanding of ratio and proportion. Rittle-Johnson and Alibali defined conceptual knowledge as explicit or implicit understanding of the principles that govern a domain and of the interrelations between pieces of knowledge in a domain. They defined procedural knowledge as action sequences for solving problems. These two types of knowledge lie on a continuum and cannot always be separated; however, the two ends of the continuum represent two different types of knowledge. More detailed examples will follow of these two forms of knowledge regarding ratio and proportion in similar rectangles as I discuss the findings of the study.
Methodology

This study investigated pre-service teachers’ interpretation of and responses to student error(s) through a classroom scenario in which an imaginary student incorrectly solved a similar rectangles problem. The study also examined how prospective teachers’ pedagogical strategies used to address the student errors are related to their content knowledge of ratio and proportion.

Two tasks (content knowledge and pedagogical content knowledge) were developed based on the literature review (e.g., Hart, 1984) and textbook analysis (e.g., Connected Mathematics). The content knowledge task was aimed at assessing prospective teachers’ understanding of ratio and proportion. The first question, called similar rectangles problem, required prospective teachers to find the missing side of a rectangle given the condition the two rectangles are similar, and to explain their solution. The pedagogical content knowledge followed the content knowledge task. After completing the similar rectangles problem, they were asked to interpret and respond to a student’s incorrect solution. According to Hart (1984), the most common incorrect strategy in finding the length of the missing side in similar rectangle is to use additive reasoning (A-B=C-B) focusing on the difference between the given length in similar rectangles, rather than focusing on proportional relationship between two figures (A/B=C/D). I based my exploration of prospective teachers’ pedagogical content knowledge (PKC) on this common incorrect strategy. The pre-service teachers were asked to identify one fictitious student’s (Sally) error(s) and then to provide a written description of how they would respond to her (see Figure 1).

You are teaching 6th graders. You asked the students to find the length of the missing side in similar rectangles shown below. After a few minutes, you asked Sally, one of your students, to explain how to solve the problem. Sally explained that the side would be 12 cm long because 4+2=6.

1. Evaluate Sally’s reasoning and explain whether it is mathematically correct or incorrect. If it is not correct, identify the error(s) in Sally’s reasoning.
2. How would you respond to Sally? Explain what type of guidance you would give Sally as much detail as you can.

Figure 1. Pedagogical Task: “What is the length of the missing side?”

Fifty-seven prospective teachers participated in this study. Thirty-one were in their senior year of the elementary teacher preparation program and twenty six were math majors seeking middle and secondary school certification at a large Mid-Western University. Prospective teachers in elementary and secondary programs were included in order to obtain a broad range of responses to the study’s task.

The tasks went through multiple phases of revisions and were pilot tested with two volunteers who were then interviewed to check for possible misunderstandings. The final version of the task was then administered as an in-class survey in three mathematics methods course sections, two elementary and the other secondary, towards the end of the semester. This study...
Summary of Results

How Do Prospective Teachers Understand Ratio and Proportion?

The findings from the content knowledge task were helpful in providing an initial framework for analyzing the PCK task. In the first problem, prospective teachers were asked to find a missing length in similar rectangles where a rectangle that began as a 4 cm by 6 cm was enlarged to a rectangle with a short side of 10 cm. All prospective secondary teachers answered correctly and 73% of prospective elementary teachers (22 out of 31) answered correctly. Among the prospective teachers who provided incorrect answers, 6 prospective teachers used a common strategy, additive reasoning, by focusing on the differences between the given quantities. One typical response was as follows:

I think that the missing side is 12 cm because the difference between 4 cm and 6 cm is 2 therefore the difference between the 2 sides of the larger rectangle would also be 2. 10 cm + 2 =12 cm

Among prospective teachers who provided correct answers, three different solution approaches were used—within ratios, between ratios, and unit-rate (or scale factors) as addressed in Figure 2.

<table>

<th>Between Ratios</th>
<th>Within Ratios</th>
<th>Scale factor method</th>
</tr>
</thead>
<tbody>
<tr>
<td>$\frac{4}{10} = \frac{6}{x}$. If the rectangles are similar, their sides are at a constant ratio. Thus you can compare the ratio between the width and length and use this proportion to find missing length from the width of same rectangle.</td>
<td>$\frac{6}{4} = \frac{x}{10}$. Assuming the 4cm side is similar to the 10cm side I must find a relationship between 6 cm and x. I create a fraction with 6cm and 4cm and set it equal to x and 10 cm. Cross multiply and solve for x</td>
<td>Ratio of smaller to bigger similar rectangle is 4: 10. $6 \times \frac{10}{4} = 6 \times 2 \frac{1}{2} = 12 + 3 = 15$</td>
</tr>
</tbody>
</table>

Table 1 shows the frequency of each type of solution strategies by prospective teachers. While the most frequently used strategy is the within ratio approach among prospective elementary teachers, the between ratio approach is used most often in prospective secondary teachers.

I was also curious to know if prospective teachers pointed out the lying idea of similarity of rectangles, the concept of similarity, when explaining their solution approaches because finding a missing length in similar rectangles involves not only understanding the concept of similarity but also procedural knowledge of setting up a proportion and performing calculations. Among prospective elementary teachers who provided correct solution strategies, 48% of prospective
elementary teachers (11 out of 23) referred to the concept of similarity while 81% of prospective secondary teachers (21 out of 26) pointed out the property of similarity of figure. This indicates that a smaller percentage of prospective secondary teachers carried out three methods as a rote procedure that requires little proportional reasoning.

How Do Prospective Teachers Identify Sally’s Learning Difficulties?

In a classroom setting, our fictitious student, Sally, was asked to solve the same problem prospective teachers completed—find a missing length in similar rectangles. Sally concluded that the long side is 12 cm since 4 cm + 2 cm = 6 cm. As I addressed earlier, finding a missing length in similar rectangles involves at least four big ideas: (1) understanding the concept of similarity, (2) determining a between ratio, within ratios, or a scale factor, (3) setting up a proportion, and (4) carrying out calculations correctly. In Sally’s case, she did not understand the concept of similarity—the lengths of the corresponding sides in similar rectangles increase (or decrease) by a constant ratio. As such, she focused on the difference, in particular, within difference, by comparing the difference between the length and the width within a rectangle. Although she carried out the calculation correctly based on additive reasoning, she was not able to find the correct missing length in similar rectangles. The fundamental error in Sally’s case results from not understanding the concept of similarity.

In analyzing the responses of the prospective teacher participants, three categories of interpretation were identified and are illustrated below. The first interpretation was to classify different ways of identifying Sally’s learning difficulties using a conceptual approach—in this case, focusing on the meaning of similarity of rectangles, in which the following hold: two figures are similar if (1) the measures of their corresponding angles are equal, (2) the lengths of their corresponding sides increase (or decrease) by the same factor, called the scale factor, and (3) the perimeter from one rectangle to another rectangle also increases by the same scale factor. The conceptual approaches also included the idea of enlargement or reduction in similar rectangles. I call this type of identification of Sally’s error as similarity-based. One typical response was as follows:

Sally does not understand that similar means proportion or she may not understand what proportional means. A proportion is a ratio of two numbers, where Sally looked at the sum (or difference, depending on how you think about it) of sides.

The procedural approach involves finding the missing value in a proportion, which relates to big ideas 2 through 4 outlined above (i.e., determining ratios, setting up a proportion, and carrying out the calculation). In this approach, prospective teachers also indicated the need for a
ratio, proportion, or a scale factor for calculation. This type of identification of Sally’s error is called *procedure-based*.

Sally did not calculate the ratio of corresponding sides, i.e., 4cm/10cm = ratio of sides. What Sally did was 6-4=2cm difference then added 10cm +2cm=12cm.

In addition to these two categories of interpretation, a third category involved responses indicating misdiagnosis of Sally’s error based either on additive reasoning or incorrect focus. In most cases of additive reasoning, prospective teachers indicated Sally’s errors stemmed from not comparing the difference between rectangles. The following are examples:

Sally is explaining the relationship between the sides 4 and 6 rather than first comparing sides 4 and 10 then 6 and x. So she should be looking at how side 4 is related to side 10, then use that same relation with side 6 to get side x.

Table 2 shows subcategories of each approach and the distribution of response in terms of similarity-oriented vs. procedural-oriented.

*Note: * represent the most frequently referred category

Four subcategories were devised with respect to the similarity-oriented approach. While prospective teachers in category one did not provide a definition of similarity, prospective teachers in category two stated specifically that Sally did not see the relationship between two similar rectangles as a constant ratio. Although teachers in category three and four stated Sally’s limited understanding of the concept of similarity, teachers in category three pointed out specifically that Sally’s errors came from not comparing the lengths between the two rectangles. In the case of category four, prospective teachers indicated Sally’s difficulty as not visualizing enlargement of the second rectangle. In terms of the procedural approaches, four subcategories were devised as well. The major difference between the conceptual vs. procedural approach lies in the focus of indication of Sally’s errors. Interestingly, when prospective teachers were asked to identify Sally’s errors, they tended to rephrase Sally’s method by pointing out the use of

difference in calculation, which is coded into the first category in the procedural approach. Table 2 shows that, although Sally’s errors came from her limited understanding of similarity rather than from procedural knowledge of setting up an equation, prospective teachers in this study tended to identify her errors more from a procedural perspective.

How Do Prospective Teachers Respond to Sally’s Work?

I performed the same analysis on the responses the prospective teachers provided for the question asking them to describe how they would respond to Sally. Table 3 shows the distribution of response in terms of concept-oriented vs. procedure-oriented.

Table 3 shows that more than half of the prospective teachers provided guidance from procedural aspects of similarity. I was intrigued to find out how the prospective teachers who recognized Sally’s error in terms of conceptual aspects of similarity would respond to Sally. A comparison of Tables 2 and 3 shows that although the frequency of focusing on the meaning of similarity slightly increased from identifying the learning difficulties and responding to it, prospective teachers tended to provide their intervention based on the procedural aspects of similarity.

In addition to this approach, I explored two forms of approaches addressed by prospective teachers to student errors—teacher-focused vs. student-focused. While 81% of the prospective secondary teachers provided teacher-directed approaches of telling and explaining, less than half of the prospective elementary teachers used a student-focused approach by engaging Sally in activities or questions. Furthermore, I also observed prospective teachers’ using the three different approaches to student errors identified by Son (2010) in their examination of prospective teachers’ pedagogical strategies to student errors in reflective symmetry: (1) Generalization, (2) Return to the basics, and (3) A Plato-and-the-slave-boy approach.

Discussion

This study investigated prospective elementary and secondary teachers’ understanding and pedagogical strategies applied to students making errors in finding a missing length in similar rectangles. It was revealed that prospective secondary teachers had better understanding of ratio and proportion in similar rectangles than prospective elementary teachers. While all prospective secondary teachers solved the similar rectangles problems correctly, a large portion of prospective elementary teacher struggled with the problem. In explaining their solution...
strategies, and even though similar strategies appeared both from prospective elementary teachers and prospective secondary teachers, a majority of prospective secondary teachers pointed out the underlying idea of similarity, whereas less than half of the prospective elementary teachers explained their reasoning for using ratios and proportion.

This study also showed that, although a student’s error stemmed from lack of understanding of the concept of similarity, a majority of prospective elementary and secondary teachers identified the student’s errors from a procedural perspective of similarity. When they responded to the student’s errors, they guided the student by invoking procedural knowledge.

Another interesting finding was that, although prospective secondary teachers showed better understanding of the mathematical concepts presented in this study than prospective elementary teachers when responding to student errors, prospective secondary teachers tended to rely on a teacher-focused approach of telling or explaining students’ errors whereas prospective elementary teachers tended to use a student-focused approach by asking questions or providing related activities to help students overcome conceptual misunderstanding. These results are consistent with the findings reported by Son and Crespo (2009).

This study has implications for teacher educators, teacher education programs, and researchers. For example, our study joins others (e.g., Ball & Bass, 2003) in highlighting the importance for teacher educators to emphasize the importance of effective interpretation and response to student errors when teaching mathematics. In particular, by identifying different types of responses and their resulting effects on students, teacher educators are in a position to raise prospective teachers’ awareness of the implications of their interactions with students. Teacher educators can also develop prompts and facilitate discussions of similar tasks to challenge and expand prospective teachers’ initial understandings and imagined practice.

SECOND GRADE CHILDREN’S UNDERSTANDINGS AND DIFFICULTIES WITH PATTERNS

Seong Hee Kim
Arizona State University
skim118@asu.edu

Finbarr Sloane
University of Colorado at Boulder
Barry.Sloane@Colorado.EDU

The goal of our research project was to understand how children extend patterns, what they know about patterns, and what difficulties they have with patterns and patterning. Sixty-four second grade children took a test and eighteen of them were individually interviewed. Sixty-one children correctly extended the simple repeating pattern (○Δ○Δ○Δ○Δ) and nineteen children correctly extended the growing pattern (ABABBABBBABB). Only five children correctly extended all the four patterns. We explored five categories of children’s misunderstanding of growing pattern extensions. The findings add to the research about children’s pattern understandings and provide a stronger basis for instruction, professional development and curriculum development.

Introduction

Several researchers have focused on the effects of teaching patterns (Mckillip, 1970; Hendricks, Trueblood, & Pasnak, 2006). For example, Burton (1982) emphasized the importance of teaching and learning patterns. Alsom Clements and Sarama (2007) noted that children have to be able to identify patterns and generate patterns throughout kindergarten and the primary grades. The processes of patterning develop early algebraic thinking and make young children’s skills in mathematics meaningful (Waters, 2004) because children can experience comparing, counting, symbolizing, classifying, measuring, representing with pattern activities (see, English, & Warren, 1998). Preschool children have been found to engage heavily in pattern analysis in their play (Ginsburg, Inoue, & Seo, 1999). Patterns are not only important in mathematics; they are a big part of children’s lives. The purpose of the study was to investigate the pattern understandings of second grade children, who have experienced patterns in their life and in school; specifically, we explored how children extend patterns, what they knew about patterns, and what difficulties they have with patterns and patterning.

Theoretical Background

Patterns are important to children’s mathematical understanding. Through patterning children can build a foundation for temporal and spatial sequences; expand the ability to recognize similarities and differences which are basic to their success in mathematics (Burton, 1982); and develop the variable concept (English, & Warren, 1998) and number concept (Mckillip, 1970).

Patterns in algebra are divided into two categories: repeating patterns and growing patterns. Repeating patterns are patterns with a recognizable repeating cycle of elements, referred to as ‘unit of repeat’ (Zazkis, & Liljedahl, 2002). For example, ABABAB is a repeating pattern and AB as the unit of pattern, A and B serve as elements. Growing patterns have discernible units commonly called terms and each term in the pattern depends on the previous term (Queensland Studies Authority, 2005). For instance, “ABABBABBABBABBB is a growing pattern and AB,ABB,ABB, or ABBBB are terms.

Recognizing of repeating patterns requires knowledge of similarities, differences, and ordinal relations (Hendricks, Trueblood, & Pasnak, 2006). Warren (2005a) investigated young children’s
thinking about repeating patterns and the instructional process. She found even though children can generalize patterns with symbols, they need to articulate patterns with “variables”.

Although early adolescent classroom uses growing patterns to bridge the gap between arithmetic and algebra, students have difficulties with the transition (Warren, 2005b). Growing patterns are more difficult cognitively than repeating patterns for children to extend. Many children struggle with growing patterns due to their lack of prior knowledge and experience. Extending growing patterns does not mean copying the given elements, but requires children to perceive the relationship between the previous term and the next term. Extending growing patterns also involves an understanding of some number concepts, such as the concept of “one more than” (Mckillip, 1970). For example, to extend a growing pattern, ABABBABBBABBBB, children need to realize that the number of B’s is growing one more than the number of B’s in the previous term. To support children’s understanding of growing patterns, it is necessary to know what kinds of difficulties children will encounter with growing patterns.

The central research question explored in this study, is how second grade children extend repeating and growing patterns, and what are their difficulties and errors to extend patterns?

**Methods**

Sixty-four children took a test and eighteen of them were individually interviewed in May of second grade on tasks involving patterns. Second graders were chosen since by then children had already have experienced repeating patterns and growing patterns in kindergarten and first grade.

**Subjects**

The subjects for the study consisted of sixty-four children in three second grade classes in Phoenix, Arizona. The school chosen was a public school and was located in an urban area. At this school, classes were organized according to children’s English level since almost all the children were of Hispanic origin [with more than 50% English language learner] and their teachers taught them in English. One of the three classes was high English proficient class, another was middle level and the third was designated a low level English proficient class. Ninety-six percent of children in the school were Hispanic in origin; two percent of the children were African-American and two percent of children were Caucasian. Ninety-three percent of the children in the school received free lunch and the other seven percent got reduced lunch.

**Tasks**

The test had two repeating patterns and two growing patterns listed in Table 1. It asked children to extend each pattern for as long as possible. Each child had an individual test sheet. Children were interviewed with the same tasks.

<table>

<tr>
<td>Category</td>
</tr>
<tr>
<td>Repeating pattern</td>
</tr>
<tr>
<td>Complex</td>
</tr>
<tr>
<td>Growing pattern</td>
</tr>
<tr>
<td>Simple</td>
</tr>
</tbody>
</table>
We assumed that the simple pattern was easier than the complex pattern since in the simple repeating pattern an element comes once in the “unit of repeat” (○ come once in every unit of repeat, ○Δ) but in the complex repeating pattern an element comes twice or three times in the “unit of repeat” (two Gs come in every unit of repeat, GGRRR). This is similar for the growing patterns. In the simple growing pattern, the fixed element comes once in a term (A comes once in every term), and the number of increasing is one (B is increasing by one each time). However, in the complex growing pattern, the fixed element comes twice (two ●s come in every term) and the number of increasing is two (○ is increasing by two each time).

**Data Collection**

Children took the test and were interviewed in May, as they were completing second grade. When a child could not read the problem, we read the problem for the child. After they took the test, we interviewed eighteen children to better understand their pattern extensions. We chose children who extended patterns correctly or who extended patterns incorrectly with particular misunderstanding, to interview. Initial questions were “why did you make it longer like this?” and the follow up questions were developed according to a child’s initial responses. When we could not understand what a child had explained, we asked the child for further explanation until we understood his or her explanation. The interviews were conducted in the classroom. During the interview we took notes. The notes and children’s test sheets were gathered to be analyzed.

**Data Analysis**

Answers were coded both in terms of whether the extensions of the patterns were correct or not and the strategy the students employed in extending the pattern. The correct extension was coded as 1 and incorrect extension as 0 for each question. There was not special strategy coded for the correct answers but errors were coded for the incorrect answers. The categories of students’ errors will be explained in results section which follows immediately.

**Results**

Five children (7.8% of the total) extended all the four patterns correctly, although two of them made a minor error on one problem, using a lower case ‘r’ instead of a capital ‘R’. Results for each of the four pattern extension are summarized in Table 2. In the next section we focus in children’s incorrect extensions of patterns as they provide critical insights about children’s pattern understanding. Consequently, the analysis focuses on both correct and incorrect renderings.

**Difficulties with the Extension of Repeating Patterns**

Three children extended simple repeating patterns incorrectly and thirteen children extended complex repeating patterns incorrectly. It was hard to find something in common from their errors not only because the number of children who got wrong answers was small, but also

---

because their answers were very different with each other except for the three children who shared the same error, which was GGRRGGR for the complex repeating pattern, GGRRRGGRRR. The following example was John’s incorrect extension of repeating patterns (Figure 1). His extension had a repeated unit without anything changing but the unit was incorrect.

![Figure 1. John’s Incorrect Extension of a Repeating Pattern](image)

Mathew’s way of extension showed his recognition of elements. He identified the elements in the unit of repeat but he did not consider the number of elements in a unit. Therefore, he extended correctly the pattern in which an element comes only once in each unit, ○Δ○Δ○Δ○Δ, however he did not correctly extend the pattern in which an element comes twice or three times in a term (Figure 3).

![Figure 2. Mathew’s Incorrect Repeating Pattern Extension](image)

**Difficulties with the Extension of Growing Patterns**

Nineteen children extended the simple growing pattern correctly and eight children extended the complex growing pattern correctly. It is not quite true that the eight children who correctly extended the complex growing pattern correctly extended the simple growing pattern as well, since the three of the eight children made a counting error on the extension of the simple growing pattern. Children’s incorrect extensions of growing patterns displayed commonalities. There are listed in Table 3. No answers, unfinished extensions or extensions which did not have a unit of repeat were categorized as “None”, which we did not focus on in this study.

</tbody>
</table>

The most common misunderstanding of growing pattern extensions was that children considered growing patterns as long repeating patterns. Since children copied the elements from the starting of the pattern without a full comparison of each term, they did not recognize the increasing number of elements. They perceived the whole elements on the task as one unit of a repeating pattern.

The following examples were from Mike's growing pattern extension and showed a long repeating pattern (Figure 3, and Figure 4). Mike copied from the starting term. Although the end of given pattern was two blacks, he started with two blacks again since the original given pattern started with two blacks.

One of the most common misunderstandings of the growing pattern extension was to repeat the simplest term to extend it. The simplest term for a pattern, ABABBABBBABB was AB so Janet used only one A and one B to extend the pattern (Figure 5). A child extending with repetition of the simplest term did not consider the number of elements in each term important. Janet circled two whites and two blacks and figured out several groups of two white in each term but she did not focus on the number of two whites (Figure 6).

Another common misunderstanding of the growing pattern extension was to extend some terms correctly then to copy the whole as a long repeating pattern. At first, Jose knew that the white circles increased by two. However, when the number of white circles was over ten, he started to draw two white circles (Figure 7).
I: How did you make this longer?
Jose: I think we have to follow this (pointing the previous black and white circles).
I: Can you explain how you followed this?
Jose: by 2’s. Six, eight (he counted white circles by two).
I: Then, you put here?
Jose: 10. It is by 2’s.
I: Then, you put two (whites).
Jose: I think this is 10 (the number of previous white circles), starts all over again.

Figure 7. Jose’s Growing Pattern Extension as Partly Growing then Repeating of the Whole

The other misunderstanding was found only from simple growing patterns but not from complex growing patterns. Children repeated one of the terms (e.g., ABBB) to extend the growing patterns. Some children repeated ABBB and others repeated ABBBB. Children who had this misunderstanding did not explain why they extended it with only ABBBB or ABBB. Marisa only said “because you need to do the order” without further explanation (Figure 8).

Figure 8. Marisa’s Repeating Pattern Extension as Repeating of One Term

The last shared misunderstanding was found only from complex growing patterns and not from the simple growing patterns. Alex said “keep two blacks and one more white” (Figure 9). Even though five children made the same error, it could have been considered as their counting error. Since four of the five children correctly extended the simple growing pattern in which B was increased by only one, more pattern problems are needed to give them to for the researcher to fully disentangle this issue.

Figure 9. Alex’s Growing Pattern Extension as Increasing Incorrectly

Extending of Repeating Patterns Correctly but a Growing Pattern Incorrectly
Thirty-five children extended repeating patterns correctly and a simple growing pattern incorrectly. That is, they recognized similarities, differences, and ordinal relations in the repeating patterns (Hendricks, Trueblood, & Pasnak, 2006) but did not recognize the relationship between the previous term and the next term, and the concept “one more than” in the growing patterns (Mckillip, 1970). Carlos extended repeating patterns correctly and growing patterns incorrectly.
incorrectly. The following example shows Carlos’ comparison of repeating patterns with growing patterns. Here, what Carlos found as a difference was between shapes and letters, but not between patterns. He did not focus on the number of elements between terms.

I: Do you think ○Δ○Δ○Δ○Δ is the same with ABABBABBBABBBB or not?
Carlos: Different.
I: Why do you think so?
Carlos: This one (○Δ○Δ○Δ○Δ) is circle and triangle and this one (ABABBABBBABBBB) is A and B.

Children who extended growing patterns correctly recognized the difference between growing patterns and repeating patterns not by the shape or letter but by the number of elements. They explained the difference by “gets bigger”, “add one more”, “goes one more” or “have more”. The following example showed Susie’s explanation about the difference between repeating patterns and growing patterns.

Susie: This (○Δ○Δ○Δ○Δ) is different to this (ABABBABBBABBBB). This is circle, triangle, circle, triangle, circle, triangle. This one is ABABBABBBABBBB. B keeps bigger.

Extending a Simple Growing Pattern Correctly but a Complex Growing Pattern Incorrectly

Five children extended a simple growing pattern and a complex growing pattern correctly. In contrast, fourteen children extended a simple growing pattern correctly and a complex growing pattern incorrectly. Tom identified the growing number of elements for a simple growing pattern but his explanation for a complex growing pattern did not show that he understood the growing number of elements when it was not one. He said “the two patterns (ABABBABBBABBBB and ●●○○●●○○○○●●○○○○○○●●) are different because this one (●●○○●●○○○○●●○○○○○○●●) is circle and this one is (ABABBABBBABBBB) letters.” Tom used a simplest term (●●○○) to extend the pattern so his pattern extension was ●●○○●●○○○○. Tom’s explanation about the difference was similar with the explanation of the children who did not recognize the difference between repeating patterns and growing patterns, which was to focus only on the type of the element (e.g., shape or letter). However, Jane, who extended a complex growing pattern correctly, focused on the difference of the growing number of elements as following.

I: Is this (ABABBABBBABBBB and ●●○○●●○○○○●●○○○○○○●●) similar or different?
Jane: Similar.
I: How is it similar?
Jane: Because it is counting by 2’s. Two blacks, two whites, two blacks, four whites, two blacks, six whites, two blacks, eight whites.
I: So it is similar?
Jane: Because this one gets one bigger, ABBBBB (which was coming next to ABBBB). It is not by 2’s.

Jane recognized that the element of both patterns was increasing, and that the number of elements that were increasing was different. One pattern was increased by two whites and the
other was increased by one B. Jane identified the similarity and the difference between both patterns.

**Conclusion**

Overall, the second grade children in this study demonstrated success in extending of repeating patterns. On the other hand, over 70% children misunderstood growing patterns and did not extend them correctly. There were five categories of children’s misunderstandings of growing patterns: they extended a growing pattern as a long repeating pattern; they repeated the simplest term to extend growing pattern; they extended one or two terms correctly but children repeated the whole as a repeating pattern; they repeated one of terms; or they increased incorrect number of elements.

Children’s reasoning presents for why repeating patterns and growing pattern are different lay in their focus on the shape and the letters but not on the patterns themselves. That is, children focus mostly on the type of element. Children need to have more experiences working with patterns where the elements are varied across the dimensions of color, shape, letter, or number. With these experiences, they need to be guided to focus more on the similarities, differences, ordinal relations, and the relationship between terms rather than element type.

To connect pattern understandings with the idea of a function, children need to generalize patterns such as “it goes one A and one B” or “white grows by 2” or “B gets one bigger”. In this study, children who used copy from the start could extend patterns without recognizing of the relationship among terms. They need to have chance not only to extend patterns but also to generalize them. This will help broaden children’s patterning understanding with critical linkages to the central mathematical concepts of variable and function.

The study assessed 21 2nd grade students’ preinstructional competence in patterning activity. Over three rounds of clinical interviews, they solved tasks that addressed various aspects of patterning work. The theoretical framework uses the phenomenological notion of structural awareness (SA). Some results: (1) SA and functional thinking (FT) were not evident in numerical patterning tasks and a semi-free figural patterning task. Empirical counting was used frequently in dealing with near and far generalization tasks. (2) SA and FT were evident in well-defined figural tasks. (3) Students employed narrow specializing on the last known stage (versus specializing with the use of analogy) in dealing with far generalization.

Introduction

In the California state standards in mathematics, elementary students begin patterning work in first grade by “describing, extending, and explaining ways to get to a next element in simple repeating patterns” using “numbers, shapes, sizes, rhythms, or colors” (California Department of Education, 1997, p. 6). In second grade, they “demonstrate an understanding of patterns and how patterns grow and describe them in general ways,” which includes skills of “recognizing, describing, and extending patterns and determining a next term in linear patterns” and “solving problems involving simple number patterns” (ibid, p. 10). By the end of third grade, they should be able to “extend and recognize a linear pattern by its rules” (ibid, p. 12). In fourth grade and beyond, students pursue patterns in a variety of arithmetical, algebraic, and geometric situations. Patterns (as objects) and patterning (as a process) in third grade are also meant to introduce students to functional relationships, while patterns and patterning in the upper elementary grades involve finding and reasoning with structure (“observe patterns,” “draw patterns,” “construct patterns,” and “use patterns” to calculate and predict outcomes).

This study addresses preinstructional cognitive issues relevant to second grade students’ (ages 7 and 8 years) competence on growth patterns, numerical and figural. Currently, there is very little information about second-grade students’ conceptions of patterns prior to formal instruction. In this report, I address three research questions, as follows. Prior to a formal study of patterns:

1. What strategies do second-grade students employ in dealing with a near generalization task (stages 9 and below in a pattern)? A far generalization task (stages 10 and above)? An inverse situation task (given an outcome, find the stage number)?

2. To what extent are they capable of discerning a structure relevant to a well-defined pattern?

3. To what extent are they capable of constructing a structure relevant to a semi-free pattern?

Literature Review

In this review, I exclude findings from patterning studies done with prekindergarten to elementary students that have been drawn from design-driven teaching experiments. Briefly,
these studies (e.g.: Papic, Mulligan, & Mitchelmore, 2009; Radford, 2009; Carraher, Martinez, & Schliemann, 2008; Blanton & Kaput, 2004) provide sufficient evidence of the significance of effective mediation from different sources in helping young children develop function-based generalizations involving figural patterns. Here I focus on a few studies that assessed children’s pre-instructional knowledge of patterns.

Lee and Freiman (2004) were recently involved in a long-term study on pattern generalization involving K children (ages 5-6), Grade 3 students (ages 8-9), and Grade 6 students (ages 11-12) in a French Montreal private school. When patterning tasks were presented to each cohort, the 35 K children were simply asked to extend the patterns, while the 31 Grade 3 participants had to obtain the answer for the 10th stage and the 23 Grade 6 students were required to obtain a generalization. Findings with the K children show success in extending repeating patterns but not so in the case of growing patterns. They had difficulty transitioning from repeating to growing patterns or at least failed to recognize one from the other unlike the Grade 3 cohort. Also, a few other K children interpreted patterns as repeating with the three given stages as the repeating unit, while two other children tried to “correct” patterns when the numerical dependent values are, say, nonconsecutive. The authors note that “(i)t is difficult to compare K and Grade 3 students on the criteria of continuing their growing patterns. Although a couple of patterns seem to be of comparable complexity, the K children had the added obstacle of having to make the abrupt leap from repeating to growing patterns. If we had accepted the solutions of children who continued to treat all patterns as repeating ones, they would have performed as well or better than the Grade 3 group” (p. 248).

Mulligan and Mitchelmore (2009) tested 103 Australian Grade 1 students (ages 5.5 to 6.7 years) on 39 items that focused on patterns and structures. Results indicate the existence of at least four stages of structural development, namely: prestructural; emergent; partial structural, and; stage of structural development. The authors also saw that the level of a student’s structural development seems to be determined by the complexity of a patterning task.

When 45 Australian Year 2 students (mean age of 8.5 years) in Warren and Cooper’s (2008) study were (pre-)tested on three pattern tasks, many students had difficulty continuing and creating figural growth patterns. When they were asked to describe a general rule in relation to a pattern task that had a rate of change of 2 units, the most frequent response (49%) is that the pattern “grows in twos” or “goes up by two, one more on each end,” followed by a no response (27%), and then the general response, “it grows” (13%).

Billings, Tiedt, and Slater (2008) collected data from 8 US students in Grades 2 and 3 through two separate clinical interviews with an intervening teaching experiment. Prior to formal instruction, the children manifested covariational generalization process that had three levels, as follows: 1-analyzing change between consecutive figures; 2-using previous figure to build a new, and; 3-identifying what stays the same and what changes. Level 3 was difficult among students especially in cases when visual patterns were complex.

Stacey’s (1989) study probed 371 Australian students (Years 4 to 6, ages 9 to 11) on linear pattern generalization tasks that were given to them near the end of the school year. With respect to the 82 Year 4 students, her data shows a decrease in their ability to obtain generalizations for a particular well-defined pattern from the 12th stage (59% correct) to the 20th stage (33%) and then to the 1000th stage (17%). Counting was used quite frequently as a strategy in obtaining a value, but in most cases it produced incorrect answers. The other strategies use multiplication, which is not relevant in this study and, thus, omitted. Stacey notes that “(t)he overall impression from the responses of the primary school students was that the children were not reluctant to generalize,
but rather that they constructed the generalization too readily with an eye to simplicity rather than accuracy” (p. 153) and that there was a “willingness to grab at relationships without subjecting them to scrutiny” (p. 163).

The three research questions stated in the preceding section address crucial issues in the second grade mathematics curriculum in the US and in other countries, for that matter, when young children’s understanding of structures is being extended from repeating to (linear) growth patterns. Also, considering the well-established research knowledge base on pattern generalization at the middle school level (see Rivera (2010) for a synthesis account), it would be interesting to assess elementary students’ competence in various aspects of pattern generalization that researchers have found valuable to investigate in the upper grades with older children.

**Theoretical framework**

In this study, I use the phenomenon of awareness of, or attention to, structure in making sense of young children’s capacity for structural thinking. Mason, Stephens, and Watson (2009) define a mathematical structure of, say, a set (of objects, of relations, etc.) as consisting of general properties that are instantiated through relationships between and among particular elements in the set. Structural thinking does not involve merely recognizing a relationship that exists as it is primarily about having a “disposition to use, explicate, and connect these [general] properties in one’s mathematical thinking” (p. 11). There is, thus, a difference between recognizing a relationship between elements in a set, which is a tendency to dwell in the specific and particular, and perceiving general properties as being instantiated in particular situations relative to the set being investigated. Mason et al’s awareness of, or attention to, structure captures this particular sense of structural thinking in which the focus “lies” in one’s “experience of generality, not a reinforcement of particularities” (p. 17). In more practical terms, learners manifest awareness of or attention to structure when they begin to focus on, say, what stays and what changes – that is, “becom[e] accustomed to considering invariance in the midst of change” (p. 13). Mason et al also use their notion of structural thinking in making a distinction between empirical counting and structural generalization, which have implications in how we can interpret young children’s actions relative to some patterning task, that is, it is interesting to know whether they perform such actions to basically obtain and generate a sequence or to become aware of an underlying structure.

**Methodology**

*Participants, Access, and Relevant Background Contexts*

Twenty-one 2nd grade students (7 girls, 14 boys; 20 Hispanic-Americans, 1 African-American; mean age of 7.5 years) participated in the first two of three clinical interviews. One student (a girl) moved to a different school, leaving twenty children who participated in the third clinical interview. On the basis of periodic district assessments, the previous year’s data on 18 of the 21 students indicate that 10 of the 18 were above and at first-grade standards. The remaining three students came from different school districts. On the basis of the first benchmark conducted this year, only one was above standard.

The three clinical interviews were conducted over five months with about a month separating each interview. A graduate student conducted the interviews in my presence. Because there were issues that came up as a result of a preliminary data analysis on the first interview, we (graduate student and myself) were permitted to conduct a second interview with the same graduate student conducting the interviews. A third interview then took place, which addressed various gaps in
our preliminary data analysis on two earlier interviews. All interviews took place outside of math time. During the one-hour math time, which was daily, we were in class doing collaborative work with the two Grade 2 teachers. Also, I needed to make sure that the children were familiar with us so they would feel comfortable during the interviews.

**Interview Protocol and Data Collection and Analysis**

Each individual interview lasted between 15 and 20 minutes. The students were asked to think aloud and to write their answers on a construction pad. A number line was provided for them to use during the first round of interviews, which was not used in the second round since they could exhibit facility with the addition algorithm. Concrete objects were always provided. Videotaped interviews and their written work were collected. I kept a log that contained my ongoing data analysis. Data analysis followed a grounded theory framework, which I have used in all my published work (see, for e.g., Rivera 2010) as follows: an analysis template was set up for each task; individual student responses were categorized accordingly; emergent themes were then established and empirically verified with the construction of case studies and relevant transcripts drawn from the interviews.

**Results**

**First interview**

**Tasks.** Three tasks were presented to the students. In the first two tasks, three puppet dogs and plastic model zebras were shown one at a time and they were asked to determine the total number of eyes in the case of dogs and legs in the case of zebras. Then they were asked to figure out the number of eyes and legs in the case of 4, 5, and 6 dogs and zebras. Next they determined the number of eyes and legs for 10 and 20 dogs and zebras, respectively. Finally, they solved inversion problems that involved determining the number of dogs and zebras when 17 eyes and 21 legs were known instead. With the two inversion tasks, I was interested in how they interpreted the “odd” values. In the third task, they were presented with the semi-free pattern task in Figure 1 with the intent of identifying the kinds of structures they were capable of developing at their level.

**Results.** Table 1 shows the frequencies of responses relative to the first two tasks and the strategies they used in dealing with the near and far generalization and inversion tasks. Results indicate their disposition toward using a count-all strategy from stage to stage, their difficulty in employing a count-on strategy from the preceding to the succeeding stage, and the absence of any other sophisticated arithmetical counting strategies. A combination strategy involves using two or more counting strategies. For example, in dealing with the total number of eyes in the case of 20 dogs, Sammy first counted on “2, then 4 plus 2 is 6, plus 2 is 8, …, plus 18 is 20” and

![Figure 1. A Semi-Free Task](image-url)

---

then used the number line to count to 40 from 20. In dealing with 6 dogs, Carl began with a count-on strategy in the case of 2 to 5 dogs but shifted to a count-all strategy in the case of 6 dogs (“1, 2, 3, 4, …, 12”). In dealing with the total number of legs in the case of 4 zebras, Manuel initially skip counted by 4s (“4, 8”) and then counted by 1s (“9, 10, 11, …, 16”). Overall, they had greater success in dealing with the far generalization task relative to the dogs pattern compared with the zebras pattern. The inversion task was difficult for most of them. Those who drew circles and sticks (representing eyes and legs, respectively) but did not group by 2s and 4s were unable to determine the correct number of dogs and zebras.

Table 2 shows the frequencies of responses relative to the third task and the extensions on the basis of the first two given stages. None of them offered a structure for the semi-free pattern. All of them ignored step 1. The ten students who decided 4, 5, and 6 circles to be plausible extensions relied on the successor notion of whole numbers (“after 3 comes 4, then 5, then 6”). None paid attention to the shapes of the two given stages. When they were asked them to determine what stayed the same and changed from one step to the next, none saw any kind of change. None could deal with the far generalization task.

Discussion. In all three tasks, none of them manifested structural awareness. Skip counting was not employed efficiently beyond single-digit cardinalities. While this observation might not be novel, what is interesting is the level of empirical counting strategies they employed in dealing with near and far generalization tasks. Their predisposition toward counting all (from stage to stage) versus counting on (from a current stage to the next) actually distracted them from attending to, or developing an awareness of, some structure that might have allowed them to successfully deal with both the far generalization and inversion tasks. Counting all prevented them from structurally thinking in terms of (equal) groups. It is also interesting to note how their ability to perform far generalization appears to depend on group size, that is, the students failed to deal with the far generalization task with zebra legs than with the far task involving dog eyes. Finally, relative to task 3, none of the students: (1) offered a repeating sequence of two objects, a first-grade skill, and: (2) manifested an “illusion of linearity,” in which growth is perceived to be
linear and, thus, underdetermining the given values. Most of them specialized on the second stage without connecting their extensions to the first stage of the semi-free pattern.

**Second interview**

*Tasks.* Five tasks were presented to the students, but only four are discussed in this report due to space constraint. After more than six weeks of daily instruction, I wanted to assess possible changes in their counting strategies relevant to the first two tasks, that is, the dogs/zebras pattern. Also, drawing on the thinking of the five students in the first interview who were successful with the two inversion problems, I wanted to assess if providing all of them with drawn pictures of dog eyes and zebra legs might encourage them to focus on counting by groups. The third task was a slightly modified version of the semi-free task shown in Figure 1. Instead of two initial stages, they were given three initial stages in a growing L-shaped pattern. On the basis of the Table 2 results, I wanted to assess whether they needed a minimum of three initial stages to be able to recognize and construct a structure for some pattern of their making. Two additional tasks were added. The fourth task involves assessing their ability to “guess a rule.” In this task, they were presented with a magic paper so that: when 1 circle has been placed under the paper, 4 circles came out; 2 circles under the magic paper produced 5 circles; 3 circles yielded 6 circles, and 4 circles produced 7 circles. They were then asked to predict what would happen when 5 and 6 circles were placed under the magic paper and to describe the effect of the magic paper in a general way.

*Results.* Table 3 shows the results in relation to the dogs and zebras tasks. More than half employed count on, skip counting, and combination strategies in dealing with both near and far generalization tasks. Examples of a combination strategy are as follows. Dexter, in obtaining the total number of eyes for five dogs, saw that there were initially three puppet dogs on the table. He then lined them up vertically and saw “3+3.” Then he counted on 2 eyes, giving him 8 and finally “10 eyes” for five dogs. In Zena’s case, she counted “3, 6, 7, 8, 9, 10,” which combines skip counting by 3s and count on. In dealing with ten dogs, Juan used a doubles strategy (“10 + 10 equals 20 eyes”).

Table 4 shows the sequences generated by the students. Again, most of them ignored the first two stages and specialized on the third stage to generate the succeeding stages. Only two students gave some indication of structure. Dexter produced a growing L-shaped pattern by adding two squares (row and column). When asked to determine stage 10, he reasoned by saying “there are 10 across and 10 up.” Gerry’s pattern of a few stages is as follows: “1, 2+1, 3+2, 4+1, 5+2, 6+1, 7+2, 8+1.”

In Table 5, none of the students articulated “adding 3.” Eight of them generated the correct dependent values 8, 9, and 10 circles in cases 5, 6, and 7, respectively. But when asked to explain the dependent values, they all relied on the fact that since the dependent terms 4, 5, 6, and 7 were consecutive numbers, the next number in the sequence would be 8, followed by 9, and then 10. Mig claims, “we are plusing it by the ones.”

Discussion. Comparing Tables 1 and 3 on the same two numerical tasks, while there was a significant change in students’ empirical counting strategies, there still was no evidence of structural awareness. Also, even when they were provided with drawings of eyes and legs, must still could not solve the two inversion problems even when the outcomes were even. This failure might be attributed to the fact that they still do not have a facility for grouping objects. Comparing Tables 2 and 4, providing three initial steps that suggested a structure in a semi-free task still did not help. Except for two students, most of them specialized on the third stage in order to generate the dependent terms after the third. Results of Table 5 indicate their inability for functional thinking in the context of a numerical task. Instead of seeing a relationship between an input and an output, they focused on the dependent terms despite repeated probing from the interviewer about the effect of the magic paper relative to each input.

Third interview

Tasks. Three tasks were presented to assess if they could discern a structure for patterns with “more familiar” features than the semi-free task used in the first two interviews. Figure 2 shows the three tasks and in each case they were asked to use pattern blocks and circle chips to determine stages 4 and 5 and then to describe stage 10 in ways other than using the blocks and chips.

Figure 2. Well-defined Pattern Tasks (HP and SP taken from Greenes et al, 2001, p. 79)
Results. In Table 6, their responses were initially categorized according to degree of structural awareness (SA). Relative to the three tasks, when they exhibited SA, it meant they attended to both shape and count on the basis of their success in both near and far generalization tasks. Having a partial SA meant they attended to either shape or count, and no SA meant a relative inability to discern a structure in both shape and count. Table 7 reports frequencies of those students who had SA.

</tbody>
</table>

In Table 6, among those who exhibited partial SA relative to the HP and SP, they were primarily influenced by how they saw the “general” shapes of the patterns. Some ignored the first two stages and began to specialize on the third case, which led to a new pattern. For example, Nikki initially interpreted stage 3 of the TP to be consisting of two groups of 3 circles. Hence, her stage 4 had two groups of 4 circles, stage 5 had two groups of 5 circles, and stage 10 had two groups of 10 circles. Damien interpreted stage 3 of the TP as $3 + 2 + 1$, so his stage 4 had $4 + 3 + 1$ circles, stage 5 had $5 + 4 + 1$ circles, and stage 10 had $10 + 9 + 1$ circles. Soraya interpreted stage 3 of the TP as a triangle with a “base” of 3 circles and two growing side lengths. Thus, her stages 4 and 5 resembled triangles having a stable base of 3 circles and the two adjacent sides growing according to stage number. In the case of the SP, Jomer saw a monster with teeth and fangs. So his stages 4, 5, and 10 had two pairs of fangs, two triangles at both ends of squares (“teeth”) that grew by the stage number. In the case of the HP, six students saw houses but paid attention only to the number of rooftops (triangles) that grew by the stage number.

Those who exhibited no SA disregarded what they saw and resorted to guessing. For example, relative to the TP, some constructed circles, a fish, and rectangles from stage 3 and did not assess the corresponding cardinalities for pattern consistency. In Table 7, of the 12 who manifested SA relative to the HP and SP, all of them drew stage 10 on paper. In the TP, Juan was the only one to successfully discern a triangle structure that followed the sequence of triangular numbers (1, 3, 6, 10, 15, 21, …).

Discussion. Consistent with the findings on the semi-free task (Tables 2 and 4), many of them employed narrow specializing on the last known stage when confronted with what they perceive to be a complex pattern. Those with SA who obtained correct far generalizations in the case of the HP and SP coupled specializing with the use of analogy. From the videotapes, this coupling was present in eye-tracking gesture when their eyes began to move from stage to stage, indicating inspection of cases, followed by a pause before finally constructing the tenth stage. In the case of complex patterns, those who engaged in narrow specializing oftentimes became fixated with the third case at the expense of the prior stages. Considering all the tasks given to the students in all three interviews and the data results, it seems that they had more difficulties with numerical than figural patterning tasks. This could be attributed to their lack of more sophisticated arithmetical strategies for counting objects beyond count-all. In the third interview, those students who exhibited partial SA discerned shape structure globally without paying attention to shape details, which affected how they constructed the succeeding stages. Finally,
among those students who exhibited SA, their primary mode of expressing a far generalization is more visually (drawing) than verbally oriented. Furthermore, while no explicit symbolic responses (i.e., use of variables) were offered, their incipient generalizations exhibited early manifestations of functional thinking in the context of figural tasks.

References
This article reports on the results of research whose objective was to document and analyze the manner in which students relate different representations when solving problems. A total of 20 students took part in the study, students attending their first year of university studies. In order to design the problem, the underlying information in each representation was deemed to be the starting point of different inferences and of different cognitive processes. The findings obtained make it possible to assert that the underlying information in each representation is not visible to all students and that a problem can foster handling of different representations, the making and verifying of various conjectures and the transfer of knowledge acquired in previous courses.

Introduction

A consensus seems to exist among researchers in mathematics education with respect to the importance of relating different representations of a mathematical concept in order to attain the solution to a problem. One example of this is that when students solve a problem that involves the concept of function, they draw a graph or build a table of values to represent it. From the graph or the table it is possible to obtain the information relevant to the function, which can then be employed so as to arrive at the solution of the problem.

Parnafes and Disessa (2004) have expressed themselves along such lines. On the one hand they indicate that student reflections are tied to the representation and context that they are using. They further state that each representation either highlights or hides aspects of a concept, and that when the students use several representations they develop a more flexible understanding of the concept (p. 251). While on the other hand, the same authors state that the relationship among different representations also provides information regarding the cognitive processes of the students in the problem solving process. The underlying information in each representation is the point of departure of different inferences and, consequently, of different cognitive processes (p. 252). The latter idea is the starting point of the research reported on here, which was undertaken with students attending first year of university. The objective of the research is to document and analyze the manner in which the students relate different representations while solving a problem.

Theoretical Framework

Since the relationship that exists among representations is the core of the research reported on here, the authors of this article believe it is advisable to clarify that in this document the term “to relate representations” is used in the sense of Goldin and Kaput (1996). The foregoing authors point out that “a person relates representations when he is able to integrate his cognitive structures in such a way that given an external representation, the individual is able to predict or identify its counterpart” (p. 416). Several authors (Duval 1988; Parnafes & Disessa, 2004; and Goldin & Kaput 1996) stress the relationship among representations as an important element in stimulating reflection in students. In particular terms, Parnafes and Disessa (2004) refer to use of varying representations in two different ways, to wit: a) use of representations in order to achieve
greater understanding of a concept; and, b) use of a representation in order to promote cognitive processes, such as abstraction and generalization.

Use of Representations in Learning a Mathematical Concept

As regards use of representations in comprehension of a concept, Duval (1988) mentions that each representation underlies information concerning the concept. As an example, he alludes to the case of a function represented by a line, in which he indicates that the relevant elements are the direction of the slope of the line, the angles that the line forms with the axis and the position of the line with respect to the origin of the vertical axis. Duval (1988), associates each visual variable with a meaningful unit in algebraic writing. The direction of the line’s slope is related to the sign of coefficient X in the expression y=ax+b; the angle formed by the line’s intersection with the axis, to the absolute value of parameter a; and the position of the line with respect to the origin of the vertical axis, to the value of b. According to Duval (1993) adequate knowledge of a concept is considered the invariant of multiple semiotic representations of the concept and it is accomplished when a student skillfully handles changes between representations.

Use of Representations to Make the Cognitive Processes of Students Visible

Parnafes and Disessa (2004) explain that each representation provides specific information and promotes certain cognitive processes. For instance they document the work of students within a computer-aided learning environment in which two representations are used. The first is a representation that simulates the movement of two turtles, while the second is a number representation made up of two lists of values, one of positions and the other of speeds. The two representations characterize the same structure –movement of two objects- yet each one is the starting point of different cognitive processes (p. 252). Based on their analysis of the data, the authors identify two types of reasoning. In one the students arrive at the solution by assigning a value to each variable in the problem, ensuring that all of the restrictions are complied with. In the other, the students create a mental model of the movement of the turtles and analyze those images in order to infer qualitative descriptions from those images.

Digital Technologies and Representations

One can also identify studies that refer to the role of digital technologies and their contribution to having students relate representations. In this respect Goldin and Kaput (1996) state that digital tools, the likes of computers, provide resources for an individual to relate representations. The foregoing is achieved when based on an action in an external representation, the subject is able to predict and identify the results of that action in another representation.

As mentioned by Parnafes and Disessa (2004), each representation is associated with specific information. The problem reported on in the latter document was redesigned so that in addition to using verbal and iconic representations, the students also build a table of values. Usage of an electronic spreadsheet (Excel) can be very useful in this type of activity. Wilson, Ainley and Bills (2004) identify three characteristics of these spreadsheets that may help students to make generalizations and to gain a better understanding of the variables, as follows: a) analysis of the calculations, b) use of notation, and c) the possibility of feedback.

Since the students had used an electronic spreadsheet in three previous activities, there were minimal technical problems related to use of the software and such problems are not cause for thought in this document. Having said this, we would not like to detract from the importance of the role of digital technologies in student reflections.

Subjects, Methods and Procedures

The research was carried out with 10 pairs of first year university students. The activity reported on here was undertaken during two sessions of one hour and one half each. The sessions were videotaped and the students submitted their work both in writing and in electronic files.

The Problem: The Triangular Stack of Boxes

The problem is proposed by Bassein (1993). It consists of determining how the quantities in a sequence of steps change and of identifying that from the very first step a relationship among the quantities is maintained.

The problem was presented to the students in the following manner:

a) Determine the number of boxes needed to form a stack of a given height.

In this problem the boxes are rectangular and are all the same size. The height of the stack will be measured in terms of the number of levels in the stack. For example, a stack made up of three levels will have a height of 3.

b) You can begin your explorations by drawing stacks made up of different levels.

c) Write down in a table the number of levels and of boxes needed in each drawing.

Two representations are referred to in the problem wording: verbal and iconic. The instruction provided under clause c) suggests to the students that they should make drawings and write down the values represented by different triangular stacks. The clause was included in order to guide the work of the students toward using a numerical representation, and having them prepare a table of values that included the variables of levels and boxes. This was done re-broaching the ideas of Parnafes and Disessa (2004) who indicate that tables of values contribute to facilitating identification by students of patterns and regularities among the series that make up the table, and that they are the basis of particular cognitive processes.

The table of values suggested in clause c) was also included with the intention of orienting the work of the students toward using an algebraic representation. It is important to mention at this point that to obtain a mathematical model that makes it possible to determine the number of boxes needed to build a stack of a given height, it is indeed advisable to work with an algebraic representation.

The students worked on the problem during two sessions. A detailed analysis of their work was subsequently undertaken and this analysis provided information on the manner in which they related the variables present in the problem and the manner in which they developed a mathematical model to represent the relation between them. The actions carried out by the students were followed very closely, paying special attention to their handling of representations.
The questions outlined below arose from the analysis of the data, questions that are the focal point of this document:

- What information do the students obtain from each representation that they use while solving the problem?
- In what manner do the students relate different representations?

Upon analyzing the data, evidence was identified that enabled us to respond to the questions. The manners of relating representations arose and are exemplified with the work of three students: Carlos, Luis Miguel, and Leonardo. The work of the three foregoing students is representative of the work carried out by the remainder of the group. The data used below come from different sources. Brief episodes of the videotaped sessions were taken up again, hence the actions and gestures are explained in parenthesis and pauses are indicated by use of ellipsis.

**First Manner. Carlos Related Verbal, Iconic, Numerical and Algebraic Representations.**

Carlos read the wording of the problem (verbal representation), drew stacks containing different levels (iconic representation) and carried out a numerical exploration (numerical representation). The instruction to draw stacks with different levels was a contributing factor in his being able to identify a relationship between the height of the stack and the number of boxes in the base level, as is shown in the following episode:

Carlos: …so, analyzing the problem you gave us, the base is equal to the height sought; so we have … if the base is two we add two plus one, then if we have a height of seven, the base is seven.

The drawings done together with the numerical exploration also contributed to Carlos’ ability to identify that the total number of boxes needed to create a stack of a given height was equal to the sum of the number of boxes in the base, plus the number of boxes in a stack with one level less, as he explained to the group:

Carlos: … if its height is seven, its base is seven. So finding the total number of boxes is seven, plus six, plus five, plus four, plus three, plus two, plus one (He places his hand in a horizontal position and raises it to indicate a different level in the stack each time he adds; seven, plus six, plus five, etc.)

The explanation provided by Carlos attests to his having associated the total number of boxes with an expression that enabled him to calculate the sum of the natural numbers from 1 to n. Carlos was already familiar with this expression.

Carlos: I don’t know if you remember, but this formula was given to us by our Physics professor when he asked us what the sum of one though one hundred was. And that was when he gave us the formula, (writes the formula on the whiteboard) Figure 2.

---

*Figure 2. Carlos writes a formula on the whiteboard*
Carlos: So to find the total number of boxes, the base is seven, plus six, plus five, plus four, plus three, plus two, plus one, in other words, all of its previous numbers, and thus we have the formula (writes the formula on the whiteboard), \( n \) is the number of levels.

With a few examples, Carlos checked that the formula worked to calculate the number of boxes needed to create a stack of a given height. It is important to point out here that it was not simply a matter of his having memorized a formula; the explanation he gave his classmates and what he wrote down on the whiteboard confirm that he had established a relationship between the numerical representation of the sum of the natural numbers from 1 to \( n \), and the algebraic representation that corresponds to that sum, as can be seen in Figure 2. What is more, Carlos was able to transfer the information he obtained from working with the verbal, iconic and numerical representations to a new context.

Second Manner. Luis Miguel Related Verbal, Iconic and Numerical Representations

Luis Miguel began his exploration on a sheet of paper, in which he represented particular cases. It is noteworthy to mention that unlike Carlos, Luis Miguel counted the number of boxes needed to obtain a stack of a given height. Apparently he did not consider the number of boxes needed to create a stack with one level less. Figure 3 depicts Luis Miguel’s drawings, submitted in his written report, where he has one stack made up of six levels with twenty-one boxes, one stack made up of seven levels with twenty-eight boxes.

In the episode included below, Luis Miguel explains to his classmates how he went from the wording of the problem (verbal representation) to the drawings of stacks containing different levels (iconic representation), from which he obtains the information needed to build a table of values (numerical representation).

Luis Miguel: I created a table in Excel (inaudible) and by levels I started with zero …
Researcher: You worked directly in Excel?
Luis Miguel: No (inaudible) first on a sheet of paper (points with his hand to the shape of a triangular stack).

In figure 4, Luis Miguel explains the manner in which he developed a table of values on the electronic spreadsheet. As can be seen during his explanation the student used Excel syntax.
Figure 4. Luis Miguel explains his work with an electronic spreadsheet

The episode outlined below includes a transcription of Luis Miguel’s participation, and represents evidence that the numerical representation contributed to his identification of a relationship among the values in the table. The relation enabled him to determine the number of boxes needed to build a stack of a given height. Nonetheless the operation that he proposes, $B4 + A4 + 1$, which corresponds to adding the number of boxes needed to create a two-level stack, plus the number of boxes in the base level of that stack, plus one, makes it possible to infer that Luis Miguel did not identify the same relation as Carlos did. Carlos pointed out: if its height is seven, its base is seven.

Luis Miguel: For one level it’s one box: for two levels, 3 boxes... And what I did was: add the two previous ones, plus 1; for example, for 3…, (He writes the formula $=B4+A4+1$, and using it he calculates the number of boxes needed to create a three-level stack).

Luis Miguel: So I would be left with three plus two is five, plus one is six. And that’s the way I would fill it in up to 50.

In order to encourage Luis Miguel to reflect upon the fact the expression he had come up with only worked in particular cases, the researcher intervened as follows:

Researcher: And what about if you have a stack made up of 75 levels?
Luis Miguel: I would have to make the list all the way down to 75.
Luis Miguel: The formula depends on the whole list (Moves his hand upward to indicate the previous numbers in the table).

Luis Miguel found a relation based on his analysis of particular cases, but he was unable to find a general expression to determine the number of boxes needed to build a stack of a given height.

Figure 5. Excel table built by Leonardo

**Third Manner. Leonardo Related Verbal, Iconic, Numerical and Algebraic Representations.**

Leonardo initially worked with the verbal representation, then changed to the iconic representation and drew stacks with different heights. From his analysis of the figures, he obtained information that he used to build a table in Excel. Figure 5 shows the table he built. Column 1 indicates the number of levels, while column 2 indicates the number of boxes.

The numerical exploration undertaken by Leonardo in the table facilitated his ability to identify relations between number of levels and number of boxes variables. The extract provided below portrays the analysis he carried out and the explanation he gave to his classmates.

Leonardo: The way I solved it is you have levels and numbers of boxes: for one level, one box; for two levels, three boxes; then for three levels, six boxes. And here what I found was that this quantity of boxes (Points to the value three in the number of boxes column) is equal to the sum of the previous [level] (Points to the value one in the number of boxes column), plus the number of levels that you want to have (Points to value two in the number of levels column).

The work done subsequently by Leonardo was divided into two sections. In each section one can identify a relation between the number of boxes and number of levels variables.

**First Relation Established by Leonardo**

In the extract provided below, Leonardo proposes an expression to obtain the number of boxes needed to create a stack containing n number of levels.

Leonardo: I found that the number of boxes is equal to the number of levels that you want to have, plus the number of boxes that you had before, and that gave the result. So I applied the formula to calculate them, equal to … (In Figure 6, he has drawn a table on the whiteboard and uses Excel syntax) cell B2 + A3 and it gives me a result of 6. So then I just copy and paste (Uses Excel-related language, copy and paste)

![Figure 6. Table built by Leonardo](image)

Leonardo identified that the number of levels in each stack coincided with the number of boxes in the base, he then used that relation to determine the total number of boxes in each stack.

**Second Relation Established by Leonardo**

Leonardo obtained the total number of boxes by adding the number of boxes needed to create a stack with one level less, plus the number of levels from the next stack. In the episode transcribed below Leonardo explains that in order to obtain the total number of boxes, it is necessary to build a table with a consecutive number of levels.
Leonardo: The consecutive continued to be maintained (Points to the column with the number of levels), but when there was a later one, from 2 to 7 for example, then it didn’t give the result, it didn’t work. I agreed that this result was correct for consecutive stacks that increased one by one.

Leonardo: So I began to investigate what relation existed between those two columns (Point to the number of levels and number of boxes columns), and thought that this result was a function of this number, with something that could be a sum with something or the product of something, and so I ended up dividing this column (Points to the number of boxes column) by this one (Points to the number of levels column) and found that this was the result (Added an additional column, and writes down the result of the divisions).

Leonardo: I divided B1 by A1 (Divides the number of boxes by the number of levels) which gives me one, then one point five, then two, then two point five, and so on and so forth, point five more each time.

Leonardo wanted to determine a formula that related the number of levels (column A) with the results of quotients (column C), so as to obtain the number of boxes without having to depend on previous results.

Leonardo: And then I began to investigate what relationship existed between column A and column C. I knew that the values in column C times the values in column A give the values in column B.

Leonardo: I cannot depend on these results (Points to the values in column B) because that is the result I want to arrive at. So what I did was to see what the relationship between column A and column C was …And I found that it was 3; number of levels divided by 2 plus 0.5; then he does calculations for the remaining values in the table.

Leonardo: So to be able to arrive at that result, I inputted in the cell the same number as the number of levels, say A1 over 2 plus .5, all of this times A1, and that way it no longer depends on the result of B. So… (He calculates a result for a 10-level stack).

\[
\left(\frac{10}{2} + 0.5\right)(10) = 55
\]

In Figure 7 one can identify the operations that Leonardo carried out in Excel.

Figure 7. Table built by Leonardo in Excel

Conclusions

From our analysis of the data, we were able to find evidence that makes it possible to respond to the questions raised in this document. Each representation provides specific information concerning the problem. The underlying information in each representation is not visible to all of the students, as can be seen in the work of Luis Miguel and Leonardo. The problem put to the students triggered usage of different representations, the making and verification of conjectures, as well as the transfer of knowledge acquired in previous courses, as can be seen in the work done by Carlos.

Use of the numerical representation, which was suggested in the wording of the problem, was a contributing factor in enabling the students to identify regularities and relations among the variables—number of boxes and number of levels—in the manner pointed out by Parnafes and Disessa, (2004). The language used by Carlos and Leonardo provides proof that they kept the context of the problem in mind at all times. The written reports submitted by Luis Miguel, as well as his participation, enable us to infer that he did not relate the numerical representation with the wording of the problem and the figures of the stacks, even when he proposed an expression to calculate the number of boxes needed to build a stack.

CLASSROOM PRACTICES THAT LEAD TO STUDENT PROFICIENCY WITH ALGEBRAIC WORD PROBLEMS

Jerilynn Lepak  
Michigan State University  
lepakjer@msu.edu

Jamie Wernet  
Michigan State University  
wernet@msu.edu

This study focuses on mathematics classroom practices that result in students’ proficiency with word problems in algebra. Our goals are to produce a deeper understanding of “teaching for mathematical proficiency,” research tools for the study of teaching for robust mathematics learning, and practical tools that can be used on a large scale for benchmarking and improving teaching practice. Word problems are central to mathematical proficiency because fluency in solving them demands a wide range of sense-making, modeling, representational, and procedural skills. Specifically, we explore the following two questions: (1) What instructional practices are frequently used by teachers judged to be doing an exceptional job of helping students to develop proficiency in solving word problems? (2) What analytic procedures can be used to characterize these promising teaching practices, with low enough cost so that connections between teaching and learning can be examined for a large number of classrooms?

Project activities the first year have included: (1) analysis of existing classroom observation schemes (including, e.g., IQA (Junker, et al., 2005) and CLASS (Pianta et al. 2006); (2) identifying tasks to assess students’ robust mathematical understanding related to solving algebraic word problems; (3) interviewing students as they work on these tasks; (4) developing and refining a new analytic system for observing mathematics classroom instruction. In developing our analytic system we are considering multiple analyses, at varied levels of grain size – from the establishment of classroom norms (Horn, 2008; Yackel & Cobb, 1996) to the detailed study of turn-by-turn classroom exchanges (Schoenfeld, 2002) – to identify mathematically productive classroom practices and related student understandings.

ELEMENTARY STUDENTS’ USE OF REPRESENTATION IN DEVELOPING GENERALIZATIONS

David Barker  Labab Cross  Chepina Witkowski  Laura Fisher
Illinois State  Illinois State  Illinois State  Illinois State
dbarker@ilstu.edu  ljcros2@ilstu.edu  jgwitko@ilstu.edu  lafishe@ilstu.edu

Representation is a critical component in the process of generalization. Unfortunately, the interpretations and development of representations in the minds of students may differ, as each mathematics learner “must progress from idiosyncratic and ad hoc representations of particular problems to conventional, abstract, and general representations that function for a class of problems” (Smith, 2003, p. 264). Of particular interest are internal and external representations. Goldin and Shteingold (2001) state, “the interaction between internal and external representation is fundamental to effective teaching and learning” (p. 2). However, the interaction between the internal and external can lead students to internalize instruction differently, leading to a variety of misunderstandings. The aim of this study is to describe the interaction between external and internal representations and how this interaction influences students’ ability to generalize.

The study focused on 16 elementary students. Each student was videotaped as they worked a generalization task; a researcher prompted them for their thinking. Data relating to the students’ use of representation were coded into the following categories: External Contextual, External/Internal Contextual, Internal/External Contextual, Internal Contextual, and Procedural. Schematics were developed to chronologically track the use of these representation categories during the generalization process. These charts were retrospectively analyzed for patterns of representation use.

Several patterns were found: (1) when students recognized an error, or become uncertain of their results, they often returned to a more external level, (2) students who progressed quickly to an internal representation were more likely to develop misunderstandings and discrepancies among their representations, and (3) errors, recognized or unrecognized, were commonly linked to a mismatch between internal and external representations. One of the major obstacles faced by the students in our study during the generalization process was the transition from external to internal representations. This ability to successfully transition between internal and external representations, and the use of context for this purpose, are paramount to the development of efficient generalizations.

FROM THE LABORATORY TO THE CLASSROOM: DESIGNING A RESEARCH-BASED CURRICULUM AROUND THE USE OF COMPARISON

Courtney Pollack
Harvard Graduate School of Education
courtney_pollack@mail.harvard.edu

Jon R. Star
Harvard Graduate School of Education
jon_star@harvard.edu

Substantial research on cognition and its development support the benefits of comparison for learning (e.g., Loewenstein & Gentner, 2001; Namy & Gentner, 2002). Grounded in this body of work, recently, building on existing laboratory studies, we have been engaged in small-scale experimental classroom studies to explore the benefits of comparison for students’ learning of mathematics, focusing on equation solving (Rittle-Johnson & Star, 2007, 2009). Our goal has been to transform a body of research emerging from the psychological literature into usable, palatable, and effective materials for use in the classroom, bridging the gap between experimental lab-based research and classroom practice.

The central focus of our curriculum is a “worked example pair,” a one page, side-by-side presentation of two problems that differ either by problem type or solution method. The worked example pairs serve as a medium to facilitate students’ comparison of and reflection on multiple strategies.

This poster shares the development process and decisions we made concerning several aspects of our curriculum, including the scope of our materials within the Algebra I curriculum; the “types” of worked example pairs included; adaptation of our laboratory research materials for classroom use; flexibility in instructional formats; student engagement with the materials; and differentiation, homework, and additional discussion support.

The creation of our comparison curriculum represents the first step in an iterative development process. Both initial refinement and pilot testing of our curriculum are in progress; the curriculum is being tested for efficacy as well. As we look ahead to further iterations, we will continue to consider questions regarding the nature of research-based curricula and curriculum development more generally.

ILLUMINATING INEQUITABLE LEARNING OPPORTUNITIES UNDERLYING EFFECTIVE COLLABORATIVE PROBLEM SOLVING IN ALGEBRA

Jose Francisco Gutierrez
University of Berkeley
josefrancisco@berkeley.edu

A thematic objective of mathematics-education researchers focusing on algebra content is to develop theoretical frameworks that account for students’ difficulty with problem solving. Yet while these frameworks are being developed, the national achievement gap is increasing, even amid calls for equity in mathematics education and, in particular, to improve the accessibility of algebra content for students from minority groups and economically disadvantaged backgrounds.

Radford’s (2003) semiotic–cultural approach theorizes mathematics learning as the personal construction of meaning for canonical semiotic artifacts (e.g., algebraic symbols such as the variable “x”) through authentic discursive utterance. By repeatedly expressing their presymbolic notions in available semiotic means of objectification, students build personal meaning for the mathematical notation and develop procedural fluency. Specifically in pattern-finding problems, students solve by progressing through factual, contextual, and symbolical generalizations.

Figure 1. Two collaborating students’ utterances over 28 minutes, by semiotic mode.

I propose an elaboration on the semiotic–cultural approach that enables researchers to delve into cognitive planes below external discursive manifestations. By applying this elaboration to empirical data from an intervention conducted at a school for academically at-risk students, I expose tension between one student’s overt, positive contributions to shared problem solving and his covert ungrounded reasoning as illustrated in Fig. 1.

Students’ effective contributions may blind teachers to underlying discontinuities in meaning construction. I thus propose: (a) a theoretical refinement to the semiotic–cultural approach; and (b) a methodological approach for distinguishing between process and product in collaborative (algebraic) problem solving.

REDUCING ABSTRACTION: THE CASE OF LOGARITHMS

Krishna P. Subedi
Simon Fraser University
krishna_subedi@sfu.ca

This study investigates learners’ mental process while coping with abstraction level of the concept of logarithms through the lens of Reducing Abstraction (Hazzan, 1999). Reducing abstraction “refers to the situations in which learners are unable to manipulate concepts presented in a given problem; therefore, they unconsciously reduce the level of abstraction of the concepts to make these concepts mentally accessible” (Hazzan & Zazkis, 2005, p.101). Hazzan (1999) categorizes three abstraction levels: 1) Abstraction level as the quality of the relationships between the object of thought and the thinking person, 2) abstraction level as reflection of the Process-Object duality and, 3) degree of complexity of mathematical concepts. However, because of the space limit, this paper discusses only the first two levels. The research was guided by two questions:

1) What errors are found in students' work when working with logarithmic expressions?
2) Can the Reducing abstraction framework suggest a plausible explanation for the source of these errors?

In order to answer these questions, I used students’ written work and informal interviews with them. Three students (Ali, Beth and Cayce- pseudonyms) who were enrolled in a college level foundation course on mathematics served as the participants for the study.

Analysis of written work and interviews showed that, Ali, Beth and Cacey, tended to relate unfamiliar logarithmic expressions to more familiar algebraic expressions and treated them with properties such as commutativity and distributivity. For Ali, log₃ 4 and 4 log₃ were equivalent; for Cacey, log₅(x+1) + log₅ (x-3) = 1 was equivalent to log₅ (x+1 +x-3)= 1 and for Beth log₃ 4 + log₃ 5 = log₃ (4+5) =log₃ 9. This can be interpreted as an act of reducing abstraction level (1). Beth’s work on evaluating the numerical value of log₃ 9 is another example of how learners tend to reduce abstraction level (2). Beth seemed to correctly evaluate log₃ 9 as evidenced in her written work, but her arguments (during interview) shows that she knew how to do it (process), but did not understand what it means (object). This is in line with Sfard’s (1991) theory of process-object duality according to which the process is less abstract than an object conception. The results emphasize the importance of paying attention to the nature of students’ understandings and possible misconceptions in designing instruction.

We present a model of how moving from private to public is a deeply affective affair that can lead to students feeling alienated especially when their contributions are carefully controlled by teachers and deemed right or wrong. We use a post-modern feminist perspective to draw analogues between the oppression of voice and identity historically with women in society and children in high school classrooms today and how this can be transformed with new classroom connectivity technology.

Introduction

This work is situated within a larger program of research that has studied the profound potential of combining the representational innovations of the computational medium with the new connectivity affordances of increasingly robust and inexpensive hand-held devices in wireless networks (Roschelle & Pea, 2002) linked to larger computers (Kaput & Hegedus, 2002). Classroom connectivity has roots in more than a decade of classroom response systems, which enabled instructors to collect, aggregate and display (often as histograms) student responses to questions, and, in so doing, create new levels of interaction in large classes in various domains (Crouch & Mazur, 2001).

Our focus has been to develop software and curriculum that aims to generate student engagement and participation in non-traditional forms by structuring the participation of students in mathematically meaningful ways. Integrated curriculum and software allow for the exchange and collection of student work that can be projected for classroom discussion and debate. For example, students can be assigned a count-off number to create a position function so that the motion of a character in a microworld (see http://tinyurl.com/64wls6 for more details of the software) moves for a duration of 6 seconds at a speed equal to their group number. So Groups 1, 2, and 3 create y=x, y=2x, and y=3x respectively for a domain of [0,6]. The important concept is slope as rate—an underlying concept of the mathematics of change and variation—and a family of functions is created by the whole class via varying the parameter $k$, in $y=kx$, where $k$ is group number. Such an activity is generative where students can individually or in small groups construct a wide variety of functions with certain constraints focused on either the coefficients of polynomials of the rate of change of elementary functions. The focus of this paper is not on the design of these classrooms or the results of the intervention—this can be found elsewhere (Hegedus et al., 2007)—but more so on the affective dimensions of moving between various zones of privacy.

We take a historical perspective to present an analytical framework that accommodates various zones of private to a theoretical concept of purely public. We propose that moving between these zones is affective and deals with many deep emotional structures that modify our identity and how we interact socially. Layering a post-modern feminist perspective on this model...
of private to public will illustrate how this framework is rooted in demonstrative dimensions such as issues of power, intimidation and identity conflict. This chronological perspective will present the consequences of expressive writing and its influence on social identity for women in the United States, from the first European settlers in 1600s to pre-Civil War 1900s. We use this approach to illustrate how such zones of privacy (see Figure 1) can be analyzed with a historical perspective, drawing analogues with the oppression of woman and their role in society pre-21st century with present day mathematics classrooms. To quote Fried & Amit (2003, p.107): “In the history of general education, a tension between public and private domains in education is not an uncommon theme”. Our conclusions position new classroom connectivity technologies as an advancement in the development of expressivity for students in mathematics classrooms, offering the potential to address some of the deeply debilitating motivation problems existing in the United States.

**Theoretical Framework**

Prior work (Hegedus & Moreno, 2009) discovered three important products when representational infrastructures (e.g., dynamic mathematics software) and communication infrastructures (e.g., wireless networks) are combined. These include: (1) new forms of mathematical expression, (2) identity formation and identification of self, and (3) new activity structures that focus on intentionality and attentionality. Our focus on a private-to-public space is most related to Item 2.

There we found at least two kinds of identity-formation processes occurring simultaneously within these classrooms. On the one hand, fairly stable social identities (Wortham, 2004), often negotiated and maintained within classrooms, are enacted. These types of social identities are often stable and well-defined both inside and especially outside the classroom and this plays a role in how a student participates in a classroom discussion, whether calls for attention are upheld and how their contributions and participatory role is accepted, e.g., the “smart kid”.

We also observe a more local identity within networked classrooms that is temporal, less stable or well defined, and constructed through the mathematical activity made possible by a networked environment. Here identity can be virtual as work is projected away from a local self to a representation space managed by a teacher. The enhanced mathematical meanings produced by that intersection is to offer an opportunity for students to reinforce their identity by gaining the floor in classroom debates. We have witnessed the outburst of gestural and more general symbolic activities as students gain a kind of emergent identity. These identities are less stable but more flexible as the technology makes it feasible for more students to participate and be engaged within the class.

Our analytical framework (See Figure 1) illustrates how a truly private to a truly public affair moves are theoretical and instead we operate through expanding zones of privacy. The space of action or interaction moves from something closed to something more open and the process becomes more and more social until it is at full disclosure (E) where nothing is private and everyone knows everything about each other (one can say theoretical and never achievable). At the other extreme is Ego, regarding the self—the inner being—and can be unknown to the human (Nietzsche, 1969). What we wish to express here is the affective dimensions involved in moving across zones. These are where we see fundamentally historically charged identity related issues that determine whether someone wishes to participate, learn, express or even be in a situation. Before we present such affective dimensions, we describe the components of the model.
Private affairs are either external forms of actions with oneself (e.g., writing journals, diaries, or self-pleasurable acts) or egocentric speech. We uphold the positions of certain authors (Furrow, 1992; Wertsch, 1979) that the origins of ego-centric inner speech are products of social speech and interaction. In fact, as we begin to apply this model to our particular types of technology-enhanced classrooms, we posit that it is through certain types of metacognitive activity such as other-regulation (observing how others makes sense and regulate their thinking) and self-regulation that we come to understand more about our self and our own thinking hitherto unknown. It is this process that one’s identity can be modified or changed through the enhanced communication infrastructure (as described earlier). Shared private affairs are with a few others. They are intimate affairs as often the members of this semi-closed zone share ideas or thoughts that they have individually constructed as a private affair. It might be deemed risky for the person to share these thoughts with one or more other people and so such a zone assumes norms of trust. A semi-open space is less intimate yet involves social norms and practices often situated within how ideas can be shared, vocalized and discussed. Aspects of agency become relevant and support meaning-making as actions advance collective understanding, especially when it engages the perceptions of the participants. This is often the case for a school classroom. Finally, a purely public space is where all ideas are public and shared. Theoretically aspects of intimacy or privacy are no longer relevant. All members of the public space are free and unemotionally attached to their place or contribution to such a space.

Extension of Private Zone

![Diagram](image)

Figure 1. Modeling zones of privacy
It is our position that expressivity occurs as a cognitive response as we are affected by our own feelings and others. These affective responses can be a progression through expanding zones of privacy and interplay between them. Sometimes we are confident to move from a personal space to a semi-open space but this is still an affective response. Our paper aims to provide an analytical framework of affective dimensions.

Expressivity occurs because you want to show others what you can do, who you are and how you have internalized the world and because you want to incorporate others into your world. Traditionally, public and private are perceived as two distinct zones whereas we have tried to separate them out further and will elaborate with historical and classroom examples later.

Private can be thought of as personal work, and public as shared work but we posit that these are not realistic definitions. We are not focused on other forms of shared-ness such as small group work or constructivist teaching but acknowledge their relevance. It is the intent of journal or diary writing, which establishes some of what is understood about privacy as a conscious and cognitive act, to serve a purpose for a relationship with someone else. This can also include oneself to better understand how one is thinking. Such is not the case in some settings, especially where power and identity conflict amongst participants. In some societies and in some schools, individuals agitate their positions in relation to power in an oppressed system denied of closed and semi-closed spaces to engage in expressive actions. We draw on a postmodern feminist perspective to illustrate how the social identity of women of the past can format our understanding of present classroom interactions. Such identities evolved via the interplay of zones enhancing private expressivity of thought and reformation of individual and collective public actions.

In the early 17th century American women were objects and had no identity. Common law “ensured the submergence of the married women’s identity under her husband as a ‘feme covert’…silent in church, subservient at home occupying a reserved space” (Woloch, 1984, p. 18). Sharing thoughts was viewed as meddling and was not condoned by religious or legal doctrine. In letter books and in public, self-expressions were tied to biblical reference. Public “communicative actions” (Coulter, 2001) were socially invisible which conditioned an absence of themselves in private thoughts. Diaries allowed women to cope with oppression and to establish modes of social interaction. In the next century, women conversed with brief home visits, after church or in exchange of letters with other women.

In the late 18th century, primary schooling expanded, women graduated from academies and entered into teaching and ministries. Legitimacy of women’s education enhanced feminine self-esteem and formulated a social identity in a civic function. “The influence women had on children, especially sons, gave them ultimate responsibility for the future of the nation” (Kerber, 1980, p. 229). In semi-open spaces, women joined literacy circles and women-libraries to reflect and exercise freedom to challenge ideas collectively. Reformation of private thoughts led to ideologically-based social changes. Themes of this ideological shift included the symbolic power of the classes, the subtleties of class stratification and the idea of home life for each class. (Delamont & Duffin, 1978).

The late 19th century, appearance of ladies magazines publicly revealed feminine thought. Ladies submitted private letters to be critically viewed and judged by women and men. Women offered creative views and an innovative way of thinking about society. Group formulated topics were now projected into a less-private sphere. An unexpected consequence was that the “woman’s sphere” gradually enlarged from the home to the larger society as women pursued the women’s role beyond the limits of the parlor and church. Education became a special talent of
women and the education of the youth moved from the home to the school. With support and integrated action of others, women were able to use journals for closed and semi-closed expressivity. Collective groups formed to share emotions, empower creativity and foster innovation, such actions led to a modification of the social identity of women in society.

More recently, Fried and Amit (2003) describe the interplay of student ideas and public thought of the classroom in math journals. The journals were to be in a semi-closed zone whereby “reflection, internalization, visualization, and the creation of math meaning” (p.92) could be represented in the student’s writing. They found an objection to this notion as the students reconstructed the design of the teacher’s notes and lacked expressive writing. Classroom instruction and pedagogy enhanced a well-defined identity structure mitigating the teacher’s judgment of students’ reasoning and thought processes.

**Modes of Inquiry**

We draw on a large dataset collected during a 4-year project in two high schools in Massachusetts. The experimental design was a controlled study design. We used two districts of similar type in terms of Socio Economic Status (SES) and achievement (as measured by the Massachusetts Department of Education), and assigned a content test as a pre-test to all incoming freshmen (9th grade/14-year-olds) and assigned a 6-week algebra replacement unit using a quasi-experimental methodology. There were 160 students who received the treatment and we observed 236 other high school students as a comparison. We also visited every classroom implementing the replacement unit and recorded observation notes and took video of the classroom from various angles. We also collected video data on some of the comparison classrooms. It is from this rich dataset that we draw examples to support our framework, which we believe will inform future analysis of similar technology-enhanced classrooms. To inform our framework in terms of its broader context which is germane to aspects of identity, privacy and oppression of voice we draw upon historical accounts grounding the significance of journals for 17th/18th Century women as a means of expressivity.

**Analysis**

We present three main affective dimensions that provide the dynamics of moving between zones of privacy. For each category, we provide a feminist historical perspective and compare and contrast this with data from our present classroom connectivity project. This will be in the form of classroom enactments or personal student data (e.g., attitude surveys, content tests, student interviews) to illustrate forms of learning and identity formation.

**Affective Dimension 1: Space and Time**

Like that of 17th century women, certain classrooms silence the thoughts of students. Self-reflection was almost absent then and expressivity was protectively melded with those in public authority. Here we begin to see public as a theoretical notion of oppression not necessarily a collection of people.

Today, in our technology-enhanced classrooms, we observed students working independently or in small groups with computers or similar technologies developing forms of closed spaces within the whole classroom. This can lead to private discussion or work that may or may not be shared. The closed, private space might be a place to explore creative tendencies, which involves risk. Students can be protective of their work in a semi-closed or independently private zone, possessive of their work and wary of sharing their creations.

---

With classroom connectivity, students can be involved in a *dynamic semiotic enterprise* where the construction they make, or the ideas they are personally invested in can be updated or reconstructed because of the affordances of the software and be something to be shared or used by others to make larger mathematical objects (e.g., families of functions). It is this shared purpose that changes the nature of closeness and how space is structured within the classroom. The invisible yet guiding nature of the wireless network allows teachers to collect and display individual and whole class sets of constructions that are personal and identifiable to each student. It is time that shapes meaning as the teacher gradually and iteratively displays a student’s work. We develop a shared intentional space. And if we project this outside of the classroom, ontogenetically, this is the world we meet through our own development. In a sense, the world is too open and we need to find ways to close it partially, because we need others. Inside a connected classroom, the nature of how work can be shared and discussed with varying degrees of openness—even with the software itself (i.e., testing a conjecture by running a simulation)—can modify our needs of others.

In an interview with one of the students (*Student A*) in our study who had gone from scoring below the class mean on a pre-test to above the class mean on a post-test, we discover how the interaction between traditional worksheets and public discussion modifies her comfort with her learning environment. The shift between privacy spaces affects her in a positive way.

For *Student A* the most enjoyable part was working as a class and having the class discussions; she felt she really understood it afterwards. When asked about the prediction questions on their worksheets, *Student A* said at first they were confusing but when everyone’s work was aggregated on the board she understood it. And as they continued with these activities, it got easier.

On a survey we developed using a 5-point Likert scale to measure changes in their attitude towards learning mathematics, we noted an increase in *Student A*’s nervousness in talking out loud in front of her classmates (even though she was often quite vocal) from pre to post intervention, yet a significant increase in her confidence regarding her mathematical ability. She also felt more comfortable talking with her own girlfriends in class.

**Affective Dimension 2: Intimacy**

With advanced literacy skills, women in the 18th century agitated power by alliances with one or two other women via letter writing. Fears and challenging thoughts were shared in a *semi-closed* intimate fashion by exchanging letters with a close friend. Again, for protection of prosecution caused by a wrongful response, women voiced thoughts in a collective action within a *semi-closed space* of one or two others. In our own study, many students in the comparison classrooms exercised limited power by not sharing their ideas with others and this was often structured by the teacher. Fried & Amit (2003) refer to such actions as “transactional” (p.104) whereby the intent of the expressions are for others and not for self-reflection.

Schorr & Goldin (2008) discuss how the software environments used in our study provide emotionally safe environments but even within such environments negative feelings can occur (e.g., frustration, impasse, or anxiety). At the same time, the dynamics of the environment “evoke the affect of curiosity excitement and challenge” (p.145). In such a framework, affective structures such as mathematical self-identity and mathematical intimacy allow for integrity and a willingness for someone to increase or open up their understanding for public scrutiny.

Intimacy is based on trust, comfort with the environmental setup and reciprocity of emotion. We have observed this to be evident in a certain kind of discourse mediated by classroom connectivity. In the connected classroom, we see frequent efforts on the part of students to convince their peers to attend to a particular object and then “see” it in a particular way that...
supports their position in an argument. A common occurrence is for speakers to bid for their peers’ and teachers’ attention to the shared display in the front of the room. In some respects, this display is a rhetorical resource for students in making mathematical arguments. Language is personal, representative of the mathematical objects and ideas that they are projecting into a shared space and are often powerful markers to signal solidarity or adherence to others (see Hegedus & Penuel, 2008 for many examples and further discussion). We claim it is the technology that allows such mathematical intimacy an individual has with their personal constructions to a group level mode of debate and argumentation. So as women in the 18th century began to voice their opinions in a collective action, so we see how such technological environments can develop voice and identity among many. The communication infrastructure integrated with a safe and well-articulated participatory framework (in terms of activity structure and pedagogical intentions) can allow many students of differing types of personality the ability to contribute and observe others ways of thinking.

**Affective Dimension 3: Intentionality**

With 19th century social changes and equal public privileges such as access to secondary and higher education and legal rights to own property, women gained access of others and executed expressivity in *semi-open spaces* such as publications. Ladies magazines were semi-open journals and served as an accessible forum for group emphatic formal statements as well as private individual letters. Women challenged topics such as education for children, the quality of home making vs. mercantile goods that evolved to joining with men to address public causes such as abolishment of slavery. *Semi-open* classrooms can empower the individual ideas of students; provide them with forum for democratic dialogue and exercise freedom to challenge the thoughts of others (Coulter, 2001). But how does this affective structure realize itself in terms of how students communicate with each other?

Bakhtin (1981) describes how we borrow words so we can mean to others, and we populate them with our own meanings and intentions so we can signify our relationship, attitude, and identity with others. Burke (1969) explains how people using representations direct others’ attention to some things, and deflects them away from others. This is called external intentionality. In directing attention, intentionality can be externalized through various forms of expression and action.

Intentionality can be structured by an intimate pedagogy that appreciates the participatory nature of the classroom. In our connected classrooms, the teacher can scaffold the classroom discourse in a highly structured way, and in a manner that allows the structure of the underlying mathematics to emerge. For example, questions in our curriculum follow a pattern of “where are you in the world?”, i.e., which colored dot or animated character represents your work? And then “what do you expect to see for Group 1?” by selecting to see just Group 1 in the world. These are all representative features of our technological environment that can show and hide student work, and representations of such work (e.g., graphs, tables, motions of dots/objects/actors in a simulated world, etc.). Intentionality can also be structured by the expressive needs of an individual.

It is important to ascertain for whom a certain private act is written or composed. Is its intended purpose prescribed or an organic process by which an individual finds a safe place within a conversation or public place? At these decision-making points, loaded with affect, the self is on the dividing line between containment and projection. And once projected, it becomes increasingly difficult for the individual to return to that point as it will be modified by others.

---

(however intimate or close they are in terms of privacy). So this stability-instability Rubicon is a place where identity is formed or modified. Belonging to a space loaded with intentionality indicates a movement away from semi-closed privacy as it has a pre-determined structure that is transformed by affective responses.

**Conclusion**

We have presented how private and public are dimensions that are not exact, occur in different forms, and are primarily cognitive affairs that as individuals in society, we move between affective responses to engage with others. The cognitive interplay and expressive actions between zones of privacy can involve positive and negative affect in a safe environment. A historical perspective using postmodern feminism provides an analytical backdrop to understand the complexity of how certain mathematics classrooms manage expressivity and identity. We have proposed that a certain kind of technology-enhanced classroom can establish new forms of communication that can support identity transformation. Such technologies can format the discursive and pedagogical practices of classrooms that can enhance participation in meaningful ways and inform curriculum development in the future.

PURPOSES OF SMALL GROUP WORK IN SIXTH-GRADE MATHEMATICS CLASSROOMS: WHAT DO STUDENTS PERCEIVE AND VALUE?

Amanda Jansen
University of Delaware
jansen@udel.edu

To construct insights about whether and how students develop productive values for engaging in small group work, I analyzed how sixth-grade students from two different classrooms talked about working in small groups. Students’ talk was analyzed to assess students’ perceived purposes and values for small group work. I interpreted these findings in relation to students’ histories with mathematical performance and teachers’ efforts to facilitate small group work. I considered whether teachers’ implied purposes for group work in each classroom were perceived and valued by students, and developed conjectures for facilitating small group work to promote productive values and dispositions.

Introduction

Small group work in mathematics classrooms can be conducted for different purposes, such as promoting learning and communication through collaborative peer interaction or to enhance direct instruction (Noddings, 1989). Not all purposes for group work or efforts to facilitate group work are similarly productive, and students may or may not interpret opportunities to participate in group work in ways that teachers intend. Following Flores and McCaslin (2008), students’ voices about their experiences in small group work can serve as an additional measure of purposes of group work (in complement to observations) and afford an understanding of affective outcomes of teachers’ efforts to facilitate group work.

In this study, I sought to understand relationships between the ways in which two middle school teachers facilitated small group work, what sixth-grade students perceived to be the purposes of small group work, and what students valued about small group work. This analysis had three purposes: (1) To determine whether students’ perceptions of the purposes of small group work aligned with the purposes promoted by the teacher, I contrasted observations how two sixth-grade teachers facilitated small group work with student interview data in which their students talked about purposes for small group work. (2) To assess affective outcomes of engaging in group work, I analyzed what students with different histories with mathematics performance valued about participating in group work. (3) To construct conjectures about how teachers can promote values for engaging in collaborative work in mathematics classrooms, I contrasted students’ values from each classroom.

Theoretical Perspective

Much of the scholarship on small group work focuses on the role of the teacher in facilitating classroom discourse (e.g. Cohen, 1994; Fuchs, Fuchs, Hamlett, Phillips, Karns, & Dutka, 1997). Fewer studies focus on students’ perceptions of purposes of small group work or values for group work. In studies when students’ roles in group work are studied, the focus is often on observable behaviors (e.g., Gresalfi, 2009; Esmonde, 2009). Outcomes of group work are usually assessed through achievement data (e.g., Fuchs, Fuchs, Hamlett, Phillips, Karns, & Dutka, 1997).

This study complements and extends those studies by listening to students’ voices rather than focusing on observations of their behavior, incorporating an alternative cognitive outcome to
achievement (students’ perceptions), and an affective outcome (values) for examining teachers’ facilitation of classroom discourse. Additionally, contrasting students’ voices from two different classrooms supported the development of conjectures about teachers’ roles in facilitating discourse and group work that can help students develop productive values about group work in mathematics class. Students’ engagement can be understood through examining their opportunities to participate in groups, whether students are aware of (or perceive) these purposes (Levenson, Tirosh, & Tsamir, 2009), and whether students merely cooperate with these opportunities or come to value them (Cobb, Gresalfi, & Hodge, 2009).

Prior research provides insights on how teachers can effectively facilitate collaborative work. For instance, explicitly teaching students to provide more elaborated conceptual explanations to each other correlated with higher student achievement (e.g., Fuchs, Fuchs, Hamlett, Phillips, Karns, & Dutka, 1997). Effective groups work together as knowledge building communities that are truly collaborative and interdependent; knowledge is generated jointly (Scardamalia, 2002). Elizabeth Cohen’s (1994) work on Complex Instruction indicates that productive small groups are equitable - students all have equal opportunities to participate, all students’ contributions are valuable, and group members have equal status. When students work together on challenging tasks, there are a number of ways to enter into and solve the problems, so there are more opportunities for more students to be competent. However, teachers may vary in the degree to which they promote engaging in group work for the purposes of promoting elaborated, conceptual explanations and collaborative, interdependent, and equitable interactions among students on challenging tasks.

In complement with understanding teachers’ efforts to productively facilitate students’ engagement in small group work, listening to students’ voices can provide insight about why they do or do not engage productively during small group work. Students’ talk about their experiences in group work affords an understanding of the degree to which students’ perceptions of the purposes of group work are similar to or different from the purposes promoted by their teachers. Students’ perceptions are worth investigating because even when students enact behaviors promoted by teachers, students’ perceptions of the purposes of participating may or may not align with what the teacher promotes (Levenson, Tirosh, & Tsamir, 2009). Students’ perceptions may serve to mediate relationships between teachers’ facilitation of students’ participation and how students participate (Peterson & Swing, 1985). In this way, students’ perceptions provide a lens to understand the nature of students’ engagement during group work.

Students’ voices can provide evidence of affective outcomes. Students with positive dispositions toward mathematics (National Research Council, 2001) believe that they can do mathematics, value the utility of mathematics, and value engaging in mathematics. Opportunities to develop these positive dispositions are situated in opportunities to enact particular roles in classrooms. As students participate in school mathematics, they receive messages about their competencies and develop their sense of efficacy in mathematics. Higher self-efficacy correlates with higher effort and interest (Zimmerman, 2000), so students with a higher sense of competence in mathematics are likely to persist in the face of challenge and be more interested in mathematics. Similarly, students who value collaborative activity may be more likely to put forth effort into sharing their thinking with peers and trying to understand the thinking of others to develop new understandings as a result of collaboration.

In this study, I described how two teachers facilitated small group work, assessed students’ perceptions of purposes of group work and values for engaging in group work through listening.
to students’ voices, and explored which instructional practices appeared to promote productive dispositions and values.

**Methods**

Data were collected in two sixth-grade classrooms in the same school in the Mid-Atlantic region of the United States. The demographics of the school’s student population were the following: 50.6% African-American, 27.5% White, 21.5% Latino/a, and 0.5% Asian-American. According to school district data, 69% of the students were from low-income families. Teachers at this school used the *Mathematics in Context* (2006) textbook series, which is a set of curriculum materials developed with funding from the National Science Foundation. The materials include mathematical problem solving tasks that have the potential to foster dialogue among students.

The two teachers in this study were Ms. Summers and Mr. Winters. Mr. Winters was a second year mathematics teacher at the time of this study. Ms. Summers was in her sixth year of teaching, but this was her first year teaching at this school. Both teachers had experience using these curriculum materials for at least one school year prior to this study. As participants in a statewide professional development activity, the two teachers studied students’ engagement with mathematics through video recordings of focus students and developed interventions for their mathematics classroom based upon what they learned about their students. These teachers asked me to interview a range of students for them as a part of their professional development work.

**Data Sources**

There were two data sources for this study: video recorded classroom observations and one-on-one interviews with students. Video recorded observations from each classroom were analyzed to describe the ways in which the two teachers facilitated classroom discourse and small group work. The set of observations was comprised of five class periods from each teacher across the school year (November to March). Data about students’ perceptions and values were gathered through one-on-one interviews that lasted approximately 30 minutes. I conducted interviews with 24 sixth-grade students (12 from each teacher’s classroom) in February and March of that school year. Interviewees were purposefully selected; I asked their teachers to identify students who they considered to be generally successful problem solvers, generally struggling problem solvers, and students who were sometimes successful and sometimes struggling. Students responded to a range of interview questions, such as, Why do you think your teacher asks you to work in groups during mathematics class? Do you like (or dislike) working in groups during math class? Why?

**Data Analysis**

When analyzing the video recorded observations, I sought to describe how each teacher monitored and debriefed group work to infer what teachers could be communicating to students about the purposes of group work. This analysis was conducted through an emergent process (Corbin & Strauss, 2008), with multiple passes through the data. Initial conjectures of significant themes were developed based upon the first two passes through the data. During additional passes through the data, I revisited the conjectures and sought to revise them by seeking confirming or contradictory evidence.

When analyzing the interviews with students, during the first phase of analysis, I sought to identify what students perceived to be the purposes for small group work in their classrooms.

---

This process involved multiple passes through the data, as described above. For the second phase of analysis through the interviews, I sought to distinguish between students’ own purposes for group work (values for group work) and what students perceived to be their teacher’s purposes for group work. Following Cobb, Gresalfi, & Hodge (2009), I conducted discourse analysis of student interview responses to distinguish between obligations-for-others (identifying perceptions of their teacher’s purposes) and obligations-for-self (what students valued). Obligations-for-others, or perceptions of teacher’s purposes, were revealed when the students said that they engaged in a behavior because the teacher required them to do so. Their perceptions of teachers’ perceptions were analytically determined through students’ use of verbs with high modality (e.g., “have to” or “need to”). Obligations-for-self, or students’ values, were revealed when students reported that they wanted to engage in a behavior or that they preferred or liked engaging in a behavior.

Results

Two Teachers’ Efforts to Facilitate Small Group Work

When monitoring small group work in progress, Mr. Winters did more cognitive work for the students than Ms. Summers. For instance, when he visited a group of students that was trying to estimate the equivalent percentage for a fraction (e.g., 156/216), after the student divided using a calculator and held it up to the teacher, Mr. Winters looked at the calculator and said, “Point 72, 72 hundredths, what percentage is that? 72% What is that, almost? 75% what do we know about that? It’s close to ¾, you could have estimated…” If a student asked Ms. Summers for help when she monitored the small groups, she would say, “That’s why you’re in groups – to be open to multiple strategies and teach each other.” Then, she would step away from the group.

During whole-class discussions after group work, teachers posed different types of questions and appeared to hold different expectations for students’ participation. Mr. Winters’ questions were “how” and “what” questions, such as asking students what answer they found, how they found it, and about which step came next in a procedure. When a student responded to his question, he would ask students to raise their hands to see how many of them agreed their classmate. The discussion continued if there was disagreement, and the class went on to the next problem if there was agreement. In contrast, during whole class discussion after small group work, Ms. Summers’s questions included many “why” questions, such as “Why does that work?” These questions arose when students went up to the overhead as a group and spent time writing out solutions at the overhead and explaining the solution strategy in detail. Students would ask their peers questions or request elaboration from one another (e.g., “I don’t understand why you…”). No students posed questions to their peers in Mr. Winters’s class.

Looking across the ways in which the teachers facilitated small group work, these teachers appeared to promote different purposes for group work. Given that Mr. Winters asked the students for single answers or individual steps during whole-class discussion, the purpose of group work appeared to be to prepare for whole-class discussion by finding a single correct solution. In contrast, the purpose of group work in Ms. Summers’s classroom appeared to be to prepare for whole-class discussion by trying to find more than one solution strategy.

Sixth-graders’ Voices and Purposes of Small Group Work: Perceptions and Values

To explore whether the teachers’ purposes for group work (implied by how the teachers facilitated small group work) were perceived or valued by students, I will present a subset of the sixth-grade students’ voices. These four students were selected as cases based upon two criteria:
data from these students represented the most prevalent themes from the students interviewed from each classroom and these students represented a range of performance in mathematics. Below, I will share how these students talked about obligations-for-others (perceptions of their teacher’s purposes) and obligations-for-themselves (what they valued) regarding small group work in their mathematics classrooms.

_Enrique: Successful problem solver, Mr. Winters’s classroom._ Enrique was one of four (out of 12 sixth-grade students) that Mr. Winters identified as a successful problem solver. Enrique said that math had been his favorite subject ever since the 4th grade. Enrique reported earning near perfect grades that year, even a grade above 100% the most recent marking period. He was aware that he was considered by peers and his teacher to be mathematically competent, as he reported that his peers relied on him for help and that his teacher said that he was the highest performing student in his class.

Enrique perceived that the purpose of group work was to complete his work efficiently. When I asked Enrique about working in small groups, he said, “Sometimes I would rather work by myself.” When I asked why, he said, “Because I’m good at math. I’m done faster by myself.” When given a choice of talking to a teacher or a peer during mathematics class, he said, “More to a teacher. He knows more.” When he talked about group work, he emphasized efficiency. At times, he thought it would be more efficient to talk with his teacher rather than his peers. Other times, he sought efficiency through dividing the work among his peers.

_We can get more done, like, faster... sometimes we just like, tell each other so we all get the one part. Like, there’s four, um, four kids in each group, and there are four problems, we just say, ‘you do this problem, you do this problem, you do this, you do this.’ Then we just share._ Although he said that he would rather work alone or get help from a teacher, Enrique was willing to work in a group of peers if it helped him complete his work efficiently. His desire to efficiently completing his work aligned with the focus of whole-class discussion in Mr. Winter’s class, which was usually to find a single strategy that reached a correct answer.

Enrique did not actively resist group work, but he did not appear to value working with peers. When I asked him why he worked with his classmates in a group, he said, “The teacher tells us to work with a group.” This suggests that he cooperated with his teacher’s request to work in groups (for the purpose of efficiently obtaining an answer), but he didn’t necessarily value collaborating with peers (as he would rather talk with teacher).

_Kiara: Struggling problem solver, Mr. Winters’s classroom._ Mr. Winters identified Kiara as one of four struggling problem solvers (out of 12 students interviewed from his class). When asked about what I should know about her as a mathematics learner, she self-identified as “one of the middle-low students, but not the lowest.” Kiara said that she had been having trouble with math lately, but she said that she liked math, particularly when she had a nice teacher, as she said that did that year. Kiara said, “I like doing math, I just have problems... I’ve been struggling through math, but Mr. Winters and my group helps [sic] me out.” She also said that she attended help sessions after school with her teacher.

When Kiara talked about group work, she perceived that the purpose of small group work was to develop social skills.

_...when we grow up we are going to have to work with people that maybe we might not like, he [Mr. Winters] tells us this, with people we might not like, but we have to work with them, anyway. So he kind of puts us with people maybe that we don’t talk much with, and then we start getting used to working with people..._
She talked about being aware of and cooperating with her teacher’s expectations when she mentioned what they “have to” do and what her teacher told the class (“he tells us this”).

However, even though Kiara appeared to be willing to work in a group, her preference was to get help from her teacher; she did not appear to consistently value working in a group. I asked her with whom she would rather work during math class. Kiara said, “Sometimes the group, but mostly, in my opinion, would be the teacher. … Well, Mr. Winters says he puts geniuses in our groups, so I listen to [classmate], and he gets it right.” Her preference appeared to be working with whoever would be most likely to help her obtain a most direct route to the correct response, such as the teacher or a “genius.”

**Carolina: Successful problem solver, Ms. Summers’s classroom.** Ms. Summers identified Carolina as one of the two strongest problem solvers in her class. Carolina self-identified to me as one of the first students to participate and get involved with her group during small group work.

Carolina perceived that the purpose of group work was to obtain multiple solution strategies.

I: Would you rather have groups, or would you rather have individual time to work?
Carolina: Groups! [I: Why?] Because, like I said, we get like multiple strategies.

When I asked Carolina for advice to give her teacher, she said, “Like to her, like not to always, like, talk. Like, she can talk and whatever, but… we can, like, brainstorm it.” I asked her whether her teacher let them brainstorm it, and she said, yes, her teacher allowed them to brainstorm, and she wanted her teacher to continue to let them do so. This suggests that Carolina believed that students were able to develop and contribute their own mathematical insights.

Carolina not only appeared to cooperate with Ms. Summers’s expectation that students find multiple solution strategies, but she appeared to value finding multiple solution strategies.

I: And what do you like about working in groups, if anything?
Carolina: Like how we, you know, like she says, find multiple strategies? [I: Yeah.] So, we, like, we found, let’s say we take…like we are working by ourselves? Then after we are done we share with each other and we have two strategies, or something like that…

I: And you like that? (Carolina nodded.) Why?
Carolina: Because we can learn from each other.

Carolina said that she liked doing what her teacher asked them to do. Also, Carolina expressed that she wanted to exercise her own autonomy when working with peers.

I: … what helps you learn math the most [in groups]?
Carolina: Like, they [peers] can, like, explain it better…like, let’s say if Ms. Summers is talking about something that I don’t understand, I ask them first, and then I ask her. So I ask them first, and they explain it better… like, he [a peer] like, tries to take care of everybody’s work. Like we got different work--

I: And you don’t like that?
Carolina: It’s taking over our work. It’s like, he’s taking over the whole group.

I: And what do you think he should do instead?
Carolina: Like, work, do his part, and everybody else does their part.

Carolina wanted to learn from her classmates, and she did not like it when peers tried impose their way of thinking onto her or others. She valued interactions that were more collaborative.

Julius: Struggling problem solver, Ms. Summers’s classroom. Ms. Summers expressed concerns about Julius as a problem solver. Julius self-identified to me as “not good at fractions,” which was the unit they were doing when I interviewed the students, but he self-identified as being generally “good with numbers.” He self-reported that he was earning a D in math at the time, and he said that he had gotten behind in his homework.

I: I don’t know you yet, so how would you say you are in math?
Julius: Well, I don’t really think nobody’s the best. I think we’re all the same, but, it’s to the point where someone, I think if they try hard enough, then they’ll all be, like, we’ll all be the same.
I: So, anybody can.
Julius: Yeah. They’re just not trying. They’re not trying to become better. They just decide, some people just decide not to do it, and that’s how they get bad grades.
I: Oh, it’s not that they can’t.
Julius: Everybody can do it!

Notice that he attributed lack of success in mathematics to lack of effort. He did not speak of mathematical ability as fixed, as if some students were geniuses and others were not.

Regarding obligations-for-others, Julius appeared to be aware of his teacher’s expectations. “When the teacher’s stopped talking, she’ll say go, and she’ll say ‘math talk’ and all that other stuff, that’s when I know it’s time to start talking.” He did not appear to resist.

In terms of obligations-for-himself, Julius appeared to value multiple strategies, as he internalized the process of finding more than one solution. I asked Julius what he would do if he was stuck when working on a mathematics problem.

Julius: I would ask myself, like.
I: You would ask yourself a question. What do you ask yourself?
Julius: Like, how would you explain it? I would explain it another way, just in case, like, somebody asked, I still don’t get it, then I would explain it another way to make it easier.

Julius described a metacognitive process of asking himself for another strategy, which suggests that he internalized his teacher’s expectations and used them as a strategy for learning.

Discussion

Students from both classrooms appeared to perceive purposes for group work that aligned with what their teachers implicitly promoted as they facilitated small group work, but Ms. Summers’s students were more likely to value their teachers’ purposes. Mr. Winters’s students did not actively resist working in a group, but they reported that they would rather circumnavigate group work and go directly to a teacher or a “genius” to efficiently complete their work. In contrast, Ms. Summers’s students appeared to value their teacher’s request to work with peers and learn multiple strategies for solving a problem, as exemplified by Carolina’s self-
reported preferences and Julius’s internalization of the process of seeking multiple strategies. A contribution of this study is the use of students’ self-reported values to assess the effectiveness of group work.

Another contribution of this study is that the results serve as an existence proof that relationships between performance and affect (productive dispositions and values) can be complex. Enrique was a case of a student who had a history of success with problem solving, but he may not necessarily be developing a productive disposition toward mathematics. Even though he was performing well in mathematics, he spoke about mathematical authority as lying in teachers or more knowledgeable others. He happened to be a peer authority in his classroom at this point in time. However, if a student like Enrique encounters challenge in mathematics repeatedly over time, will he give up or will he persist? Compared to Enrique, Carolina was an example of a successful problem solver who was developing a more productive disposition toward mathematics, as she talked about students being able to make sense of mathematics. Julius was a case of a student who appeared to be struggling with problem solving, but he appeared to be developing a productive disposition toward mathematics. Although he was not performing well in a unit about fractions, he expressed that everyone and anyone could do math, and he attributed lack of success to lack of effort. This suggests that he could be likely to persist in mathematics when he encounters difficulty because he said that it was possible for him to be mathematically successful, in contrast to Kiara (who talked about others being geniuses).

I conjecture that efforts to facilitate group work similar to Ms. Summers’s efforts would be likely to promote values for engaging in collaborative work. Consider that a purpose of small group work may be to prepare for whole-class discussion. Mr. Winters’s classroom discussed one solution strategy for each problem, with a focus on the correct answer. Ms. Summers’s classroom discussed multiple solution strategies, even if the strategy was not necessarily correct, with a focus on understanding the process. A focus on answers in Mr. Winters’s classroom could lead to a decreased need to engage with mathematics collaboratively; successful students would be those who correctly answered his questions first, and then the conversation would end. Alternatively, if there is a focus on multiple solution strategies, as in Ms. Summers’s class, there can be more opportunities to be successful (Cohen, 1994) and more reasons to interact about mathematics. Values for collaborative work may be promoted through an emphasis on understanding relationships between multiple solution strategies, because the conversation does not end once a correct answer is obtained.

EXAMINING MOTIVATIONAL CONSTRUCTS IN MATHEMATICS FOR STUDENTS ACROSS ELEMENTARY GRADES

Sandra M. Linder
Clemson University
sandram@clemson.edu

Julie B. Smart
Presbyterian College
jbsmart@mail.presby.edu

This study examined how cognitive and social cognitive constructs of motivation might relate to elementary students’ math achievement. A motivation survey was constructed and administered to 1,018 students in grades one through five. Factor analysis of the survey yielded three underlying scales, which were labeled math anxiety, math self-efficacy, and value of math. First grade students reported significantly lower math anxiety than third, fourth, and fifth grade students. First grade students also reported significantly higher self-efficacy in mathematics than third, fourth, and fifth graders. Fifth grade students reported significantly lower value for mathematics than second and third graders. These results are discussed in relation to student motivation and achievement in mathematics as well as implications for mathematics education.

Introduction

The purpose of the present study is to investigate students’ motivational constructs in mathematics across grades one through five in schools that are currently implementing an inquiry-based mathematics curriculum. Results of this study can provide data about motivational patterns in elementary mathematics in early to late grades and may have implications for curriculum implementation and instructional strategies of teachers. This study also sought to establish the reliability of a survey instrument designed to measure motivational constructs related to mathematics in elementary students. Though the survey was previously piloted with a smaller sample (N=79 students), the current study focuses on examining the reliability of the instrument with a larger student sample (N=1,018).

Perspectives

Motivation is a psychological characteristic integral for students to be successful (Schunk, 1991). Studies have shown that highly motivated students are more likely to engage in behaviors that enhance academic performance (DiPerna, Volpe, & Elliott, 2005; DiPerna & Elliott, 1999; Whang & Hancock, 1994), including effective goal-setting, focusing effort, and persisting in academic challenges (Ormrod, 2006). Highly motivated students also are more likely to view academic tasks as valuable and important (Pintrich & Schunk, 2002; Eccles & Wigfield, 1994).

Motivation has also been connected to students’ level of cognitive engagement and use of metacognitive strategies (Pintrich & DeGroot, 1990). Students who exhibit high motivation for a task are more likely to utilize effective cognitive strategies for encoding new information (Ryan, Ryan, Arbuthnot, & Samuels, 2007). These students display a tendency to employ critical thinking skills in problem-solving situations and integrate prior knowledge with new information. Highly motivated students may also employ more effective metacognitive strategies such as planning how to approach a new learning task, evaluating progress, and monitoring comprehension of new material (Pintrich & Schunk, 2002; Pintrich, 2000). Motivated students, in other words, are better equipped to learn than unmotivated students.

Research indicates that student motivation is domain-specific and can vary across curriculum areas (Ormrod, 2006; Stipek, 1988). Students as young as 8 years have demonstrated the ability
to differentiate between subject areas in relation to motivational constructs (Alderman, 2004). In the area of mathematics, student levels of math motivation have been associated with math achievement. For example, DiPerna, Volpe, & Elliott (2005) found a significant positive correlation between motivation and math academic achievement and engagement in math tasks for primary students. This boost in achievement might be explained by other research that suggests students who have high intrinsic math motivation may also have a greater conceptual knowledge of math topics (Stipek, Salmon, Givvn, Kazemi, Saxe, & MacGyvers, 1998; Nichols, 1996) and may persist at challenging math tasks (Eccles & Wigfield, 1994). In short, if a teacher wants to ensure students are successful in math, a critical first step is to ensure an appropriate level of student motivation.

Measuring psychological constructs in young children has proven problematic and inconsistent (Thorndike, 2005). Motivation research typically has focused on the academic drive and related learning outcomes of older students. Thus, the needs of early elementary school teachers who wish to measure and then attempt to enhance their students’ motivation have not been fully addressed. This is unfortunate, because early elementary years (Kindergarten through third grade) are critical to a child’s development of attitudes about schooling, as well as a child’s academic motivation (Perry & Weinstein, 1998). Such formative years can often set a precedent for either academic success or failure in later grades. The current study aims to address the topic of math motivational constructs in elementary children and examine possible interactions between grade levels.

Methods

Participants
Participants were 1,018 students from a suburban school district in the northwest area of South Carolina. Students ranged from grade one to grade five, with the following numbers represented from each grade level: grade one (137 students), grade two (209 students), grade three (241 students), grade four (200 students), and grade five (231 students). Students were recruited from five school sites, all of which were participating in a three year grant from the Commission on Higher Education in South Carolina dedicated to improving teacher quality through the implementation of an inquiry-based mathematics curriculum and professional development program. This program is described briefly in the section below. The only criterion for student participation was parental consent.

Program implementation
Participants at these five schools were in the process of implementing a K-5 mathematics curriculum development at Clemson University through the college of Engineering and Science in an effort to increase student achievement and improve teacher quality in mathematics. This curriculum, called Math Out of The Box, is designed with four interrelated strands: Developing algebraic thinking, developing Geometric logic, and developing number concepts. Teachers at these schools taught three out of the four strands in the 2007-2008 school year when this study occurred. The fourth and final strand, developing number concepts was implemented in the school year following data collection for this study. Teachers were trained on the Math Out of the Box materials through a professional development model where they were immersed in inquiry-based tasks while the facilitator supported a collaborative learning environment.
**Instrumentation**

A 17-item survey was designed to measure cognitive and social cognitive motivational constructs related to math for elementary students. Differing items contained positively or negatively phrased statements of disposition toward math, prompting students to respond with a four-point Likert-type scale (4 = *Just like me*, 3 = *Sort of like me*, 2 = *Not really like me*, and 1 = *Definitely not like me*). Items were evaluated and reviewed for clarity and appropriateness by a measurement expert. Following this evaluation, the measurement expert and researchers refined the instrument together. Items in the instrument were written to prompt a judgment related to (1) anxiety (Shipman & Shipman, 1985), (2) interest (Hidi & Anderson, 1992), (3) task value (Wigfield & Eccles, 2002), (4) self-efficacy (Bandura, 1986), and (5) goal orientation (Elliott & McGregor, 2000).

**Procedure**

A total of 117 classrooms participated in this study in the spring of 2008. Each student’s involvement was contingent on informed consent. All surveys were administered by the teacher or a school math coach in the students’ regular classroom setting and no surveys were given to students individually. In order to control for reading ability, each item was read aloud to the students in grades one through three, who then made their rating selections before the next item was read aloud. Participants were given a wait time of 10-15 seconds to complete each item. All surveys were completed during the same two-week time period during the last month of the school year.

**Results**

**Reliability**

Reliability for the math motivation scale was estimated by computing the Cronbach’s Alpha (0.833). This coefficient demonstrated high reliability for the scale. Further, an examination of “Cronbach’s Alpha if Item Deleted” suggested that the Cronbach’s Alpha increases to 0.846 upon deletion of Items 4 and Items 9. However, this increase was not significant enough to warrant the removal of these items from the scale.

**Factor Analysis**

The dimensionality of the 17 items from the motivation scale was analyzed using principle components factor analysis. A varimax rotation yielded three factors with eigenvalues greater than one, and each factor yielded an interpretable factor solution. Three items loaded on more than one factor. Factor 1 (which accounted for 29% of item variance) was defined by six of the scale items. Because these items were related to varying constructs of math anxiety, Factor 1 was labeled *Math Anxiety*. Factor 2 (which accounted for an additional 11% of item variance) was defined by seven of the scale items and was labeled *Math Self-Efficacy*. The third Factor was defined by five of the scale items, accounted for 8% of item variance, and was labeled *Value of Math*.

**Analysis of Variance**

A one-way analysis of variance was conducted to evaluate the relationship between grade level and each of the following factors: (1) math anxiety (2) math self-efficacy and (3) value of math. The independent variable, grade level, included five levels, represented by grades one...
through five. The dependent variable was the student score for each factor on the motivational scale, identified through factor analysis.

The ANOVA for grade level and math anxiety was significant, $F(4, 1013)=13.554, p<0.001$. Follow-up tests were conducted to evaluate pairwise differences among the means. Levene’s Statistic revealed equal variances, resulting in the use of Bonferroni’s post hoc comparison. Students in grade one reported significantly lower math anxiety than grades three, four, and five. Grade two also reported significantly lower math anxiety than grades four and five.

The ANOVA for grade level and math self-efficacy was also significant, $F(4,1015)=5.928$, $p<0.001$. Bonferroni’s post hoc was selected to evaluate pairwise differences among the means, since variances were equal. Students in grade one reported higher math self-efficacy than students in grades three, four, and five. There were no additional significant differences between self-efficacy and grade level.

The ANOVA for grade level and value of math was significant, $F(4,1013)=3.215$, $p<0.001$. Finding equal variances, Bonferroni’s post hoc was conducted to examine differences among the means. Students in grade five reported significantly lower value for math than students in grades two and three.

Results from this study indicate that students in the lower grades at these five schools report less math anxiety and higher self-efficacy in mathematics. These results raise questions about possible reasons for this discrepancy, including the need to investigate issues of increased math anxiety as a result of testing pressure or rising levels of difficulty in content. The correlation existing between math anxiety and achievement in mathematics has been well documented in the research literature (Ashcraft, 2002; Beasley, Long, & Natali, 2001). The results from this study introduce the possible correlation between math anxiety and reduced self-efficacy in mathematics.

These results also raise questions about factors at the schools that may account for the reduced levels of motivation at the higher grades such as classroom environment, teacher quality, or fidelity of implementation. Fifth grade students at these schools report a significantly lower value of mathematics than students in other grades. Value is essential for students to be motivated in mathematics (DiPerna, Volpe, & Elliott, 2005). It is necessary to explore how the role of the teacher and the curriculum account for such a change in attitudes. It would also be beneficial to compare the motivation of upper elementary students whose teachers are using an inquiry-based curriculum to students whose teachers are using a more traditional mathematics curriculum where procedural knowledge is emphasized over the development of conceptual understanding. While students at the upper elementary grades report less motivation for mathematics than students in lower grades, it is unclear if they have more motivation than students in other schools where a traditional mathematics curriculum is implemented.

Conclusions

This study provides insight into students’ motivation in mathematics in relation to grade level. This data may be helpful in informing curriculum decisions and instructional practices that may sustain students’ motivation as they progress from early to late elementary grades. Special attention should also be given to increasing levels of math anxiety as students advance through the grade levels. Identifying and reducing this anxiety in students in the mid to late elementary years may result in more positive experiences with mathematics in the middle school years. In addition, a drop in reported value for mathematics during fifth grade may suggest a need for authentic experiences that help make mathematics meaningful for these students.
This research also provides information for stakeholders at these schools acting in a supportive role as teachers implement this new mathematics curriculum. These stakeholders include the math coaches at each of the schools who provide daily support to teachers in addition to facilitators from Clemson University who provide weekly support through content-focused professional-development for grade-level teams of teachers. The need to increase student motivation at the upper elementary levels in these schools will become a primary goal of these professional development sessions. Next steps for this line of research include investigating the impact of instructional practices on student motivation in mathematics. A mixed methods sequential explanatory design will be used to examine this correlation. Researchers will use the survey that was developed and validated in this study as a method of participant selection to identify a sample of teachers whose students display either a high level or a low level of motivation. A case study design will then be utilized to determine how instruction can influence student motivation in mathematics.

HIGH SCHOOL STUDENTS’ PERSPECTIVES ON COLLABORATION IN THEIR MATHEMATICS CLASS

Corey Webel
Montclair State University
webelc@mail.montclair.edu

Collaborative learning formats are being used increasingly in mathematics classrooms. However, students working in groups often remain dependent on their teacher as the distributor of knowledge, or turn to peers to fill this role. In this project, I used viewing session interviews to investigate high school students’ perspectives regarding collaboration in their mathematics class. I highlight two students who characterized their responsibilities as class members differently, but expressed similar beliefs about the purpose of group work and the nature of mathematical understanding. I argue that viewing collaboration as “helping” may limit the potential benefits of having students work together.

Introduction

Students’ experiences in mathematics class, including their experiences with collaborative learning formats, can affect their identities as learners and doers of mathematics (Boaler, 2002). Cobb, Gresalfi, and Hodge (2009) used interviews to show how students in two classes with very different pedagogical approaches constructed identities differently in terms of their mathematical obligations to each other, their opportunities to exhibit agency, and their view of the teacher as a mathematical authority. But even in a class where student interaction is a central component of instruction and where the teacher seeks to establish a community approach to learning, students may construct mathematical identities that are individualistic and passive in nature. These identities are influenced not only by the nature of instruction, but also by their beliefs about the purpose of collaboration in their mathematics class, as well as their beliefs about mathematical understanding more generally. These beliefs may be resistant to change, and may constrain the ways that students are able to engage in collaborative work.

In this paper, I compare and contrast the perspectives of two high school students in the same mathematics class where collaborative work was common. Sevanye (a pseudonym) described her responsibilities primarily in individualistic terms, rarely expressing concern for contributing to the understanding of her peers. In contrast, Jordan’s description of learning was more community-focused, acknowledging a responsibility not only to improve her own knowledge, but to help improve others’ knowledge as well. At the same time, both students seemed to hold similar beliefs about the purpose of collaboration and also about the nature of mathematical understanding. Both Sevanye and Jordan described working together primarily as passing knowledge from capable students to struggling peers, and seemed to see mathematical understanding as knowing procedures. I argue that these beliefs may be related to each other and that they have implications for the strategies that teachers use to implement collaborative learning in their classrooms.

Framework and Research Questions

Particularly when they are working on problems for which solutions are not already known, students will inevitably struggle. Clearly, teachers in classrooms with 20 or 30 students will not be able to attend to each student and help them resolve their confusion. Putting students into
groups can be seen as one way of resolving this dilemma, as the stronger students can help those who are struggling. Some research has suggested that students working in groups tend to position themselves asymmetrically, where select students take on an “expert” role, telling other students what to do, while their peers defer to their authority (Esmonde, 2009; Kotsopoulos, 2007).

Some strategies for implementing collaboration seem to assume (and may even promote) asymmetric positioning by, for example, training students to give better explanations when helping their peers (Fuchs et al., 1997; Webb & Farivar, 1994). Even in a study which claimed that students created a “collaborative zone of proximal development” in their classroom, descriptions of student interaction suggested asymmetric positioning: “Some students additionally adopted teacher-like scaffolding strategies to assist less capable peers, for example, by asking questions that led their partner to locate an error or reconsider a plan” (Goos, 2004, p. 282). While these interactions deemphasized the teacher as the distributor of knowledge, some students still seemed to be positioned as knowledgeable while others were positioned as less able to contribute.

Another view of collaboration suggests that students could be positioned more symmetrically while generating knowledge. According to this view, knowledge need not be possessed by any individual in order for it to emerge among a group of learners (Davis & Simmt, 2003). That is, students may co-construct new ideas through activities such as reiterating, redefining, or expanding on the ideas of others (Mueller, Maher, & Powell, 2007). Scardamalia and Bereiter (2006) argue that this is precisely what takes place in research institutions—groups of people come together, construct new ideas through discourse, and together advance the knowledge of society. This process of knowledge building should not be limited to the research laboratory, these researchers argue; it should be integral to schooling.

One of the goals of this paper is to argue that the former view (collaboration as helping) may undermine the benefits that might be gained from having students work together, particularly if this view is adopted by students and teachers. I set up this argument by using multiple lenses to examine two students’ perspectives on working together. First, I investigate the extent to which each student describes personal obligations to help her peers, as well as the extent to which each describes her classmates as resources for helping her. Then I examine each student’s beliefs about the purpose of collaboration; in particular, does she describe working together as a process of building new knowledge through the contributions of multiple individuals, or as a process of passing ideas from knowledge-giver to knowledge-receiver? Finally, I explore each student’s beliefs about the nature of mathematical understanding in order to explore connections between these beliefs and beliefs about the purpose of group work.

Methodology

Sevanye and Jordan were both in Mr. Neal’s “Integrated Math 3” class, the third in a sequence of courses taught with the Core Plus mathematics curriculum materials (Hirsch et al., 2008). They were both in 10th grade and both reported typically receiving B’s in mathematics.

I spent 23 days in Mr. Neal’s class, recording video of whole class discussions and small group work. I interviewed eight students from the class twice, including Sevanye and Jordan. In the first interview, I asked them questions about working with their peers, such as whether they liked working together and why, what they saw as the goal of group work, what they saw as their role or “job” when working in a group, and under what circumstances they felt comfortable sharing their ideas publicly in whole-class discussions. In the second interview, I showed each student video clips of their own participation in various collaborative activities and asked them...
questions about how they participated. Using these viewing sessions helped students be more specific about their roles, and allowed them to address any inconsistencies between stated beliefs and observed behavior. The data was analyzed by categorizing portions of interviews according to recurring themes that were developed and refined throughout the analysis process (Glaser & Strauss, 1967). In this paper, I focus on three of these themes: how Sevanye and Jordan characterized their personal responsibilities as members of the class, how they described the purpose of collaboration, and how they talked about mathematical understanding.

### Results

**Responsibilities: Individual Versus Community**

When Sevanye discussed her role during group work, she emphasized a responsibility for making sure she understood rather than a responsibility to the members of her group for improving collective understanding. During the initial interview, I asked her about situations where her group mates might get off-task, and she shrugged, saying,

> If you don’t want to do your work, I’m not going to say anything to you. We’re all in high school, graduating in two years. If you can’t be smart enough to know I need to get this work done ’cause there’s a test next week then…that’s not my problem.

In another section of the interview, she said, “It’s up to everyone…. I can’t expect anybody else to carry me ’cause I don’t know what I’m doing. That’s not fair to anybody. Especially if they know what they’re doing ’cause they paid attention.” These comments suggest a rejection of obligations to contribute to her peers’ understanding.

In one video clip, Sevanye was seen allowing a group mate to copy her answers. She explained the behavior in the interview: “It doesn’t bother me, as long as in the end she understood what we were doing. If you wanna copy my answers, I mean…I don’t always get the right answers, so if I mess up I’m gonna have to erase.” Here Sevanye does mention her classmate’s understanding, but since she made no effort to help her peer understand, this can be interpreted as a responsibility she put on her classmate, not herself. In general, for Sevanye, the responsibility for understanding seemed to lie with the individual rather than the community.

Unlike Sevanye, Jordan did express more of a concern for helping others understand. She said, “…we’re supposed to help each other or whatever, and I don’t know, I just don’t feel as though we should go on, leaving one person sitting there stuck, because…I don’t want to be left there stuck.” Jordan seemed to see helping others in terms of reciprocation—helping others was important because she might need help from them at a later time. This came up when discussing the nature of help as well: “Like, I don’t like giving people the answers, like I like explaining it to them, because I don't want nobody giving me the answer. Like I like if somebody explains it to me so I can know how to do it.” Here Jordan seems to be expressing a responsibility not only for sharing her answers, but for explaining how to solve problems.

Sevanye and Jordan also differed in the extent to which they saw their peers as able to help them understand. In many cases Sevanye described her classmates as incapable of helping her. In one episode where she became confused, rather than ask her group members about their ideas, she raised her hand to call the teacher over for help. When I asked her about this, she replied,

> They didn’t know what they were doing…. I asked Lindsay a little bit about like what she was doing, and she didn’t really seem to know. If I would have asked her some more, she probably would have confused me more than what I was already confused about…so I just went right to Mr. Neal.

---

In this case, Sevanye did not seem to see her peers as resources for helping her understand. Sevanye also said, “When I work in group I like to work with people who already know what they’re doing,” but other comments suggest that this was a rare occurrence for her. In general, Sevanye seemed to prefer explanations from Mr. Neal rather than from her classmates. In one episode, Mr. Neal conducted a whole class discussion in which he gave an explanation for a solution that a student had written on the board. I asked Sevanye if she would have preferred that the student explain his solution rather than Mr. Neal. She replied, “No. I like it when Mr. Neal explains it better. Like, he just breaks everything down…. I’d rather Mr. Neal do it because he knows exactly what he’s doing.” This quote again suggests that Sevanye did not see her peers as able to help her understand, and seemed to see Mr. Neal as the primary mathematical authority in the classroom.

In contrast, Jordan explicitly described her peers as capable of helping her learn. She stressed the importance of sharing ideas with others:

Yeah I like group work because you get to share your ideas, and everybody has different thoughts or whatever. I think it’s better to see what everybody else thinks about the problems or whatever, because….like Mr. Neal says, more approaches to a problem, whatever…so we don’t have to just do it the way he shows us. Jordan acknowledged that it was possible to learn from others without relying on Mr. Neal. In the case of a disagreement between students, she said that “if you both explain how you got your answer, then maybe you all can come up with something. Maybe if you go through it again, you see somebody make a mistake, something like that.” Jordan acknowledged that “some students come up with their own ways, like ways that the teacher doesn’t even explain yet,” although she claimed that this was rarely the case for her.

Jordan indicated that she valued other students’ explanations during whole class discussions as well as during group work. She said that rather than Mr. Neal providing all of the explanations, he should allow students to explain because “maybe the student had a different approach than the teacher had. Or maybe some students understand it better from a student.” Jordan seemed to see students as capable of contributing to each others’ understanding, and wanted Mr. Neal to provide opportunities for students to share their ideas with their peers.

The preceding sections have outlined some ways that Sevanye and Jordan described their roles in Mr. Neal’s mathematics class. While Sevanye primarily described her responsibilities in individualistic terms, Jordan expressed a sense of responsibility for helping others and also saw her peers as resources for improving her own understanding.

Beliefs About Collaboration

While Sevanye and Jordan’s expressed obligations as members of their mathematics class seemed different, they described similar beliefs about the purpose of collaboration. In particular, both Sevanye and Jordan expressed the view that working together was primarily about those with knowledge “giving” that knowledge to those without. In other words, they described collaborative work in asymmetric terms, with some students positioned as knowledge-givers and others as knowledge-receivers. Sevanye was quite explicit about this. When asked about the purpose of group work, she said, “You put the stronger people with some people who may not know the subject as well and it helps them.” She also indicated that “being knowledgeable ” was a prerequisite for being able to help others. “I wouldn’t want to tell somebody how to get the answer if I wasn’t one hundred percent sure how to do it,” she said. As I described in the previous section, she also was hesitant to listen to her classmates if they did not have a solid
understanding. This suggests that for Sevanye, working together was primarily about giving knowledge to others who were confused. This activity seemed to hold little value for her, which predictably resulted in a generally negative view of group work.

Jordan also seemed to believe that working together that was primarily about students “helping” each other. When I showed her a video clip where there was very little discourse between her and her group members, she explained: “When somebody needs help, we help each other…. Even though we work at a different pace, we still stop if you don’t understand something, we’ll explain it.” Here Jordan is again expressing a view that learning is a collective effort, but she is also describing this collective activity in terms of stopping and helping, particularly when someone does not understand. This implies that some members of the group already do understand and could go on if they were not obligated to help their classmates. It also suggests that for Jordan, a primary reason for discourse is to express confusion and get or give help. Later she talked specifically about a partner who helped her understand. “I know my partner, it makes sense to him, ’cause he always knows. I’m like, ‘do you understand this?’ And he’s like, ‘yeah.’” She described a specific case where she was confused: “…so I asked my partner. He understood it. He explained it to me.” In this sequence she describes her partner as knowledgeable, herself as lacking knowledge, and working together as the process of him explaining to her. These quotes suggest that for Jordan, working together was often a process where students who had good understanding explained to students who did not.

So while Jordan described her responsibilities in the classroom as extending beyond improving her own understanding, both she and Sevanye described working together in terms of passing knowledge between students. This finding suggests that promoting collaboration in the classroom may mean more than getting students to feel obligated to help each other. It may also involve addressing students’ beliefs about the purpose of group work, beliefs that may be tied to students’ views about the nature of mathematical understanding.

Beliefs About Mathematical Understanding

During the interviews, Jordan and Sevanye articulated the belief that mathematical understanding consists primarily of knowing procedures. This was apparent in their descriptions of what they valued when giving and receiving help, which often included concerns with what to do rather than providing and evaluating arguments for why ideas were true.

When I asked Sevanye about how working in a group might help one understand, she said, “Because whenever you do something wrong you know how not to do it…and how you should do it.” Her emphasis on how to do it suggests a procedural focus, and this was repeated throughout both interviews. Here she explains an episode where she had the wrong solution:

I was in a group…and we had both gotten the answer but my answer was wrong. And I asked [my partner] how she got it. She had, her answer was right. I didn’t put a negative sign where it was supposed to go and she was like, ‘oh, well this is how you’re supposed to do it. But you just have to remember to put your negatives in the right place or you’re gonna…get the wrong answer again.’

Again, the emphasis appears to be on what to do, rather than on providing justifications for why the solution was correct. Later, she said that she asked questions in whole-class discussions because “I wanna know how each step goes or how to answer the question.” She did not talk about giving help in terms of providing mathematical justifications, and rarely expressed a desire for the teacher or her peers to explain why their solution was correct.
Jordan also expressed an emphasis on procedures. An example can be seen in an interview regarding a video clip in which she was helping a group mate with a problem from her textbook (Hirsch et al., 2008, p. 336), reproduced in Figure 1. When I asked Jordan about the explanation she gave her classmate for this problem, it became clear that she was merely mapping the regions on the diagram to the terms in the equation $2x^2 + 7x + 6$: “I just told him that the two $x$ squared was the two blue ones…plus the three green down there, and the four green up here, that’s the seven $x$, that’s the b. And then c was the, uh, the six yellow blocks.” When I pressed her to explain how the picture showed the relationship between $(x + 2)(2x + 3)$ and $2x^2 + 7x + 6$, the only explanation she provided was the standard “FOIL” procedure (multiply the First, Outside, Inside, and Last terms, and add them together). This explanation, and that which she offered to her group mate, suggest that Jordan missed the point of the diagram, which was to use an area interpretation of multiplication to show how and why the FOIL procedure works $(2x + 3$ can be seen as $x + x + 1 + 1 + 1$, which is the length of the rectangle, $x + 2$ as $x + 1 + 1$, which is the height. Multiplying them gives regions that can be seen as having areas of $x^2$, $x$, and 1, and these regions can be separated into four parts to show the four products in the FOIL procedure).

Not only did Jordan fail to describe to her group mate how the areas were generated by the multiplication of the binomials, she also seemed to be satisfied with her explanation and did not ask the other members of her group about their solutions. This can be seen as an indication that knowing why $(x + 2)(2x + 3)$ is equivalent to $2x^2 + 7x + 6$ is either not important, or that the FOIL procedure is a sufficient justification for Jordan, although there was no evidence to suggest that her understanding of FOIL included anything more than the ability to complete the four steps it entails. This suggests that Jordan was satisfied with knowing the procedure for multiplying binomials, failing to press her group mates or herself for justification. This example is consistent with other comments in Jordan’s interviews.

![The next diagram illustrates a visual strategy for finding products of linear expressions.](image)

**Figure 1.** A task designed to reveal the conceptual meaning of binomial multiplication

*Note: In the textbook, the large squares were colored blue, the rectangles green, and the small squares yellow.*

**Discussion and Implications**

The fact that both Sevanye and Jordan tended to describe working together in terms of passing knowledge between individuals could be related to the fact that they seemed particularly concerned with knowing procedures. That is, if mathematical understanding is primarily about
being able to complete a procedure, then mathematical understanding is dichotomous—one can either do the procedure or one cannot. This dichotomy extends into the social fabric of the classroom. If you know the procedure, then you are likely to be positioned as a knowledge-giver. If you do not know the procedure, an efficient way to learn it is finding someone who knows it and getting them to explain it to you.

Thinking about mathematical understanding as grasping concepts and the relationships between them makes it possible to view collaboration in a way that does not position students asymmetrically. This perspective acknowledges that it is possible for one to understand quite a bit and still not be able to complete a procedure, and also for one to be able to complete a procedure with very little conceptual understanding. Mathematical understanding is much more complex than simply knowing what to do. Students are likely to have a variety of ideas, which, rather than being seen as correct or incorrect, could be seen as revealing different aspects of a mathematical concept. With this view, working together might be easier to see as a process of improving what is known collectively rather than a process of passing knowledge between individuals. Students might position themselves more symmetrically when working together. They might more readily accept that one not need be “knowledgeable” in order to contribute, and be more inclined to persist even in the absence of a knowledge-giving peer (or teacher).

On the other hand, if students see working together only as passing knowledge between individuals, this may affect the extent to which they are able to engage in truly collaborative work. In particular, students who take this perspective and consider themselves to be knowledge-givers have little incentive to work with their classmates. For Jordan, the possibility of reciprocation was an incentive for her to help her peers, but this incentive was not enough for Sevanye—perhaps because Sevanye more often was positioned in a knowledge giving role and saw fewer opportunities for reciprocation from her classmates. It should also be noted that, in light of the beliefs that both students seemed to share, Sevanye’s lack of a sense of responsibility for her classmates’ understanding is perfectly reasonable. If solid understanding (i.e., knowing a procedure) is a prerequisite for making contributions, and her peers rarely demonstrate this kind of understanding, then there is not much for her to gain by working with others.

One implication for teaching is that if Mr. Neal attempts to improve collaboration in his classroom by trying to help Sevanye be more like Jordan—to develop in her an obligation for helping others—then he may be missing the core problem. Perhaps the more fundamental issue is that neither one of the students may see mathematics as a complex set of relationships that can be understood in many ways and from many perspectives. Thus, they may reject the possibility that others can contribute if specific guides for action are not present. Simply placing students in groups and relying on goodwill (or the belief that one might at some point need help from others) may not be a reliable strategy for encouraging consistent collaboration.

Teachers might address this problem by paying attention to the way they portray mathematical knowledge and what it means to work together. Webb, Nemer, and Ing (2006) suggest that students are likely to adopt the helping behavior that is modeled by their teacher. In particular, if the teacher models knowledge-giving behaviors and emphasizes procedures, then students may not be challenged to see working with each other in less asymmetric ways. In this class, Mr. Neal did not often directly help students during group work; however, during whole-class discussions, he did resolve issues of correctness and provided explanations for problems that students had worked on. A more detailed analysis of Mr. Neal’s teaching practices might reveal more about how they could have been adapted to challenge students’ beliefs about collaboration and mathematical understanding.

Conclusion

In this paper, I used the perspectives of two high school students in the same mathematics class to argue that the beliefs students have about the nature of mathematical understanding and the purpose of group work can affect the extent to which their participation in “collaboration” is truly collaborative. Promoting collaboration means more than making sure that students adopt responsibility for helping other understand; it means addressing and challenging these underlying beliefs.

JUXTAPOSING MATHEMATICAL IDENTITIES: SAME STUDENTS WITH DIFFERENT CONTEXTS, PERSPECTIVES AND LANGUAGES

Carlos A. López Leiva
University of Illinois at Chicago
clopez3@uic.edu

In mathematics the intricate relationship between learning and identity is predicated upon students’ quality of social engagement with mathematical practices. In this paper, I explore five Latino/a students’ actions in and narratives about a mathematics afterschool program over a three-year period. Students juxtaposed their experiences within the program and those in the regular mathematics classroom, claiming a difference in the nature of mathematics and in the type of interactions with the participants. Their mathematical experiences, however, were mediated by both their language preference and their reified positions in mathematics, which, in turn, informed their perspectives on what counts as mathematics.

Introduction

In this paper, I explore Latino/a students’ interactions in a mathematics afterschool program and their narratives about their experiences in both the program and their regular mathematics classroom; and at the same time, how these experiences mediate their mathematical identities. Thus, I explore the formation of subjectivities or actors’ thoughts, sense of self, and self-world relations (Holland et al., 2003). My exploration is on the socialization processes, on the quality of the students’ interactions and experiences in specific environments, especially in terms of how they situate themselves and on how they are situated by others with respect to mathematics and language preference. This focus bridges contents and contexts, a situated perspective of students’ experiences (Martin, 2006), here bilingual Latino/a students. Students’ ideas about what mathematics is and its use seem impacted by the different ways students engage with others around mathematical practices (Lave & Wenger, 1991; Nasir, 2002), this simultaneously shapes participants’ dispositions, i.e., “ideas about, values of, and ways of participating with a discipline” (Gresalfi & Cobb, 2006, p. 50). Learning and identity evolve dialectically (Martin, 2006, in press; Lave & Wenger, 1991).

Previous research on after-school settings have capitalized on children’s interests and choices and promoted interactions in flexible environments where participants enacted multiple identities (Cole & the Distributed Literacy Consortium, 2006; Vásquez, 2003), and allowed the blurring of categories, such as: student/teacher, play/learning, and school/home. In La Clase Mágica, this system nurtured students’ social identities as they needed e.g., amigo (friend), jokester, wizard’s assistant, etc., though the Mexicano identity was the prevalent across cases. Vásquez explains that despite instances refusing to speak either language, students continuously constructed a bilingual identity for immediate purposes.

Latina/o students represent the largest (15.4%) minority in the US (US census, 2007). Llagas & Snyder (2003) report Hispanic students having higher high school dropout rates than White or Black students (p. 40), over one-half of Hispanic students speak mostly English at home (p. 72), and that most Hispanic students attend schools where minorities are the majority of the student body (p. 26). More recently, Flores (2007) demonstrated unequally distributed opportunities to learn mathematics for all students. Specifically for African American, Latino, and low-income students who are less likely to have access to experienced and qualified teachers, more likely to
face low expectations, and less likely to receive equitable funding per student. He reframed the achievement gap problem to opportunity gaps for minorities. Latinos’ social situation further aggravates under deficit model approaches—on language, race, or ability (Cashman, 2008). In fact, arguments against languages and cultural diversity are based on the belief that diversity brings divisiveness. Students need to understand that loyalty to the country does not have to go along with denial of their ethnic and linguistic heritage (Brisk, Burgos, & Harmela, 2004, p. 167). As a result, negative attitudes awareness toward their heritage language results in refusing it. Language then is a tool for socialization, and the use of language is socialized (Jackson, 2009, p.177).Thus, given with ideas in mind, I deem pertinent an exploration of the processes conforming their mathematical and bilingual identities.

Setting and Cases

The afterschool program “Los Rayos de CEMELA” was developed as an adaptation of the Fifth Dimension (Cole, 2006) and La Clase Mágica (Vásquez, 2003). Los Rayos—a non-remedial mathematics program—is a hybrid space promoting both languages; with playful approach, but not play; with a school subject, but not school (Khisty & Willey, in press). Its curriculum included probability, proportions, geometry, and pre-algebraic thinking. Students met twice a week for ninety minutes and solved problem-solving tasks in small groups that they selected (2-3 students, 1-2 facilitators—pre-service teachers called “UGs,” and at times mothers).

Participants, mostly (US-born) from a Mexican background, were all bilingual (Spanish and English). Thirty-one students participated over a three-and-a-half period having an average of seventeen per semester, though twelve of them consistently attended the program. It started with their 3rd and ended with their 6th grade. Students self-selected to be part of Los Rayos. The hosting public school in Chicago—dual language school—had 98% Latino, 91% low income students, 9% special education students, and 62% English language learners—ELLs (Office of Research, Evaluation, and Accountability, 2008). For this project, I selected five student cases—Ramón, Rolando, Candy, Graciela, and Letty (general contexts with multiple embedded cases, Yin, 2009). For comparative purposes (Miles & Huberman, 1994), I selected students that differed from each other in their mathematics performance in regular school. They respectively had the following average scores in mathematics: A, C, B, A, and C.

Procedure

The process of exploring students’ bilingual and mathematical identity had various stages. Students were interviewed at different times during the program. For the purpose of this paper, I include data obtained from: the debriefing session (about 20 minutes) at the end of school year 1; five student interviews (40 minutes) held respectively during the end of school year 2 and 3; and finally, three focus-group sessions (30 minutes) developed during last semester. Questions explored purposes of the program: students’ experiences in the afterschool activities, their experience with using and learning mathematics in and out of school, their language use and preference (Spanish, English, or both). They ranged from semi-structured to open-ended formats; when students brought up ideas, the interviewer followed up that lead until finished and then moved onto another item. Facilitators conducted interviews either in Spanish or English depending on students’ preference. In addition, I analyzed teachers’ interviews, UGs’ field notes, and videotaped interactions at Los Rayos, but not from classrooms. Here I explored students’ discursive identities by selecting episodes from the beginning, middle, and end of the program.
Analysis and Framework

I based my analysis on theoretical prepositions, case descriptions and rival explanations (Yin, 2009). First, I started observing the videotaped interview sessions identifying general themes. My notes also included any aspect related to following questions:

■ What meaning do these students make from their own participation in mathematical practices?
■ What does it mean to these students to do mathematics as a bilingual person?

From my pool of notes, I separated episodes referring to mathematical or bilingual identity and developed an open coding on them. I noticed students were differentiating between the quality of mathematics they experienced in regular school and in the afterschool. With respect bilingual identity, they seemed to address language preference differently. Second, I revisited the selected episodes using transcriptions, videotaped interaction, teachers’ interviews, and field notes developing conceptual themes and concomitance with already identified concepts.

My conceptual frame has an eclectic approach rooted in a sociocultural perspective. I draw from the multilevel framework for mathematics socialization and identity (Martin, 2000). Correspondingly, I delineate mathematical identity as socially negotiated the dispositions, beliefs about one’s ability to participate and perform effectively in mathematical contexts (Martin, 2006); and I identify mathematics as a type of practice (Moschkovich, 2004; Nasir, 2002). Thus, mathematics learning, development, and identity (Boaler, 2002; Martin, 2000; Nasir, 2002) are determined by way students engage in these practices—or not—(Lave & Wenger, 1991). I observe students’ narrative (i.e., relevant, reifying stories, collectively co-constructed practices about being a kind of person, Gee, 2001) and discursive identities (i.e., actions that students engage in during practices). Along this process, I examine how students may align (completely fulfilling), merely (hardly), or not with the obligations and sociomathematical norms (Yackel & Cobb, 1996) co-constructed in the mathematical spaces they share (normative identities). These obligations imply a control or distribution of authority (to whom, the persons in a space; and about what, actions or concepts in that space) in their mathematical learning and agency (Cobb, Gresalfi, & Hodge, 2009). I understand agency as a reactive and proactive self-efficacy process, “beliefs in one’s capabilities to organize and execute the course of action required to produce given attainments” (Martin, 2000); agency being either conceptual—advancing human action—or disciplinary —linked to discipline structures, formal procedures—(Boaler, 2002).

Finally, as mathematics learning and identity develop by doing and thinking, and these are linked to speaking (Vygotsky, 1978), and so the use of language is connected to identity (Brisk et al. 2004; Cashman, 2008). The connection of language and mathematics becomes relevant as one enacts and makes meaning of life situations inseparably from who one is. Thus, I envision bilingual identity as a set of recollections on experiences and beliefs from intimate and socialized events about language skills, and a sense of value on one’s linguistic preference.

Key Themes and Results

I present results on students’ mathematical identities in tree sections: 1) in different contexts, 2) in different perspectives, and 3) different languages. I describe and contrast students’ identities as they are depicted through their narrative and discursive identities.

Development of mathematical identities in two contexts:

Students’ descriptions seemed to juxtapose their experiences in each context. For ‘Context’ I refer to the relationship between a setting and how participants interpret it (Moschkovich &
Brenner, 2000). Students distinguished context in three main dimensions: (a) the quality of interactions, (b) the access to resources, and (c) the quality of mathematics.

(a) Students asserted that the nature of interactions they had in each context mediated the meaning and quality they saw for each context. Partly it relates to the number and the kind of adults they worked with in each setting. Graciela (G) asserted having enjoyed working with older people—their UGs (undergraduate facilitators,) because they are not only “cool and popular,” but also they understand them and being able to speak about “outside school stuff:”

F (facilitator): So you just think that with the UGs you can talk about things at another level?
G:  Yeah, it is like having an older sister that I never had. Se siente bonito porque nos tienen confianza.

It seems that the level of trust with the UGs is connected to a greater level of intersubjectivity that they share with students, maybe due to a similar age. While with teachers there was a gap connected to the school structure. Similarly, Letty (Ly) and a friend (A) argued a qualitatively different attention from classroom teachers:

A: Because teachers do not really . . . , okay when they give us a problem, they just say to do it. They do not really ask us, they ask us if we need help when we are doing the work. We usually need more time, I do not know more information about what is it going to be about. You are usually there and if you understand fine, and maybe it is going to take a different way.
Ly: Yeah, they say you can ask them, but then when you ask they say: “Why weren’t you paying attention!!!” yeah…But here the UGs see if I really get it.

Students reported a more formal mathematics environment in class, where they had less of a central role and less support during the meaning making process in mathematics; aspects that seem connected to the type of negotiation that students had access to as well as to the level of authority exercised by the teacher. These circumstances transferred to unproductive dispositions about the way they did mathematics in their classroom. Contrarily, they seemed to identify with the normative identity at Los Rayos, and noticed different mathematical support, generating different dispositions about the context and themselves. Rolando and Ramón reported themselves interacting differently where mathematics is part of their social interaction and vice-versa. Letty said “at school we really get to speak to each other only during lunch time.” Conversely to classroom practices, . . . these interactions involved specific distribution of authority, collaboration, problem solving, discourse, meaning making, and fun— their sociomathematical norms. Students engaged in various games that nurtured relationships among themselves and their interest in mathematical concepts. Students enhanced their understanding on the underlying mathematical concepts by manipulating and playing with them. Thus interaction patterns in afterschool nurture networks across and within generations around mathematics.

(b) Students described differently accessing resources, materials (e.g., manipulatives) in each setting. Ramón and Rolando contrasted their experiences based on their opportunity for choices:

Ramon:  In class the teacher picks the groups, but in CEMELA we pick our own.
Rolando: Yeah, in CEMELA we can choose our friends and whatever we want to use.
Ramon: Yeah, in class we just have paper and stuff.
C (facilitator): Are you saying that you cannot use manipulatives like blocks, calculators and stuff in your class?
Ramon: Yeah, but the teacher decides when, then we just got pens and paper.

Students deemed relevant not being able to access materials and friends as resources, but also choosing when to access them while working in mathematics. Los Rayos capitalized on students’ choices by not only having them select their resources, but also the tasks they wanted to work on. Thus, students asserted different distribution of authority and negotiation in each setting: facing passive-active roles on decision making, and open-limited access to resources. Schoenfeld (1985) declares selection of heuristics in problem solving nurtures metacognitive development.

(c) Students also expressed they engaged in a different kind of mathematics in the afterschool. One way was about the role of control in each setting especially to whom students were accountable. Ramón and Rolando described having a critical role by being accountable to each other in the afterschool, arguing for a collaborative process and exercise of conceptual and disciplinary student agency in mathematics; while in the classroom, the authority and control resides on the teacher. Similarly, Rolando characterized his mathematics experiences in class as “boring”, thus limiting the development of productive dispositions towards engaging and becoming a problem solver. In a way, he negotiated these practices by resisting them. During the second interview, Rolando role played what he meant by boring, he stood in front of the blackboard asking me to copy what he wrote (i.e., 5 x 1 = 5, 5 x…, etc.). And when he role played Los Rayos’ math, he constructed a small clay dinosaur and compared it with a taller toy dinosaur and asked me: “How many times it [small one] needs to grow to become as big as this one [tall one]?” He solved it by developing a multiplicative structure. He affirmed it was fun math: “you do something not only numbers and reading; you talk, make, and learn;” a ‘dance of agency’ (Boaler, 2002).

The rest of cases coincided with Rolando’s perspective. Furthermore Graciela, who was consistently a high-performing math student in their class, argued that math started becoming different to her when she joined Los Rayos; this transformation was connected to discovering and experiencing mathematics with comfort and enjoyment. Finally, Candy developed an activity creating various perimeter/area designs—which she argued having learned in class:

Candy created “a flying snake.” She did not want to find out the perimeter because it was too difficult, so she only found the area. She used a strategy of grouping and counting cubes by colors and even though she was finding the area, she added. So, there was no presence of the previous rule/formula she mentioned. Alma suggested getting the area by multiplying chains of blocks that were the same length (CL field note).

Though she brought this math content from class, she not only ‘rehearsed’ and ‘played’ with it, but she deconstructed and recreated it widening and exploring its applications and concepts.

Summarizing, students seemed to have developed “a particular relationship with the discipline of mathematics” (Boaler, 2002, p. 10) and with each other at Los Rayos, which differed from mathematical practices associated with the classroom: ways of reasoning, arguing, and symbolizing mathematical ideas (Moschkovich, 2004). Thus, students indentified two ways of doing and relating to mathematics, two parallel rather than intersecting mathematical identities.

A regular school teacher during an interview commented: “Los Rayos helped kids to strengthen
their self-esteem...these students take leadership roles in the classroom. I think the UGs provided lots of strategies, it’s like what Beth Warren says about the hidden curriculum.”

Development of mathematical identities in two perspectives:

Although all student cases described having productive dispositions about the mathematics in the afterschool and taking different leadership roles; still some students reported having, belonging to a marginal participation in mathematics:

C (facilitator): How do you share your strategies and solutions in class?
Ro: I don’t know, then the teacher just asks... I just ask Graciela, she always knows, and then she tells us.
C: But you can have your answer, right?
Ro: The thing is that we ask them [pointing to Ramón] because they are so smart. They have like a big, big, big brain. They are like the fastest. And us [pointing to another male peer], ours are like dead!

As Rolando (Ro) detached himself from the practices promoted by his teacher, he also declared having certain difficulty understanding the task, consequently he willingly relied on others’ reified (Graciela and Ramón or the teacher) positions—having a more central role in the mathematical practices; at the same time, it seemed to inform his beliefs about himself—belonging to more a marginal role and with less disciplinary agency. It seems that the socialization and reification of certain roles in his regular class may have been internalized and used as a way to consistently identify one another. Nevertheless, Rolando claimed that that social construction and structure of performance trespassed settings, privileging some and excluding others—like him—in mathematics (Cohen, 2000): Ramón “sometimes gets to do all the work” in the afterschool. Even though Rolando identified a pattern across contexts, he seems bothered by that privilege in the afterschool and not in the classroom. In fact, Rolando took up leadership roles at Los Rayos. At the end of the program, when Rolando 6th “tutored” 3rd graders, he made various tasks; these showed not only what Rolando knew, but the math he thought as “fun.”

Letty’s CEMELA/ Los Rayos evaluation
I enjoyed Cemela because we made panekillos and we have a party and I made muffins. I love Cemela. I love myugs. I love the way we tried the muffins. Ilike math. From what Ilove games, I love the way we add are marble. Ilove mino and party. I love the way they teach me. Ilove the teachers.

Graciela’s CEMELA/Los Rayos
I enjoyed Cemela a lot. My favorite thing was that we did cupcakes and got to learn more math and I love to talk to Miriam when we had problems. She would help us. I loved the games we did and the trip to the fire station and the digital movies and we wish you guys.

Figure 1. Students’ write-ups

These conflicting perspectives in Rolando’s case are similar to Letty’s, who also took active roles doing mathematics in the afterschool. For example, during a recipe project she changed the mathematical course of a project by making claims based on realistic considerations about the measurement proportions they were using. Despite some episodes of ownership, there was a disconnection to their self-perspective. In a way, they engaged in these tasks, but they did not

Chapter 3: Affective Issues and Learning

exactly see themselves engaging with mathematics, but just with an activity with math as a functional tool. Thus, they associated the meaning of belonging to the activity, but not to the mathematical practice. To illustrate these perspectives I use two students’ write-ups, as illustrated in Figure 1.

Even though these students worked continuously together, notice how Letty contrasted every practice as either ‘loving’ or ‘hating’ it; and locating math in the latter category. Graciela’s write-up partly resembles Letty’s; however, she pointed: “got to learn more math.” So, as Graciela loved the projects, she learned/loved the math. Participants—though in the same task and context—developed subjectivities and connections to mathematics at different levels. Cohen (2000) informs status carries over settings, here it seems about connecting meaning and status to belonging, a transferability of a fixed experiential identity. This perspective could be related to students’ mathematics definition. Perhaps Letty’s is what she hates: a decontextualized, formal subject demanding disciplinary agency. While Graciela’s includes a broader definition: “math with a fun side.” In any case, situations call for reconsidering students’ experiences, not only on what and how they are imagining their participation (Nasir, 2002) but with what perspective.

Development of mathematical identities in two languages:

Although students spoke either language in the afterschool, English dominated, but in some projects students used more Spanish (e.g. recipes); a plausible explanation is that those projects drew more from home-related experiences. Regardless of student’s discursive language preference, overt negotiation of language was tensional. Students’ language choices appeared to give students different identity perspectives aligning—or not—to powerful (English) or less powerful (Spanish) paradigms. For example (italicized text has been translated from Spanish):

Ramon: [reading] that are common to the circle and the pentagon, but not in the triangle or the rectangle
A: Do it [read] in English!
J (facilitator): He can do it however he wants. He can do it in English or Spanish.
A: I can’t understand him!
J: [to Ramon] Can you tell him what you mean?
J: [to Ramon] Ok, let's take a look at it. That are common to the circle and to the..., what is it?
A: Read it in English!
J: [to A] I will.
[to Ramon] But not in the triangle or the rectangle. Does it mean that it is ...

Students’ demand to use English often resulted with facilitators switching to English sometimes during the rest of the activity. Conversely, instances demanding Spanish never emerged. The argument here is not whether students choose one language or the other, but that the process represents a much contested space, in which the dynamics are likely to privilege the dominant paradigm, English. In this regards, all students reported “having to speak Spanish at home because their parents do not speak English.” Their statements deemed a necessity to justify using other language than English at home. Students used verbs implying obligations rather than an option or an asset. Twelve out of fifteen students from the afterschool self-reported higher fluency in English. Consequently, students privileged a disciplinary agency by identifying with the dominant language, though they were in the position to pick both languages.
Conclusions

Students’ narrations and actions asserted experiencing differently the interactions in each space: Los Rayos and regular classroom. These dimensions included reconsidering the perspectives of students in learning, interacting, and being; thus becoming bilingual mathematical learners. It is argued that an education that honors the diversity of Latino students’ experiences is constructed on a genuine knowledge of their real identities—not those projected onto them (Gutiérrez, R., 2002). This tensional space may illuminate new realizations about what it means to promote and support students’ bilingual resources. Perhaps it goes beyond simple assumptions of providing bilingual translations and having bilingual facilitators and students in educational contexts. I argue for a re-consideration of the connection between language, learning, social spaces, mathematical practices, and students’ identities and perspectives, so we may promote students’ more genuine motivation and engagement in mathematics, where goals, identity, and learning intersect (Esmonde, 2009; Nasir, 2002).

MANIFESTATIONS OF MATHEMATICAL INVENTIVENESS IN AT-RISK (IMMIGRANT) HIGH SCHOOL STUDENTS PERFORMING ARITHMETICAL CALCULATIONS

Daniel Clark Orey
California State University-Sacramento
orey@csus.edu

The paper reports a research inquiry with 40 mathematically disadvantaged high school students in Israel, including 30 students who indicated that their first language was Russian. The data constituted the students’ responses to the Algorithm Collection Project Questionnaire and videotaped task-based interviews with seven students. We looked at the students’ computational strategies through the lens of the concept of relational creativity or inventiveness and inquired which conditions might stipulate its manifestations. We argue that though mathematical knowledge of the participants was weak, their thinking bore signs of such creativity-related constructs as flexibility and relative novelty.

Introduction

The invention of a new problem solving method or algorithm is one of the essential manifestations of both absolute and relative mathematical creativity (Silver, 1997; Shye & Yuhas, 2004). The distinction between absolute creativity and relative creativity (Leikin, 2009; Liljedahl & Sriraman, 2006) is rooted in the observation that an adjective "new" can be utilized for characterizing a problem solving method or an algorithm in two different meanings. In the absolute meaning, new means that one’s mathematical product is unknown and can be essential for mathematical community at large. In the relative meaning, a mathematical product is new mostly for a person or a group who created them (Leikin, 2009). The development of the relative creativity in all students is being nowadays considered one of the most important objectives of school mathematics education (e.g., Leikin, Berman & Koichu, 2009; Sriraman, 2008).

Creativity may be manifested only in response to a challenging task that cannot be otherwise solved (e.g., Shye & Yuhas, 2004). Shye and Yuhas (2004) wrote that a person, when faced with a challenge, tackles it in the simplest and most straightforward way, in a sense he or she utilizes mental functions. Similarly, Koichu and Berman (2005) and Koichu (2008) suggested that human beings solve challenging problems in accordance with the principle of intellectual parsimony, i.e., the tendency to minimize intellectual effort. According to Shye and Yuhas (2004), a mere recall method of solution is a low mental function associated with problem solving. If an appropriate method cannot be straightforwardly retrieved from the memory, the would-be solver tries to infer the solution from some known examples that can be considered analogous to the given problem. Finally, if no recalled or inferred method can help to solve the problem, the would-be solver may turn to inventing a new method or a new kind of analogy by raising very openly a number of ideas. This process constitutes the essence of creative or inventive thinking.

Goldin (2009) asserted that inventiveness can be manifested in an emotionally safe environment where students’ mistakes, problem solving impasses, and criticisms of one another’s ideas are not avoided or downplayed, but come to be regarded as the productive outcomes of bold and praiseworthy intellectual efforts.
Performing arithmetical tasks as an arena for manifestations of inventiveness

Performing arithmetical tasks by high school students is rarely seen as an arena for manifestations of inventiveness. In part, this is because all students are normally expected, when in high school, to fluently perform basic arithmetic calculations and understand their meaning (OECD/PISA, 2006). However, extensive research teaches us that this is not the case. For example, Clarke, Clarke and Horne (2006) found that by the end of Grade 6 less than 60% of students were able to perform arithmetic exercises with multi-digit numbers by any mental or pencil and paper method; Thomas (2002) reported that 47% of 14-year old students thought \(6 \div 7\) and \(6/7\) were not equivalent.

The availability of calculators in high school can partially camouflage the deficiencies in students' arithmetical knowledge. Consequently, the request to perform a multi-digit arithmetic computation without the use of a calculator may constitute a challenge for many high school students. Further, one can argue that computational tasks are comprehensible for the majority of high school students. Indeed, arithmetic tasks are brief and contain few words. The considerations of briefness and clarity of the tasks are especially important when the first languages of the students differ from the language of schooling, as in our study. Often the need or ability to compute mentally in their native language aids in accuracy and fluency.

For all these reasons, we considered computational tasks both feasible and challenging for mathematically disadvantaged or at-risk (immigrant) students and decided that such tasks are appropriate for exploring the students' inventiveness. Specifically, this report focuses on two interrelated research questions:

- How do the mathematically disadvantaged (immigrant) high school students utilize standard computational algorithms when working on which for them may be challenging arithmetical tasks?
- Which calculation methods do the students invent in cases that they cannot (or prefer not to) utilize standard computational algorithms?

Method

Participants

Forty 12th grade students, 22 boys and 18 girls, took part in the inquiry. On average, the students were 16.7 (SD=0.57) year old. The students studied mathematics at the lowest (one credit point) level in a school situated in underprivileged urban area in Northern Israel. The socio-economical status of the students' families is described as low to average. Thirty students indicated that their first language was Russian, and 10 students – Hebrew. Hebrew was indicated as an additional language by 26 students. Thirteen students were born in Israel, and the rest – in the countries comprising the former USSR. Many of the students were actually bi-lingual, however, for the sake of clarity the students who indicated that their first language is Russian or Hebrew are referred to as Russian-speaking students and Hebrew-speaking students, respectively. The seven students who took part in the interviews represent well the entire group in terms of gender, language and educational history.

Instruments

During 30 minutes all forty students individually filled-in the Hebrew version of the Algorithm Collection Project (ACP) questionnaire (Orey, 1999). The students were asked not to use calculators and show their work on the questionnaire sheets; those who had difficulties in understanding Hebrew instruction were provided explanations in Russian. It was explained to the
students that their questionnaires were not be graded. The questionnaire consisted of 16 tasks, as shown in Table 1. Note that all of the tasks allow the use of standard algorithms of long addition, long subtraction etc. Simultaneously, the tasks are chosen so that computational shortcuts can be implemented. In addition, the order in which the tasks are given is designed to see whether the students would use the result of the previous calculations in the next ones.

Table 1 also presents the percentages of the correct answers to the ACP questionnaire; 40 is taken for 100%. Only seven students correctly responded to all 16 APC exercises, 6 students – 13-15 exercises, 17 students – 10-12 exercises and 10 students – between 5 to 10 exercises. These findings are in good agreement with past research (Clarke, Clarke, & Horne, 2006). They show that the questionnaire was not too simple for the majority of the participants and that most of the difficulties were related to multiplication and division, in general, and to multiplication and division involving fractions, in particular. We did not find essential differences between Russian-speaking and Hebrew-speaking students' rates of success.

The interviews were conducted immediately after the students completed the questionnaire. Each interview took from 35 to 40 min and was done using the first language to ease the comfort level of the interviewees. The interviews were videotaped, and consisted of the following stages. First, the interviewees were asked to reflect on their math experiences in Israel and, in the case of immigrants, in their country of birth. We then asked them to talk us through several ACP questionnaire problems. Specifically, the students were asked to explain their computational strategies and to deliberate when and how they had learned them. The chosen conversational interviewing methodology (Patton, 1990) enabled us to probe for answers, while taking care to be flexible and sensitive to the students' preferences as well as quite supportive when the students found themselves in an unusual position of inventors, and not just persons trying to recall the appropriate methods.

**Results and Discussion**

*How did the students utilize standard computational algorithms?*

Table 2 presents the numbers of students who showed their work as performing long addition/subtraction/multiplication/division algorithms. The numbers of students who wrote anything in response to an item is given in parenthesis. For every item, the difference between the second and the first number represents the number of students who only wrote the final answer or made brief notes suggesting that they had used some form of mental calculation or computational shortcuts.

The first observation from Table 2 is that the numbers of responses were decreasing from 40 for addition tasks to less than 25 for the last two division tasks; the most abrupt change in responses is from 36 (for $203 \cdot 6$) to 28 (for $23.16 \cdot 2.5$). We suggest that for some of the students who did not have a clue how to calculate the latter exercise, it created expectations of failure also
from the rest of the questionnaire. Thus, it is possible that at that stage several students decided to skip the rest of the questionnaire or even to cheat in order "to maintain face" (cf. Schorr et al., 2008). This hypothesis is strongly supported by the interviews. For example, Luda, one of the Russian-speaking interviewees, confessed that she fairly approached most of the exercises, and cheated when solving the task $0.37 \div 3$. Note that such a confession became possible only when an atmosphere of trust was developed in the interview.

The second observation is that the number of students who consistently used long-calculation algorithms varied throughout the questionnaire and appeared to be the lowest for the division exercises. The first two addition and subtraction exercises were calculated mentally by about 45% of the participants, and the third and forth addition and subtraction exercises – by about 38%. For example, Becky, a Hebrew-speaking student, calculated the first and the second addition and subtraction exercises mentally ($4001+199=4000+200=4200$) and used the long algorithms in order to calculate the third and the second ones. She explained in the interview that she could calculate all the exercises mentally, but for situations like 295-86 it was easier for her to use the long-calculation algorithms. This finding means that Becky had two available strategies for the addition and subtraction exercises and chose one of them, apparently, in accordance with the principle of intellectual parsimony (Koichu, 2008).

Which calculation methods did the students invent?

It seems that many students did not have much choice when it came to multi-digit multiplication and division exercises. Some of them merely did not remember the algorithms and tried to invent computational shortcuts or approximate the results, and the others implemented only the algorithms.

Michel, a Hebrew-speaking student, calculated all multiplication exercises using the repeated addition scheme. For example, she calculated 203 times 6 in two steps: $203+203+203=609$; $609+609=1218$. The intermediate additions were done by the long addition algorithm, so some measure of flexibility and inventiveness, though rooted in her lack of knowledge, can be seen in her calculations. She also wrote that $37 \div 3 = 12.1$ and explained her method as follows:

Michel: Let's say that you have 37 sticks [she drew 37 sticks]. I now divide them into the groups of three sticks [she crossed out the sticks by three]. How many groups do we have? Twelve [she counted the groups], and one stick is left, so the answer is 12.1.

When asked how she had got familiar with this method, Michel answered that she invented it herself when in elementary school. Four more students obtained the answer 12.1 in that exercise, and, based on the described interview episode, we deem that their mistake (12.1 instead of $12.333\ldots$ or $12\frac{1}{3}$) was of the same origin as the Michel’s one.
Valentine, who had attended elementary school in the former USSR, wrote in the questionnaire only the final answers (11 correct responses). He explained to us that he forgot all the algorithms and invented various effective calculation methods by himself. For example, he mentally calculated $23.16 \times 2.5$ as follows: (i) $20 \times 2.5$, which is $20 \times 2$ and half of $20$; overall $50$; (ii) $3 \times 2.5$, which is $2.5+2.5+2.5$; overall $7.5$; (iii) $0.16 \times 2.5$, which is $0.16 \times 2$ and half of $0.16$; overall $2.40$; (iv) the answer is $57.90$.

We were astonished by his ability to keep in mind all the intermediate results. When asked about this, Valentine told that it is easy for him, but then confessed that some of the intermediate calculations he wrote not in the given sheets but "on the table". Three more interviewees, including two Hebrew-speaking students, indicated that, despite the request to show their work, they preferred to write in the questionnaire sheets only the final answers or "standard" computations. In other words, they declined to show us their private methods of calculations in the format of a written test and agreed to do so during the interviews, when some trust was developed. Looking back, we suggest that some of the 16 students who computed $230 \cdot 60$ by long multiplication as though they had not calculated $23 \cdot 6$ a minute ago, in fact, could know the shortcut but preferred to show us the more "standard", in their opinion, method.

These findings shed new light on the phenomenon described in work by Sfard and Prusak (2005). Sfard and Prusak observed that most of the Russian-speaking students wrote little in spite of the teacher's request to show their work in writing. Their actual learning has been later proven more substantial than that of many Hebrew-speaking students who wrote more readily. The researchers interpreted this phenomenon using the distinction between substantial learning (i.e., learning for inner understanding which is not necessarily shared with the teacher) vs. ritualized learning (i.e., learning by mere conforming the teachers recommendations and requests), and further, in terms of different identities (i.e., narratives of the participants about themselves as learners) of Russian-speaking and Hebrew-speaking students. In our study, the desire for mathematical intimacy and trust seems to be directly responsible for both Hebrew-speaking and Russian-speaking students' sharing behaviors. Note however that the comparison between the two studies is constrained by the fact that Sfard and Prusak (2005) studied a class following an advanced mathematics program, whereas our study's participants were mathematically disadvantaged students.

**Concluding Remarks**

Our inquiry shows that creativity-related constructs, such as flexibility and relative novelty, can be found even when the students demonstrated the lack of knowledge bordering with mathematical ignorance. In line with Goldin's (2009) suggestions, we observed that even mathematically disadvantaged students can be inventive if they succeed to overcome anxiety and anticipation of failure when facing a challenge.

Two potentially powerful, from the creativity development perspective, situations, were observed in the study. The first one occurs when students are in a position to choose the best method from several available ones; this situation potentially evokes the manifestations of flexibility. The second one is when students do not have any readily available method of solving the problem; this situation can potentially evoke the manifestations of relative novelty. It seems that the realization of this potential is stipulated by positive answers to subtle yet crucially important dilemmas of an affective and social nature that students resolve for themselves. Examples of these dilemmas include: "Is it praiseworthy to engage in solving the given task?", "If a solution method is not readily available, is it praiseworthy to keep trying?" "Is it safe
enough to show the invented method of solution?" Consequently, our task, as mathematics educators, is to assure that our students have a fair chance to positively answer these and such questions in our classrooms.

Endnotes
1. We wish to thank Yaniv Biton for his help in making arrangements that made data collection in Israel possible. The second-named author thanks the office of the President at California State University, Sacramento and the Center of Learning Sciences of the Technion who generously supported his travel to Israel.
2. An extended paper based on the results of our study is to appear in Mediterranean Journal for Research in Mathematics Education in 2010.
3. For example, some of the students preferred to be interviewed individually, and others – with a friend; some of them wanted to think in silence before voicing their responses and others were ready to think out loud from the beginning.

CARING AND COMMUNITY IN A COMPLEX INSTRUCTION FRESHMAN ALGEBRA CLASS

Lauren Persky
University of Washington
persky@uw.edu

This study grew from a larger research project supporting teachers’ implementation of Complex Instruction (CI) in secondary mathematics of three urban high schools in a large Pacific Northwest school district. The pedagogy of Complex Instruction (CI) interweaves teacher moves and student participation aiming to form a learning environment of mutual engagement, that is, placing both students and teachers in dual roles as intellectual resources and learners (Jilk, 2007). CI pedagogy lies at the intersection of its three facets: multiple ability curricula, instructional strategies, and status and accountability (Cohen & Lotan, 1997). This study examined secondary students’ mathematics experiences to understand the four affective requirements of caring in community as delineated by Osterman (2000): sense of belonging, membership matters, shared faith, and commitment to group.

Semi-structured interviews were conducted with four students in a mixed-ability algebra class whose teacher demonstrated strong implementation of CI. Interviews were transcribed and coded according to each of the four criteria above. Two examples are provided below.

**Sense of Belonging.** Absolon, a 14 year-old African-American male demonstrated a sense of belonging when he described everyone in his class as a potential friend through learning math. Through interactions with his peers, Absolon expressed that he learned about math, himself, and others, indicating friendships built through the learning process because of a strong sense of belonging to the class.

**Membership Matters.** Tom, a 14 year-old European-American male demonstrated how important his membership was to the class in his desire to help his peers. He insisted that learning was not a competition but rather an opportunity for everyone saying. Membership in the classroom matters to Tom because he sees his role as a learner and teacher, something he both receives and gives.

Further analysis of all participants’ interviews suggested that a classroom with strong CI pedagogy promotes mathematical learning concern for peers’ success—mathematical gains while fulfilling social interaction. This implies mathematical discourse and reform teaching practices can support student relationships with a potential bend towards social justice.

**References**

This poster introduces a re-conceptualization of mathematics curriculum as a mathematical storyline and argues that this conceptualization can enable teachers and curriculum developers to represent the momentum of curriculum, rather than particular moments. This analysis builds from Dewey’s (1902/1998) conception of mathematics curriculum as both logical and psychological, as well as his metaphor of curriculum as a journey, where the psychological layer represents the continuous experience of a journey and the logical layer represents the mapped points along the way.

To understand how the logical and psychological layers of mathematical development may appear in mathematics curriculum, a geometric investigation described by Hofstadter (1992) is presented and analyzed. It is shown that when taken separately, neither the logical nor the psychological layers of his story encapsulate his intellectual and emotional experience. However, when taken together, his mathematical story emerges, which include his mathematical insights, motivations, and emotions. Hofstader’s journey and all of his “logical” conclusions were influenced by his aesthetic desire for balance, surprise, and completeness.

I argue that when teachers craft and enact daily experiences, students also produce mathematical stories that, while different than Hofstader’s, contain both logical (the content) and psychological (their personal connection to the experience) layers. These stories contain a certain level of drama – sometimes very little (which is possibly why many students describe mathematics as boring), and at other times ample, when there is much interest and students feel compelled to move forward. Thus, the story is more than the scope and sequence of the content, which is solely the logical. It is also the way that content is developed and experienced. These stories develop over time – within a task, within a lesson, and over multiple lessons. The curriculum is the progression through these moments: the momentum.

This conceptualization of a mathematical story can inform curriculum developers, who can aim to develop “better stories.” As textbook writers develop and sequence content (the logical), additional attention needs to be paid to the aesthetic experiences intended for the student (the psychological), as well as the continuity that strings the curricular events together. To illustrate, an example of an intended mathematical storyline from a textbook is introduced.

This presentation explores, both empirically and conceptually, the obligations researchers may have to use educative tasks when performing assessments for research purposes, particularly when working in high-poverty, rural schools. The presentation draws on video data of student assessments gathered during the pilot of a three-year longitudinal study. Early analysis suggests that informal activities may provide rich opportunities for both assessment by researchers and learning by students.

Introduction

This presentation emerged out of the pilot year of an NSF-funded, longitudinal study that proposes to follow children’s formal and informal mathematical learning as they move from prekindergarten to first grade in a rural school. Nearly all of the students at the school are African-American and all receive free lunch. In addition to ethnographic work inside and outside of classrooms, the study proposes to formally assess children at the beginning and end of each of the three years of data collection. This assessment process is the focus of this presentation.

Initially, the research team selected items for the assessment protocol (Appendix A) because they had been used successfully by previous researchers to elicit young children’s thinking around number concepts and geometry. As part of the literature review in selecting these items, we found a number of recommendations for teachers about choosing assessments that not only measure children’s learning, but that also create pedagogical opportunities for the children who engage in them (e.g., NCTM, 1991; Wilcox & Lanier, 2000). Although many of the tasks presented by researchers as part of studies about young children’s mathematical thinking had pedagogical features, little attention was paid to this quality and there seemed to be no expectation that questions used by researchers did more than uncover children’s current understandings. That is, children were not expected to know more mathematics after participating in the research. In fact, in many ways, the notion that the assessments themselves teach children is problematic and complicating for researchers who are seeking to describe children’s mathematical learning in relation to some other variable or intervention (a new curriculum, a parent workshop, a teaching strategy, etc.).

In our own study, our initial instinct was to minimize the impact of our assessment sessions so that we could more accurately describe the mathematical learning that goes on in our focal school and surrounding community without the intervention of university researchers. However, as we talked more about our particular context – an isolated, high-poverty school with few opportunities for teacher professional development and a back-to-basics curriculum, we began to wonder if we had an ethical obligation to foster, rather than minimize, opportunities to intervene in students’ mathematical learning through our assessment process.

Purpose

In this article we will address two questions:

- How can researchers balance ethical obligations they have as educators while preserving the integrity and validity of their research?
- What kinds of assessment questions and tasks are most likely to be productive for children’s mathematical learning?

The first of these questions we explore conceptually, examining previous thinking on researcher roles. This occurs in the perspectives section of this paper. The second question we explore empirically in the second half of the paper, examining video data from the pilot study for evidence of opportunities for mathematical learning. The goal of the presentation will be to solicit feedback on the research team’s decisions in relation to both of these questions in order to inform the official launch of the three-year data collection period.

Perspectives

Ethics of Involvement

For some time now, qualitative researchers have concerned themselves with the ethics of involvement with their participants, concerning themselves with the impact of involvement on the integrity and validity of the research (Bogdan & Biklen, 2003; Douglas, 1976) as well as the moral obligation that researchers may have to make a positive contribution to the lives of their participants (Duneier, 1999; Taylor, 1987; Weis & Fine, 2000; Whyte, 1992). As researchers, we found ourselves struggling over this dilemma. The expressed goal of the project is to document the mathematical learning of young children in their school and home lives. To do this, we planned to observe children in their school and homes and to conduct formal assessments periodically. In crafting the assessments, we debated whether we ought to design tasks where the goal was only to reveal the mathematical learning taking place in the home and school settings or to design tasks that would create opportunities for children to learn math, potentially in different ways that those they were exposed to in the home and school. The argument for teaching seemed particularly compelling in this setting where the adopted curriculum of the school system focused on memorization of numbers and shapes and, later, on test-taking skills, rather than on mathematical reasoning and problem solving. We reasoned that interactions with the research team might provide one of few opportunities for children in the study to engage in more sophisticated mathematical thinking and could potentially provide an opportunity to teach mathematical play that students could adopt productively in their homes and their classroom.

However, we did not make the move toward intervention lightly. A number of researchers have noted that continued observation of troubling practices, even including abuse, allows researchers to document conditions in schools and institutions in ways that may lead to broader and more systematic changes than intervening only in the site of research (e.g., Bogdan & Biklen, 2003; Taylor, 1987). Furthermore, the conditions at the proposed research site in our study in no way approached the level of abuse. Children were generally happy and treated kindly by their teachers. However, the back-to-basics mathematics curriculum significantly limited children’s opportunities to learn and attempts to alter this may unwittingly paint too positive a picture of the learning at this rural school serving poor children, which in turn, might make broader curricular interventions as a result of the research findings less likely. From this perspective, the argument would be to use assessments that impacted children’s learning as little as possible so as to most
accurately report the learning opportunities available in the natural settings of the school and then to use these research findings to argue for broader change.

Ultimately, we decided against trying to claim validity by limiting our interventions as much as possible, in part because of the impossibility of non-intervention. Bogdan and Biklen (2003, p. 35) argue that because researchers cannot study participants’ lives in a natural setting, they instead much use their rich knowledge of the social context to interpret “what they actually study – ‘a setting with a researcher present’.” Following this thinking, our research team decided that even questions designed to be unobtrusive would, in fact, intervene in the lives and the mathematical thinking of the children we intended to study. Given this, we decided that the risk to the integrity and validity of our data – our representation of what the children at this site knew and could do mathematically – was not as significant as the ethical obligation that we had as people with financial, educational, and mathematical resources to offer opportunities for learning to the children we encountered. Drawing on Bakhtin (1993), we decided that we were answerable to the children and their parents in the moments of our interactions with them as well as to the broader researcher community and to children in other contexts. At the same time, we acknowledge a need for us to carefully record and analyze ways that our own engagements with the children may shape their mathematical performances in other contexts (in the classroom, with parents, etc.). We anticipate that our plan to collect data in many sites will help to place these assessments in an appropriate context.

Research and Assessment Tasks

Once we decided that we would attempt to maximize, rather than minimize, our child-participants’ opportunities to learn mathematics through our interactions with them, we needed to find assessment tasks that would both appropriately uncover children’s thinking around number and geometry (the focus of the larger study) and create opportunities for further thinking. Appendix A lists our original list of tasks. We included a number of tasks that asked children to count in various ways (orally and in writing, with and without objects, forwards and backwards) and tasks that asked children to identify and describe shapes because these tasks are common in the research literature (e.g., NRC, 2005; Saxe, Guberman & Gearhardt, 1987; Thompson & Van de Walle, 1980). However, once we began to consider the educative properties of tasks, we found some evidence that these counting tasks may not help children develop skills and understandings that transfer to other contexts (Aunio, Hautamaki, & Van Luit, 2005). At the same time, we found no literature on the use of games as assessments, but found a few articles that described children’s productive interactions with mathematical games in other settings (e.g., Anderson & Gold, 2006; Ramani & Siegler, 2008). We decided as a result of this work to include games in our assessments and also decided to add puzzles. Again, the use of puzzles was uncommon – although not unheard of -- in the assessment literature of young children. We hoped that they might present the same sorts of productive opportunities as game playing (e.g., Clements & Battista, 1992; Hannibal, 1999). Overall, based on the literature on assessment aimed at teachers, we decided to evaluate the proposed tasks in the pilot based on their ability to produce interactions that other researchers and teachers had found to be pedagogically productive, including those that promoted dialogue, encouraged students to ask questions, offered students opportunities to manipulate materials (Schwerdtfeger & Chan, 2007; Zack and Graves, 2001).
Modes of Inquiry

This study draws on theories that see learning as participation in social contexts (e.g., Greeno, 1997; Lave, 1988; Lerman, 2000). From this perspective, as Lerman (2000, p. 26) noted, “knowledge has to be understood relationally, between people and settings: it is about competence in life settings.” Thus, mathematical knowledge and learning cannot be seen as fixed or as easily summarized. Instead, mathematical learning is seen as evidenced in enacted practices related to the discipline of mathematics in a variety of social settings. For this presentation, we are concerned with a small part of the larger study: children’s mathematical performances during formal assessments.

The site of the study, Oliver County Public School (a pseudonym) is a PK-12 school in central Georgia with fewer than 300 students. The county does not have a single stop light, fast food restaurant, or pizza parlor. Most of the students are African American, and, because so many students qualify for free lunch, the school decided not to charge any of its students for meals. These characteristics make it an ideal setting to study the mathematical learning of underrepresented students in a rural (as opposed to the more-commonly studied urban) context.

At the same time that we were piloting observation instruments in the classrooms, we also used the tasks described in Appendix A with a small group of children in preschool, kindergarten and first grades, the three grade levels that we intend to follow children through in the larger study. We planned to have five children in each grade level respond to the tasks (about one-third of each class) over the course of two months. We video taped these interactions for analysis and presentation later. Our discussion of the results focuses on what children did and said during these formal assessments, actively acknowledging that they in no way summarize all of the mathematical performances of which the children were capable.

Assessment interviews took approximately 20 to 30 minutes, depending on the age of the child. Not all the tasks in the assessment protocol were used in each interview, although all tasks will be used at least three times. Interviews took place in the school library with the first author. The video recorder was placed on a tripod.

Technology designed for examining video segments was used during analysis. The Video Analysis Tool (Recesso et al, 2008) allows researchers to identify and code small segments of video tape. For this presentation, the research team developed codes related to mathematical learning around number, geometry, problem solving, and representation. In addition, codes were developed to identify qualities of engagement with the task based on previous research. The research team identified instances of conversation and silence, active use of materials and reluctance, and volunteering of questions and thoughts. Segments of tape were then sorted by the codes for analysis.

Because data collection and analysis will be on-going throughout the spring, the results presented in the following section are preliminary. A major goal of the presentation will be to share video data with other researchers and to solicit feedback.

Results

We began our pilot assessments with the current preschool students so the results reported here come from just this classroom. Many of the school-like tasks in interviews seemed to produce little engagement and conversation from students. In most cases, students completed the tasks and we were able to determine something about their knowledge of number or geometry in this setting. However, in most cases they seemed uninterested in continuing a conversation about the problem or in continuing to work with the materials. Many of the counting tasks engendered
a great deal of silence such as in the following episode. Amy had previously asked D’Andre, a prekindergarten student, to count by 1s out loud, which he did to 29, skipping 17. Then she had him place number cards in order from 1 to 12. He did this correctly and silently.

She then gave him 5 green cubes and asked him to count them. He began to tap on the table with the cubes like a drum stick.

Amy: Can you tell me how many you have there?
D’Andre: 4 seconds silence
Amy: Can you count them?
D’Andre (pushing the cubes on the table like a train) 6 seconds silence
Amy: How many cars are in your train?
D’Andre: (pointing to each cube and whispering). 1,2,3,4,5.

Ultimately, in this episode, Amy persuaded D’Andre to perform the mathematical task that she intended, but the process produced little pleasure for her or for him. In fact, in the face of his disengagement, Amy decided to end the interview early rather than continue to push him.

One exception to the predominance of silence in these counting tasks occurred when Amy asked one of the boys to count plastic dinosaurs instead of bears in a counting task. He continued to play act with the dinosaurs for a few minutes and wanted to take them with him; however, the conversation was not mathematical. In fact, when we observed the boys playing with these dinosaurs later in the classroom they made “families” with them and used them to hunt, but did not engage in either counting or sorting activities.

In these early assessments, Amy alternated playing Hi-ho the Cherry-O and Cadoo with most children at the end of the assessment. These interactions seemed to produce more interest and conversation on the part of the children than the other traditional academic tasks, although the less familiar children were with the games, the less this was true. Explanations and corrections related to the rules of the games seemed to reduce spontaneous interactions.

In Hi-ho the Cherry-O, players put ten plastic cherries on their trees. During each turn, players spin a spinner, which has “good” spaces that show one, two, or three cherries and “bad” spaces that show a dog, a bird, and a bucket tipping over. When the spinner lands on a picture of the cherries, the player removes that many cherries from the tree. When the spinner lands on the bird or the dog, the player replaces a cherry from the bucket. The tipped over bucket space requires that the players take all their cherries from their bucket and replace them on the tree. The first player to take off all ten cherries wins.

Unlike in the more school-like tasks, children volunteered information about their counting and thinking when playing games. For example, Candace spoke after each of her turns, exclaiming: “I get to take 3 more off” when she spun the space with three cherries or noting, toward the end: “I’m going to win. See, I got one left.” She made this second statement after the spinner landed on the space with two cherries, but before she actually removed them. Thus, she was able to quickly look at the space and recognize that it meant “two,” look at her tree and imagine taking two away from the three cherries that remained and realize that only one cherry would remain. This sort of problem solving is very similar to the kind of thinking we were trying to get at in the interview when children were asked to solve problems with cubes, bears, and dinosaurs.

At this time, we are still continuing to search for tasks that afford students with opportunities for genuine talk and engagement with the mathematics and a way of providing more possibilities.
for us to access mathematical knowledge and for students to learn more about mathematics, particularly problem-solving and reasoning. To this end, we are trying out puzzles and spatial reasoning games in the assessments scheduled for the fall.

Discussion

As a research team, we became persuaded that we had an obligation to make sure that our interactions with children were as productive for them as possible in addition to meeting our goals as researchers. Our initial piloting of the tasks suggests that game-playing and puzzle-completion may provide rich sites for assessing children’s mathematical knowledge in ways that are more pleasurable for them and which, therefore, might be more likely to promote positive feelings toward mathematics as well as a desire to engage in more of these mathematical experiences. We plan to continue to experiment with putting more traditional assessment tasks in the middle of game-playing or puzzle events, hoping that we may create an environment where children come to see these other tasks as pleasurable. In addition, we plan to make our assessment materials available to children in their classrooms to see if they choose to use them at other times of the day.

In addition to meeting the needs of the children, we have begun to wonder where assessments embedded in games might be quite useful to us as researchers. Although there is much less standardization in a game and it requires more analysis to identify mathematical thinking, it provides a slightly less formal context for observing children. Many studies about the mathematical knowledge of young children have depended on children’s completion of tasks in formal interviews (e.g., Saxe, Guberman & Gearhardt, 1987; Thompson & Van de Walle, 1980). We have begun to wonder whether interviews that are based on games rather than formal tasks might shed new light on what we believe children, particularly non-majority children, can and cannot do mathematically and look forward to exploring this question in our own work and in conversations with others.

COMMUNICATING QUANTITATIVE LITERACY

Karl W. Kosko
The University of Michigan
kwkosko@gmail.com

Jesse L. M. Wilkins
Virginia Tech
wilkins@vt.edu

Quantitative Literacy (QL) has been described as the skill set an individual uses when interacting with the world in a quantitative manner (Steen, 1999). A necessary component of this interaction is communication. To this end, assessments of QL have included open ended items as a means of including communicative aspects of QL. The present study sought to examine whether such open ended items typically measured aspects of quantitative and/or mathematical communication or of mathematical skill. Results indicated that the proportion of items in QL assessments measuring aspects of mathematical skill was significantly more than items assessing aspects communication.

Introduction

Quantitative Literacy (QL) has become a topic of increased focus at both the national and international level in the past thirty years. Sometimes referred to as quantitative reasoning, mathematical literacy, or numeracy, QL focuses not on an individual’s mathematical skills but on their ability to interact with the world around them in a quantitative manner (Steen, 1999). This characterization of QL can be found in many supporting documents in the past 30 years. However, one element of these characterizations often mentioned but seldom discussed is that of communication itself. Further, there is little to no supporting research that examines the communicative aspect of quantitative literacy. However, several well known large-scale assessments have evaluated QL using open-ended items. These open-ended items can be viewed as opportunities to assess communication in QL. In an effort to examine the state of communication in QL, the current study examines how these large-scale QL assessments examine responses to open-ended items for communication.

Theoretical Perspective

Communication in Quantitative Literacy

In 1982, the British government published a report titled Mathematics Counts, or the Cockroft Report. This report is perhaps the first major modern report describing the importance of QL, or numeracy as called in Britain. The report provided several statements on the mathematics education in Britain and the level of numeracy of its citizens. One such statement reads:

We believe that all these perceptions of the usefulness of mathematics arise from the fact that mathematics provides a means of communication which is powerful, concise and unambiguous. Even though many of those who consider mathematics to be useful would probably not express the reason in these terms, we believe that it is the fact that mathematics can be used as a powerful means of communication which provides the principal reason for teaching mathematics to all children (Cockroft, 1982, p. 1).
Later describing the specific characteristics of numeracy, the Cockroft Report (1982) reemphasized the importance of communication in the definition of what it means to be numerate, or quantitatively literate (p. 11).

The Cockroft Report was followed by other documents in the United States. One of the most influential for mathematics education (and QL) was the *Curriculum Standards for School Mathematics* published by the National Council of Teachers of Mathematics (NCTM, 1989). Unlike the later 2000 standards, the 1989 standards purposefully discussed the concept of QL and identified five goals or requirements for students to obtain a degree of mathematical power in terms of being numerate. Among these was learning to communicate mathematically. Further describing what it means to communicate mathematically, NCTM stated: The development of a student's power to use mathematics involves learning the signs, symbols, and terms of mathematics. This is best accomplished in problem situations in which students have an opportunity to read, write, and discuss ideas in which the use of the language of mathematics becomes natural. As students communicate their ideas, they learn to clarify, refine, and consolidate their thinking.

Within the same year that the 1989 NCTM standards were released, the National Research Council (NRC, 1989) published the report titled *Everybody Counts*. *Everybody Counts* characterized QL as a type of number sense that evolves from “concrete experience and takes shape in oral, written, and symbolic expression” (p. 47). The report further emphasized the need for problem solving approaches to be described orally and in writing.

The excerpts from each of these three reports characterize the communicative aspect inherent in QL. A quantitatively literate person is described as demonstrating the ability to communicate in a quantitative way. By the descriptions from these earlier publications, mathematical communication is an aspect of QL. Logically, it follows that since communication can be considered a demonstrated aspect of QL, then QL can be measured by an individual’s ability to communicate quantitatively.

Following the release of the NRC and NCTM publications, several international and U.S. assessments made strides to measure QL. These studies included the Third International Mathematics and Science Study (TIMSS-95), the National Assessment of Adult Literacy (NALS) in 1985 and 1992, the International Adult Literacy Skills (IALS) beginning in 1994, and the Program for International Student Assessment (PISA) beginning in 2000. While none of these studies limited themselves to QL, each assessed it and as part of their assessments used open-ended items. Including open-ended items encourages written communication on the part of the test taker.

The national and international assessment of QL was accompanied by a host of literature. Similar to the reports published in the 1980’s, the newer literature continued to emphasize the importance of communication in QL. Cobb (1997) characterized QL as requiring “a difficult integration of four very different kinds of thinking. This makes it a kind of cognitive emulsion...that constantly threatens to separate into its more basic forms of thought.” (Cobb, 1997, p. 76). These four forms of QL are: computational/algorithmic; logical/deductive; visual/dynamic; and verbal/interpretive. This last form represents the communicative aspect thus far characterized above. As did NCTM (1989), Cobb outlined communication as one of the main aspects of QL.

De Lange (2003) cited the International Life Skills Study (2000) as characterizing QL as partly being communication. De Lange later identified communication as one of eight competencies needed for an individual to be quantitatively literate. Specifically, mathematical
communication was characterized as “expressing oneself in a variety of ways in oral, written, and other visual form; understanding someone else’s work” (p. 77). In a later publication, De Lange (2006) referenced the PISA study as being “concerned with the capacities of students to analyse, reason, and communicate ideas effectively as they pose, formulate, solve and interpret mathematics in a variety of situations” (p. 15). Therefore, according to De Lange (2003, 2006), at least two large scale assessments of QL focus on a communicative aspect.

Adding to the descriptions mentioned already, Grawe & Rutz (2009) articulated three components of QL: a set of elementary quantitative skills that the individual has a sophisticated understanding of; the ability to solve problems within context; and the ability to communicate the results after they have solved a problem. Grawe and Rutz note that while it is essential to be able to communicate mathematics to make effective arguments, this relationship is reflexive in that “sophisticated rhetoric is also important for effective [quantitative reasoning]” (p. 3).

Up to this point it may seem that much of the review of literature has been a list of excerpts and quotes from QL literature that makes mention of communication in some form. Such an assessment would be mostly correct, and unfortunately so. Moreover, such an assessment only emphasizes the need for an examination of communication in QL assessments that the present study proposes. Various QL literature makes mention of communication as being an important element of QL but goes little further in providing specifics. Yet the consistent description of communication as an essential component of QL represents its significance. “Taken together, these imply that a numerate person should be expected to be able to appreciate and understand some of the ways in which mathematics can be used as a means of communication” (Cockroft, 1982, p. 11). Yet one of the main ways that QL appears to be measured is by tests of mathematical skill (Steen, 2000).

From Mathematical to Quantitative Communication

The previous section used existing literature to illustrate the implied significance of communication in QL. Yet, very little literature exists that describes communication in QL. Therefore, it is logical to examine aspects of mathematical communication, in which there is a body of literature, and see how such aspects can be applied to examine communicating quantitatively. In mathematical communication, the purpose is to communicate about mathematics itself (Lee, 2006). For QL, the purpose of communicating is inherently tied to its context and is not done specifically for or about mathematics (Steen, 2001). A newspaper article may use statistical polling data to explain why one candidate is winning an election, but the article is written to communicate about the election, and not the mathematics itself. In this and other similar scenarios, mathematics might be viewed as the means of communication. While this last facet is similar to mathematical communication, what might be termed quantitative communication involves mathematical means but varying, context-based purposes for communicating about mathematical or quantitative information. Therefore, the difference between mathematical and quantitative communication is the purpose for the communication. Since there is currently no literature describing quantitative communication, it is necessary to identify aspects of mathematical communication that may be present in quantitative communication.

Mathematical communication has been described as being written, spoken, or visually represented (Danesi, 2007). Indeed, these different forms of mathematical communication are sometimes used interchangeably or in place of one another (Steele & Johanning, 2004). Since these are mathematical means of communicating, it is logical that they are aspects of quantitative
communication. Therefore, the current investigation examines how various assessments of QL evaluated written, spoken, and visually represented communication.

Research conducted on mathematical writing has identified simplistic, procedural, and conceptual types of writing as areas of focus for examination (Kosko, Wilkins, & Pitts-Bannister, 2009; Shield & Galbraith, 1998). While Kosko et al. and Shield and Galbraith used the term descriptive rather than conceptual, the two terms are arguably related. Simplistic communication consists of memorized statements or the answer to a problem/task (Kosko et al., 2009). Procedural communication entails descriptions of procedures or strategies while conceptual communication consists of explanations, justifications, or conjectures (Schleppegrell, 2007). Visual representations have not been identified as being procedural or conceptual, but it is logical to conclude that they could be used in both procedural and conceptual ways, but may only be determined as such through use of either written or spoken communication. Dossey’s (1997a) description of measuring QL also uses the terms procedural and conceptual in referring to the different levels an individual engages quantitatively with the world. Given this background in mathematical communication, it is prudent to investigate how the different large scale assessments measuring QL (i.e. NALS, IALS, TIMSS-95, PISA) examine different forms of communication. Therefore, the current study seeks to answer the following research questions for quantitative communication:

1. To what degree do assessment rubrics in large scale examinations of QL examine responses that are simplistic, procedural, conceptual, and/or include a representation?
2. Do item-rubrics assessing mathematical communication (mathematical purpose) differ from items assessing quantitative communication (context-based or quantitative purpose) in the degree to which the rubrics of such items assess simplistic, procedural, conceptual, and/or representation responses?
3. Are there differences between assessment of purpose and response types across the different large scale assessments of QL?

**Methods**

**Measures**

The current investigation examines whether the communication assessed by large scale QL tests involved simplistic, procedural, or conceptual communication, or asked for representations (simplistic; procedural; conceptual; representation). These codes were assigned so that every item that contained any of these codes was assigned each. Therefore, an item rubric may have been coded 1,2,4 to denote that it looked for simplistic and procedural communication and looked for the creation or extension of a representation as well. This was done to examine the combination of mathematical communications assessed instead of simply the most sophisticated or a particular type.

A separate code was used to assess the purpose of communications in open response questions. A mathematical purpose was assigned if the assessment sought out a reply for a specifically mathematical context. A quantitative purpose was assigned if the assessment sought out a reply for a context other than, but possibly related to, mathematics. Additionally, a loose quantitative purpose was assigned if the assessment’s context appeared contrived.

**Sample**

Public-released items and rubrics from the IALS, 2006 PISA study, 1995 TIMSS study, and 1985/1992 NALS were used as the sample for the current study. These four studies claimed to

assess QL / numeracy and each included open response items. Therefore, the publicly released items for each assessment were examined. Information about these items is presented in Table 1.

Analysis

Our first step was to examine all released items from each assessment and select all open response items in the QL assessments. The final sample of rubrics examined is represented in Table 1. Our second step in analysis was to examine each item’s rubric to see what type(s) of response was being sought (simplistic; procedural; conceptual; representation). Then, the purpose of the response sought was examined within context of both the item and the item’s rubric. For example, rubrics in which the purpose of the test-taker’s response was to communicate explicitly about the mathematics involved was coded as having a mathematical purpose, but rubrics whose communication purpose was to communicate about the context, based upon the underlying mathematics, was coded as having a quantitative purpose. After all rubrics were coded, Chi-Square analyses were conducted to determine if there were (1) relationships between the different response types (simplistic, procedural, conceptual, representation), (2) relationships between item-rubric purposes (mathematical, loose quantitative, quantitative) and response type, and (3) differences between the QL tests (e.g. IALS, PISA) in terms of response type and purpose. Following Chi-Square analyses, post hoc analysis using a standardized residual method ($Z_{\text{crit}}=1.96$) was employed to examine specific cell differences in the contingency tables (MacDonald & Gardner, 2000).

Analysis

Our first step was to examine all released items from each assessment and select all open response items in the QL assessments. The final sample of rubrics examined is represented in Table 1. Our second step in analysis was to examine each item’s rubric to see what type(s) of response was being sought (simplistic; procedural; conceptual; representation). Then, the purpose of the response sought was examined within context of both the item and the item’s rubric. For example, rubrics in which the purpose of the test-taker’s response was to communicate explicitly about the mathematics involved was coded as having a mathematical purpose, but rubrics whose communication purpose was to communicate about the context, based upon the underlying mathematics, was coded as having a quantitative purpose. After all rubrics were coded, Chi-Square analyses were conducted to determine if there were (1) relationships between the different response types (simplistic, procedural, conceptual, representation), (2) relationships between item-rubric purposes (mathematical, loose quantitative, quantitative) and response type, and (3) differences between the QL tests (e.g. IALS, PISA) in terms of response type and purpose. Following Chi-Square analyses, post hoc analysis using a

standardized residual method ($Z_{CR}^2=1.96$) was employed to examine specific cell differences in the contingency tables (MacDonald & Gardner, 2000).

**Results**

An examination of differences between each response type across all items indicated a relationship between simplistic and procedural ($\chi^2(1)=8.67, p < .01$); simplistic and conceptual ($\chi^2(1)=29.69, p < .01$); and simplistic and representation ($\chi^2(1)=22.86, p < .01$), signifying that certain response types were found more or less often in combination with other response types. For the other combinations of response types, no statistically meaningful relationships were found. Post hoc analyses found item rubrics that sought simplistic responses were less likely to seek a response that was conceptual ($Z=-2.30, p < .05$) or include a representation ($Z=-2.10, p < .05$). Non-simplistic items were more likely to seek procedural responses ($Z=2.50, p < .05$), conceptual responses ($Z=4.50, p < .05$), and representations ($Z=4.00, p < .05$).

Descriptive data related to the second research question can be found in the bottom row of Table 2. No meaningful relationships were found between purpose type and response type. Therefore, rubrics assessing responses for a mathematical purpose, loose quantitative purpose, or quantitative purpose did not appear to differ in the degree to which they asked for simplistic, procedural, conceptual, or representation responses.

An examination of communication purpose across tests found a statistically significant relationship ($\chi^2(6)=33.87, p < .01$), signifying that some tests were more likely to assess certain communication purposes over the other tests. Post hoc analysis found that, when compared to the other tests, IALS had more rubrics assessing a loose quantitative purpose than would be expected by chance ($Z=3.30, p < .05$). Compared to other tests, NALS was found to have fewer rubrics assessing a loose quantitative purpose ($Z=-2.80, p < .05$) and more rubrics assessing a purely quantitative purpose ($Z=2.0, p < .05$). Compared to other tests, PISA was found to have more rubrics than expected by chance assessing a mathematical purpose ($Z=2.0, p < .05$). Table 2 illustrates this latter finding as PISA is the only test containing items with a mathematical purpose. Also, IALS had a larger proportion of loose quantitative purpose items than any other test. NALS was the only test consisting of rubrics assessing only a quantitative purpose. These findings suggest that in terms of the purpose of communication, NALS items were more oriented towards eliciting a response with a quantitative purpose than any other test. Similarly, IALS was more likely to have loose quantitative purpose items and PISA was more likely to have items evoking responses with a mathematical purpose.

Descriptive data related to comparisons between test and response type can be found in the right-hand column of Table 2. A statistically significant relationship between test type (i.e. IALS, NALS, PISA, TIMSS) and simplistic responses was found ($\chi^2(3)=9.34, p < .05$). Post hoc analysis found that TIMSS had fewer than expected rubrics assessing a simplistic response ($Z=2.40, p < .05$). Results also indicated no statistically meaningful relationship between test type and procedural, conceptual, or representation response types. These results suggest that while TIMSS had fewer than expected rubrics assessing simplistic responses than other tests, for the most part, the different tests were found to be similar in regards to response type.

Discussion

The analysis of open response item rubrics for QL assessments illustrated two things. One, with the exception of TIMSS, all tests’ open response rubrics were more oriented towards assessing simplistic responses. Two, item rubrics assessing simplistic responses seldom looked for procedural or conceptual descriptions, or the use of representation. Rephrasing these two points, the majority of open response rubrics looked for answers and did not look for procedural or conceptual descriptions that might accompany them. While many items on these QL assessments may have required the test-taker to think critically and deeply about the mathematics they were using, few items in these tests assessed such thinking. Rather, they assessed the answer provided, not the reasoning or the ability to communicate such reasoning. With such findings, it appears that the majority of QL assessments appear to assess quantitative communication as the ability to produce a simple answer, which may or may not be preempted with showing one’s work. Too seldom do these assessments examine whether the test-taker can describe what they are doing or why they are doing it.

Wilkins (in press) stated that “although several national and international projects have considered the assessment of quantitative literacy, ultimately the notion of literacy that has been emphasized is one focused solely on mathematical achievement” (p. 20). The results of the rubrics for open items presented in the current study supports Wilkins’ statement. While Wilkins’ focus on QL was not on communication, but on the incorporation of beliefs and dispositions, his words appear well placed when he stated that “evaluation of learning is often reduced to the use of measures of achievement alone, which only takes into account one component of the overall quantitative literacy construct” (p. 20). As explored in the current study, 79% of open response rubrics sought simplistic responses (see Table 2). A simple calculation will show that 80% of these simplistic responses looked for answer-only types of responses. This means that 70% of all item rubrics sought answer-only responses. Only 6% of items looked for procedural responses, 15% conceptual, and 9% sought a representation. The 79% of items seeking a simplistic response from the test taker were less likely to seek a procedural or conceptual description. Recalling that these were open response items, and not multiple choice/response, these results are disturbing.

The implications of the current findings are straightforward. If communication is to be regarded as a critical and essential element of what makes an individual quantitatively literate, then communication must be assessed in QL assessments. To do this, more than a simple answer should be required for a larger number of open response items. While many items are, necessarily, answer-only, far too many require no more than showing one’s work and stating the answer. QL assessments must evaluate whether an individual can reason and argue in a way that demonstrates their QL. If QL assessments do not do this, then they truly are reduced to simply another achievement test that happens to have open response items.

JUXTAPOSING CHINESE AND AMERICAN MATHEMATICS EDUCATION COMMITMENTS

Thomas E. Ricks
Louisiana State University
tomricks@lsu.edu

Using video data of urban Chinese secondary mathematics classes, supplemented with interviews, collected artifacts, and other data, we juxtapose American and Chinese mathematics education commitments along three cross-cultural dimensions (student, school, and culture) to argue that Chinese excellence on international comparisons may stem as much from these interrelated factors as from actual instructional practice.

Introduction

China is a world leader in student mathematics performance as measured on international comparisons, and its students consistently outperform American students (Fan & Zhu, 2004; Hiebert, et al., 2003; Huang & Bao, 2006; Huang & Li, 2009; Lin & Tsao, 1999; Stevenson, Chen, & Lee, 1993). This study examined underlying educational factors (besides actual instruction) that might contribute to Chinese students’ excellence on international mathematics comparisons. We assumed that juxtaposing aspects of Chinese and American mathematics educational efforts could provide answers for how China manages to consistently outperform the United States on international assessments, and perhaps suggest areas of potential improvement for American educators.

This study is a cross-cultural comparison of educational commitments; cross-cultural studies are known to benefit each population studied (An, Kulm, & Wu, 2004; Kaiser, 1999; Robitaille & Travers, 1992; Stigler & Perry, 1988; Wolcott, 1999). In May 2009 we collected data in mainland China by videotaping 11 different mathematics lessons in five schools, conducting post-lesson debriefing interviews with each teacher, and collecting student and school artifacts. We also participated in two versions of Chinese lesson study and interviewed a variety of Chinese educators (university researchers, other teachers, and administrators) and students (Figure 1). We have likewise drawn from the literature on cross-cultural comparisons to inform our analysis. Analysis is ongoing, and we follow Glaser’s (1965) constant comparative method. This is an instrumental study (Stake, 1994) that generates theory for broader application.

Results

Juxtaposing Chinese and American mathematics education commitments revealed stark differences; principally, those of the Chinese were stronger, with American commitments weaker (or in some cases, non-existent). We present our results in the form of a theoretical framework that organizes these comparisons along three dimensions: 1) student, 2) school, and 3) culture.

Student Commitments

Chinese students appear more committed to their mathematics education than American students. For example, during mathematics instruction, they are more involved with teacher-posed tasks, are more willing to proffer their ideas during discussions, and spend far more time on their out-of-school mathematics studies than American students (Huang & Li, 2009; Lin & Tsao, 1999; Stigler & Perry, 1988). Chinese students also miss very little school (Stevenson &
Stigler, 1992). The Chinese students we interviewed indicated that mastering material often required the self-assignment of additional homework, and claimed that their courses covered twice as much mathematics content as American lessons. Chinese students often attend cram schools to prepare for examinations.

Some of the interviewed: (left to right) Ms. Han, a Chinese teacher who had also taught in a New York public high school as part of an exchange program; an American researcher; Jin, a student; Mr. Leung, the school’s principal; Ms. Yu, a new teacher.

Between-class exercises at an urban mainland Chinese school. The school buildings are behind the camera in the foreground; in the background are apartment buildings and businesses.

Figure 1. Chinese collective recess (exercises) and four interviewees

Chinese families also appear more committed to their child’s education than American parents (Chao, 1994; Stevenson et al., 1990; Tsui & Rich, 2002). Chinese parents emphasize academic achievement more than American parents (Chao, 1994; Lin & Fu, 1990). China’s family-size restrictions allow two parents (and four grandparents!) to focus on a single child’s education; 90% of parents want their children to enter higher education institutions, and 19% want their children to obtain a Ph.D. (Zhu, 1999). Personal desks and dedicated study times in Chinese households also facilitate students’ studies, which are often lacking in American households (Stevenson & Stigler, 1992).

School Commitments

Additionally, Chinese school commitments appear stronger than those in the United States, as measured by teacher, cohort, and professional development factors. For example, Chinese teachers possess a profounder understanding of fundamental mathematics and place a greater emphasis on conceptual knowledge than do American teachers (An, Kulm, & Wu, 2004; Ma, 1999). They connect ideas to prior knowledge, concrete models, or students’ lives, and stress students’ proficiency with computational skills; they also possess a broader repertoire of questioning strategies, representations, and possible student misconceptions, emphasize abstract and algebraic reasoning, and ask more focused questions to develop better student reflection abilities than American teachers (An, Kulm, & Wu, 2004). Chinese teachers use student errors as a starting-point for further inquiry, promoting a climate of openness to discuss mistakes during the struggle to learn mathematics; because American teachers interpret errors as an indication of a failure to learn, mistakes are discouraged and hid, often leading to student embarrassment (Santaga, 2004; Schleppenbach, Flevares, & Sims Michelle Perry, 2007; Stevenson & Stigler, 2010).

Despite lessons being teacher-controlled and lecture-based; there are student-centered features (Huang & Li, 2009; Mok, 2006). Chinese students’ scores (compared to Western students’ scores) on the International Assessment of Educational Progress study were proportional to the amount of class time (average minutes per week) spent on mathematics study (Lin & Tsao, 1999). Dropout rates are low in China: less than 1% in primary grades (Liang, 2001).

Chinese teachers often teach multiple grades as they advance with their students from one grade level to the next (which form multi-year cohorts as they jointly progress), and studies indicate such prolonged contact matters for student achievement, especially with less-experienced teachers (e.g., Park & Hannum, 2001). There is no diversification of curriculum at primary or junior secondary levels, nor ability grouping in China (Liang, 2001; Park & Hannum, 2001), allowing for focused collective effort at the school level.

Mr. Tsao’s (left) lesson, with observing teachers.

Another view of Mr. Tsao’s class. Notice my cameras.

The visitors (other teachers, administrators, a district supervisor, and a university professor) sat on stools along the wall (left) and in the back (3 rows deep).

Mr. Tsao had distributed copies of his lesson plan to facilitate visitors’ observation. They also used this handout during the debriefing session, afterward.

Figure 3. Mr. Tsao’s lesson, an example of ‘exemplary lesson development’

The school is structured to help with professional development, a required part of teachers’ promotional advancement as they participate in school-based research (Huang & Bao, 2006; Ma, 1999). For example, the clustering of Chinese teachers’ offices promotes collaboration (Figure 2). Additionally, Chinese teachers “undergo rigorous, multifaceted evaluations of their performance each year” (Park & Hannum, 2001, p. 2). While in China, we filmed two common forms of Chinese lesson study where the collaborative study of teaching material, collective lesson planning, consistent peer observation with debriefing, and re-teaching lessons after refinement helps teachers to grow together (Huang & Bao, 2006; Ma, 1999). In particular, we collected data (see Figures 3, 4) on exemplary lesson development (the Keli model) where a teacher allows colleagues, university professors, district leaders, and master teachers to observe their developing lesson, offer feedback, and—after further reflection and revision—repeat the process (Huang & Li, 2009). We also participated in the Chinese practice of inviting a model teacher to teach a model lesson with the school’s faculty observing (Figure 5).
We noticed no class interruptions during our visits in Chinese mathematics classes, although security cameras were often at the front of every classroom. Chinese class sizes are unusually large in comparison to American classes (Huang & Li, 2009). Raised lecture platforms are at the front of the room. We also noticed the prevalent teaching laboratories dedicated to professional development, complete with two-way mirrors, (remote-controlled) cameras equipment, in-house editing software, and specialized ceiling microphones.

**Cultural Commitments**

Besides student and school commitments, China’s cultural commitment to education differs from the United States’. Chinese culture is a Confucian culture that places great emphasis on education for the general masses (Zhu, 1999), perhaps best modeled by the Confucius saying ren yi xue wei shang—education and learning is the highest priority of the people (Liang, 2001). Confucian culture assumes all are educable and ‘perfectible’ (Hoyle, Morgan, & Woodhouse, 1999), rather than the Western view that education is the elites’ opportunity.

China has made education one of its top national priorities, and plays a role in its emergence on the global scene. The sheer size of China’s educational system is staggering: in mainland China alone, there are roughly 600,000 primary schools serving 139 million primary students (Liang, 2001). China has a centralized national curriculum (Huang & Li, 2009; Ministry of Education, 2003). With only 5-6% of students able to attend higher education (Zhu, 1999) and fierce competition for jobs, China has developed an exam-driven system to facilitate acceptance and hiring processes, which culture is continued elsewhere by Chinese immigrants in cram schools (Lin & Tsao, 1999). For the Chinese, education matters: it is also the way out of poverty.

The Chinese also have dedicated teaching-universities apart from their research institutions, with teaching-university professors working in groups with selected schools on professional development; these are non-existent in the United States.

Western mathematics has been historically shaped by Euclid’s *Elements*, an axiomatic and deductive work; the Chinese mathematics tradition stems from *Nine Chapters*, a book containing a selection of everyday problems loosely arranged by category into nine sections. From these problems various rules or theories are derived for solving similar problems in a constructive and mechanistic process. The work emphasizes the algorithmic nature and applicability of mathematics (Leung, 2001). China’s current culture toward mathematics is a by-product of the ancient pragmatic approach where mathematics was a tool for the common folk serving a utilitarian function through its algorithmic applicability (Leung, 1999), not a highly-regarded academic discipline reserved for the elite. In China, mathematics is for everyone; Leung (1999) argued that the Chinese cultural perception of mathematics as an applicatory and problem-solving skill rather than a philosophical mind training of the elite, has contributed to the notion of mathematics for all (Fowler, 1979). Math-phobia, now an ingrained part of American culture (Paulos, 1988), is not yet apparent with the Chinese.

**Conclusion**

In trying to understand Chinese mathematics success as measured on international comparisons, we recognize that many factors affect the educational process, actual instruction practice being just one. This study made no judgment about the quality of instructional practice in China or the US; rather, we examined the educational commitments underlying Chinese success to present a framework that organizes commitments along three dimensions, each of which is stronger for China: student, school, and culture. Some would argue that Chinese success...
on international comparisons is due more to these extrinsic factors affecting mathematics education—as opposed to the inherent quality of the mathematics instruction itself (Hoyles, Woodhouse, 1999; Lin & Tsao, 1999). Others would argue that superior instruction is the principal reason China succeeds (Dewey, 1960/1933; Ma, 1999; Stigler & Hiebert, 1999). We feel that student-related, school-related, and cultural factors support instructional practice (whatever that may be) to give China an edge in international comparisons.

These three factors appear to be interrelated and mutually reinforce one another; for example, because Chinese parents are focused on one child’s academic performance, they likewise can focus on a single school’s—and multi-year cohort’s—performance. By contrast, not only are American students, school factors, and culture weaker than in China, but also they appear fractured and disconnected. For example, the structure of American education means teachers can only be committed to particular students (or classes, no cohorts) for a single year, preventing any longer-term investment in a specific group of children’s learning by the teacher. Similarly,

American schools have no coherent, unified professional development system for their teachers, no centralized curriculum, no mechanism for sharing professional practice, and no teaching-universities working in tandem with US schools. Some American education ‘reform attempts’ may also be more fad than fact: China’s large class sizes and lack of ability-grouping calls into question the American push for small classes and better ability-grouping as advocated by some. Similarly, Chinese teachers’ model lessons—taught by an expert teacher in unfamiliar territory (someone else’s class)—challenges the common American belief that the ‘teacher-must-know-the-student-before-teaching’. In closing, juxtaposing student, school, and culture related commitments between China and the United States suggests that China’s commitments are stronger and interrelated. We suggest further research into how other countries can strengthen their own educational commitments by learning from China’s educational commitments.

USING THE SIX INSTRUCTIONAL DESIGN PRINCIPLES TO ASSESS THE MODELLING COMPETENCIES OF STUDENTS IN MATHEMATICS CLASSROOMS

Piera Biccard  
University of Stellenbosch  
pbiccard@yahoo.com

D.C.J. Wessels  
University of Stellenbosch  
dcjwessels@gmail.com

This paper presents partial findings of a study that documented the development of modelling competencies of students working in groups. Six principles for instructional design were used as a framework for assessing modelling in a holistic way. This paper presents the findings of using these design principles to assess group modelling. In keeping with the theme of the conference, we felt it apt to include modelling since it optimises student learning in mathematics. Furthermore, this paper addresses the need for new assessment approaches in mathematics.

Introduction

Modeling has been identified as a mathematical competence (Blomhoj & Jensen, 2007, p. 47). Modeling involves solving a complex, multifaceted task. It entails working with a multipart real situation and creating a model for that situation. The general definition of a model described by Lesh and Doerr (1998) as a scheme that describes a (real life) system (p. 362). It assists in thinking about that system, making sense of it or making predictions. A model consists of elements, relationships, operations that describe how the elements interact and patterns or rules that apply to the preceding relations or operations. A model focuses on the underlying structural characteristics of a real life system being described. Therefore a model can be a description, explanation or prediction of a real life situation.

Allowing students to model is important in mathematics education. According to Niss, Blum and Galbraith (2007, p. 19) modeling can make ‘fundamental contributions’ to a student’s development of mathematical competencies while Lingefjard (2006, p. 111) affirms that modelling is one of the main and most useful applications of mathematics.

Assessing modelling is difficult since the process students are involved in and products students create when modelling are different from traditional instruction. In an endeavour to assess students overall modeling ability, we envisaged an assessment framework that encompassed the broad aims of modeling. Modelling can be assessed by the various competencies required to model a real situation. The following modelling competencies of groups were identified and characterised in the main study (Biccard, nd) but the same competencies would apply to individuals: understanding, simplifying, mathematising, working mathematically, interpreting, validating, presenting, arguing (Maaß, 2006, p.1360, using informal knowledge (Mousoulides et al., 2008, p. 390), beliefs, ‘sense of direction’ and ‘planning and monitoring’ [Treilibs, Burkhardt, & Low, 1980, p. 52].

These competencies occur throughout the modeling process. There is a need however to mesh the assessment of these individual competencies and a holistic ability to model in some way. Clatworthy (1989) developed an assessment rubric that was used in a modeling course to assess modeling competence and provided each student with a feedback sheet. He concluded that the development of reliable methods for assessing modeling remains a challenge. The move away from single type assessment towards a dynamic model that could be adapted to each task is closer to what we envisaged. The shortcoming of rubrics is that criteria of achievement and
levels of achievement must be re-specified for each task and often before the task commences. We wanted a framework that could be used for reflective assessment also.

English (2007) addressed the cycles of mathematical development displayed by primary school students. She used a purely qualitative approach, transcribed audio and video tapes. This is a valuable approach to assessing modeling holistically. We also wanted a framework that could be used to code any modeling task or student age/experience/ability level. Jensen (2007) suggested a multidimensional approach to assessing mathematical modeling competencies. Three dimensions of competency were explored: the degree of coverage; the radius of action and technical level. Jensen adds that these three dimensions provide vocabulary for discussing quality in performance. It was decided to include the ideas of Jensen and English and to further the discussion on assessing modeling. A qualitative, multidimensional approach informed by instructional principles would provide the necessary vocabulary to discuss quality performance and would be appropriate in evaluating the entire modeling process. We found that rewording the six instructional design principles for modeling created a suitable framework for assessing modeling abilities holistically. The framework allows one to unpack a group’s modeling experience and will assist in dealing with the vast amount of data collected. More significantly it will allow one to develop assessment protocols for modeling that teachers can use in the classroom.

**Instructional principles and assessment**

The practice of assessing modeling is varied and based on different aspects of modeling. Researchers and educational practitioners have different needs and perspectives when it comes to assessment. According to Gijbels, Dochy, Van den Bossch and Segers (2005) “many educators and researchers have advocated new modes of assessment to be congruent with the education goals and instructional principles of problem based learning” (p. 31).

We considered it important when assessing modeling to depart from the instructional principles for modeling. It would then be possible to meet some of the needs of researchers and educational practitioners. Principles in Realistic Mathematics Education (RME) have a strong philosophical base, give better account of the realistic nature of modeling problems and crystallize the interrelationship between instructional design principles and assessment. This allows a better understanding of how mathematics instructional design principles interact with, and inform assessment principles. According to Van den Heuvel-Panhuizen (1994) in RME, teaching and assessment are ‘strongly connected’ and that “assessment plays a role in all stages of the teaching processes” (p. 31), while Treffers (1987) notes that a description of what is intended by instruction offers support for the evaluation of that instruction. Similarly, the Van Hiele levels of thinking (Treffers, 1987, p. 243) are theoretically based, but manifest in both teaching design and assessment. The levels inform instruction by allowing teachers to focus on which level is appropriate for the students and which activities will support students at these levels. The levels also allow teachers to assess at what level students are working. This duality in principles means that teaching, learning and assessment form a coherent whole informed by theories of learning.

Biggs (1996) also suggests a model of instruction that includes students being placed in situations that are likely to elicit the necessary learning and that assessment tasks address the same performances that are stated in the curriculum. Students have to model to be evaluated on modeling.

An assessment framework should have the following characteristics/features. It should:
be aligned with instructional principles
reveal both strengths and weaknesses in student thinking, and
use authentic tasks in an authentic environment (Baxter & Shavelson in Gijbels et al., 2005, p. 32)

Our framework stems from modeling instructional principles, places students in authentic situations and allows us to gauge student thinking.

The study

Twelve students were selected for the study and worked in three groups of four students in each group. The groups were purposively selected and comprised two groups of students who were stereotyped as ‘weak’ (Group 1 and Group 3) in mathematics and one group of students who were stereotyped as ‘strong’ (Group 2) in mathematics. The students were selected based on their school results in traditional mathematics assessment. Part of the results of the full study included comparing the development of modelling competencies in ‘weak’ and ‘strong’ students. Student ages ranged from 11 to 13 years. They worked once a week for 60 minute sessions for a period of 12 weeks. They solved 3 modelling problems during this time. These students had not been exposed to modelling problems before. All contact sessions were audio recorded and transcribed. Transcriptions were coded each week in terms of the competencies identified. Transcriptions were also coded in terms of the six principles for modelling instructional design. Students had to complete a number of progress documents each week. Their written work was also scrutinised in terms of developing responses to the questions. At the end of each task students presented their solutions to the other groups. These sessions were video recorded. The following table gives a brief description of the task instructions:

| Supporting Material: Example of footprint (size 24). Groups had to model how to find the height/size of this person and also provide a toolkit on how to find anyone’s height/size from their footprint. |
| Supporting information: Catalogue prices from 1999 and 2009. Groups had to assist another student who had written a letter stating that his pocket money is the same as his sisters’ ten years ago. He needed assistance in convincing his parents that he needed more. They also had to provide an amount with suitable reasons. |
| Groups were given a quilt pattern together with the size of the completed quilt. They had to provide the correct pattern pieces together with cutting and stitching guides. |

Six principles for instructional design and modelling assessment

Six principles of instructional design (Lesh, Hoover, & Kelly, 1992) are used in modelling task design to ensure that tasks are indeed model-eliciting. It was found that if these principles were re-worded, they could be used as a suitable framework for assessing modelling. The six principles for instructional design are:
• The Reality principle - requires that the task encourages students to make sense of the situation based on extensions of their own personal knowledge and experiences. Re-worded: To what extent does the group make sense of the real life situation?
• The Model Construction principle - requires that the problem must confront students with a need to construct a model. Re-worded: To what extent does the group construct a model?
• The Self-Evaluation principle - requires that the task allows students to be able to judge for themselves when their responses are good enough. Re-worded: To what extent does the group judge that their ideas, responses and models are good enough?
• The Model-Documentation principle - the task must elicit a response to the problem that requires that students reveal their thinking about the situation. Re-worded: What is the quality of the documentation that the group produces when modeling?
• The Simple Prototype principle - requires that the situation is as simple as possible while still creating the need for a significant model. Re-worded: At what level is the group progressing on a continuum of simple to complex when modeling?
• The Model Generalization principle - does the model constructed apply only to one situation or can it be applied to a broader situation? Re-worded: To what extent does the group develop a prototype, generalizable model?

The instructional design principles can be re-worded so that is it the group or student that is the focus of the teacher/researcher and not the task. The same features that were deemed important for creating modeling tasks are now considered in terms of how groups of students display these features. Moreover, using these principles allows one to focus on what students are achieving holistically in their modeling endeavors. They also allow teachers or researchers to focus on the essential products and processes of modeling. The main study documented the development of modeling competencies of students working in groups. For that reason the design principles were reworded using the term ‘groups’, but the word ‘student’ can also be used when rewording the questions. A brief discussion on each re-worded question follows.

The Reality question - clustered within this question are competencies of the groups’ understanding of the problem, to what extent they use their informal knowledge, their mathematizing skills and interpreting of their model. It is important to gauge whether the ‘students school mathematics’ ability is functioning with their ‘real life sense making abilities’ (Lesh etal., 2000, p. 616).

The Model Construction question - this will cluster group competencies of mathematizing, working mathematically and presenting the solution. Group planning and monitoring will also play a significant role here. It is important to remember that the products of a modeling task include: predictions, explanations, justifications or descriptions (Lesh, Hoover, & Kelly, 1992) Therefore group models should be assessed on a combination of these products and how well they integrate elements of these in their final presentations.

The Self-Evaluation question - this will cluster competencies of their understanding, their ‘sense of direction’ (Treilibs, Burkhart, & Low, 1980, p. 52), their use of informal knowledge and validating their model. This also means that students will sense that they have sufficiently dealt with the problem, and will not continually ask the teacher ‘is this good enough’ (Lesh et al., 2000, p. 620). It is important to ascertain whether the group detected deficiencies in their initial thinking; compared alternative ideas and judged them according to their use in the problem; integrated strengths from these alternative ways of thinking; extended or refined the
interpretations and assessed the adaptations that were made (Lesh et al., 2000). From this we can see that a number of reconceptualization cycles are necessary in modeling.

*The Model-Documentation question* - this clusters competencies of simplifying or structuring the problem, mathematizing, working mathematically and a sense of direction. In documenting the solution process students will use various forms of representation. These forms of representation allow one insight into student thinking. Lesh and Doerr (2003) remind us that the modeling process leaves an ‘auditable trail of documentation’ (p. 31). Modeling tasks usually require a product (a letter, a report etc), but in leading up to the product groups will produce other documentation that can be used to judge some of their modeling competencies.

*The Simple Prototype question* - what progress is the group making in terms of their mathematical thinking when exposed to modeling tasks? Competencies of understanding interrelatedness of the task elements, verifying the model and argumentation are pertinent here. It is important to remember that it is not necessarily complex mathematics that is required or anticipated but rather as Iversen and Larson (2006) explained modeling as complex thinking using simple mathematics, as opposed to traditional teaching which involves simple thinking using complex mathematics.

*The Model Generalization question* - competencies include arguing, validating and presenting. The extent to which the group can generalize their model to the situation and to other situations is indicative of having mathematized the problem at a significant level. The ability to generalize a model concurs with a shift in the students’ thinking, from thinking about the modeled situation, to a focus on mathematical relations Gravemeijer, 2002). According to Gravemeijer (2002), when this happens then the dissimilarity between the model and the situation model dissolves. A group’s (or individual’s) advance in creating a generalizable model will confer with Freudenthal’s idea of modeling as ‘organizing’.

The six questions were used over three tasks to gauge each group’s competence at modeling in a holistic way. The questions could also be used to assess individual students when working on individual modeling tasks.

**Results**

Using the six principles for assessing group modeling means that the teacher/researcher needs to consider both the difficulty level of the task and the age/ability/experience of the students. We were able to make the following conclusions about each group’s performance for each task using the six questions after coding transcriptions and the group’s written work.

The Reality question: This allowed us to consider exactly how much of their own knowledge are students prepared to bring into a situation and to what extent this assisted (or hindered) them in solving the problem. Each group made better real life sense of Task 2. This may be that the task was the best context match for them. They spent much more time discussing issues of fairness and family relations. We needed to discern between two types of real life sense. There were times when the groups used real life information to assist them (M) while sometimes it was just peripheral information (T). This question allowed us to focus more carefully on how much real life information students were using and what they were doing with the information.

*M: You get some people that are short and have big feet (Task 1).*
*T: nowadays you pay more for the popcorn than you do for the (movie) ticket (Task 2).*
The Model Construction question: This enabled us to focus specifically on the model students were constructing. In considering the groups’ model constructions, we found that groups produced better models for Task 1 than the other tasks. When the need for a generalisable model was very well specified, we found that the situation model was improved. It is important that tasks are set up with the need for a generalisable model well specified. Group 2 set up a very comprehensive model for Task 2 while the other groups simplified the information given too much, which led to models that did not take enough information into consideration. This question allowed us to focus on how well the model described or explained the problematic situation and what factors the groups focussed on and not simply if a model was generated or not.

The Self-evaluation question: Groups were starting to judge their own responses without calling for the teacher by Task 2. A feature of the weaker groups is that individual members became distracted and unfocussed by each other’s input and ideas. They had difficulty detecting deficiencies in their initial thinking. They were largely unsure of what a ‘good’ idea (G) is or a ‘weak’ idea (W). The following shows how this group moved from an arbitrary ‘plus’ or ‘times’ to making their first measurement.

W: Then, I think you have to plus..... (a little later)... I think we have to times it.
G: Let’s measure how tall I am before we do anything.

We found the following type of comments of groups judging themselves more frequently during Task 2 and Task 3.

S: come on people, they want a method.
S: what is this going to help us?
N: That doesn’t give us an answer.
N: Ya, that’s a good idea.

This question allowed us to track what groups thought of what they were doing throughout the problem solution and not only their final solution. The stronger group displayed more incidents of judging what they were doing for themselves.

The Model-documentation question: Groups’ working documents started off being very disorganised and haphazard. By the third task they were producing more structured working sheets with notes indicating what their measurements were about. Students initially only kept their final answers. It was after they needed to find some of their calculations and measurements that they kept more detailed explicit notes. The need to present their solutions at the end of each task was a contributing factor. We were able to observe the types of representations groups preferred to use and the meanings they gave to the representations. This question allowed us to focus on all the written documentation that students produced, not only their final presentation sheets.

The Simple Prototype question: The length of the study made it difficult to assess if students were working in more complex ways. This question is still valuable to use over a longer period of study. We did find that groups used very basic mathematics. Treilibs et al. (1980) remind us that student abilities to apply mathematics to real situations lags by at least three years after their first learning of it.

The Model Generalization question: Both Group 1 and Group 2 created strong models for Task 1 and were able to generalize their model. Strong models are models that take the full
situation into account while some groups produced weaker models where they selected only a small part of the given information. Since the tasks were all based on proportional reasoning, strong models included multiplicative reasoning while weaker models included reasoning that was additive which made generalizing very difficult. Group 3’s (weaker) model for Task 1:

M: Why don’t we say this number (22.5 a group member’s foot length) plus what or times what equals his height? (They wanted to reach a result of his measured height of 148).
E: 22.5 times 9 is too much….22.5 times 6 is 136.
G: So, times 6 plus…You times it by 6, and then you plus 12.

For Task 2, all groups worked so deeply in the situation model and were not confident about their situation models that this resulted in little or no attention being given to the generalizable model. For Task 3, the process of creating the situation model largely tied in with the process for creating a generalizable model. Students have to a take elements of their situation model that are the basis of the generalizable model. These elements reflect the essence of the mathematics that is relevant in solving the problem. This question allowed us to focus on what underlying features of the problem did the students detect. It also allows one to focus on more than just the solution to the problem. If groups are able to reach a level of being able to generalize a model to other situations then they have reached much higher levels of thinking.

Conclusion

Using the six instructional design principles as a framework for assessing student modeling has proven useful to us. The questions can be used to describe broader areas of modeling ability than only focusing on individual competencies. Group or individual modeling can be gauged holistically in terms of very important modeling aims. These questions encompass the aims of modeling: that students do make sense of a real situation, that students do judge their solutions for themselves, that they do create ‘auditable trails of documentation’ (Lesh & Doerr, 2003, p. 31) and that students do construct models for situations. The competencies relevant to achieve positive responses to these questions and successful modeling are on a much higher mathematical thinking level than assessment in traditional instruction. The six principles will allow teachers to focus on the important products of student modeling: that students make sense of a real life problem, that they construct a model, that they judge their responses for themselves, that they document their progress, work towards more complex models and eventually create generalizable models. The questions, each in turn, cover areas such as: reality, construction, reflection, representation, thinking and prediction. The questions should not be considered in some hierarchical way since they cover areas that are distinct but integrated.

Using these six questions not only allows one to assess student modeling in a holistic way, but also allows one to find weaknesses in task construction and formulation, task-group match, student thinking as well as weaknesses in teacher interaction, practice and decisions. These exposed weaknesses, once reflected upon, will allow one to improve modeling experience. The framework provides a suitable way for unpacking of the entire modeling episode as well as providing the vocabulary to do so. The questions are broad enough to be applicable to all modeling problems not only in terms of student assessment but for practitioner reflection.

References

This study investigates variables influencing student achievement in mathematics using the NCES Early Childhood Longitudinal Study (ECLS). Initial analysis of the results identified that the amount of mathematics discussion, frequency and duration of time that students do mathematics in their classes are significantly correlated with achievement scores. However, no relationships were found between student achievement in mathematics and the amount of teacher course work in teaching of mathematics, teacher employment status, teaching experience in the grade, or certification type. Parental involvement and extracurricular activities were significantly correlated to 3rd graders’ achievement in mathematics.

Introduction

The National Council of Teachers of Mathematics (NCTM) and the National Association for the Education of Young Children (NAEYC) highlighted the importance of a well-designed mathematics curriculum on early childhood mathematics. Educators should “use curriculum and teaching practices that strengthen children’s problem solving and reasoning processes… actively introduce mathematics concepts, methods and language through a range of appropriate experiences and teaching strategies” (2002, p. 4). Wang (2009) also suggests that educators aim to provide young children the opportunity to learn high quality, challenging mathematics, especially accessible to children. The purpose of this study is to investigate variables influencing elementary school students' achievement in mathematics. The study specifically addresses research question, “How are the teacher’s attributes and instructional practices associated with student achievement in mathematics?” and “What variables, other than teacher attributes and instructional practices, influence elementary students’ achievement in mathematics?” The study used the National Center for Education Statistics (NCES) Early Childhood Longitudinal Study (ECLS) data. The ECLS data provides descriptive data on a national basis of children’s status at entry into school, children’s transition into school, and their progression through grade 8. The ECLS provides a data set on how a wide range of family, school, community, and individual variables affect early school success (http://nces.ed.gov/ECLS/).

Perspectives

Teacher Qualifications and Students’ Achievement

A number of studies reported the significance of teacher attributions impacting on student mathematics achievement. Teacher attributions include a teacher’s personal traits, experience, qualifications, instructional approaches, and so forth. In this study, we will focus on teachers’ qualifications and their instructional approaches. The No Child Left Behind (NCLB) Act mandated only highly qualified teachers be hired (USDE, 2002). This requires teachers to have minimal background qualifications, such as state certification and a bachelor’s degree. Some researchers even argue that the most important predictor of student achievement is teacher quality (Darling-Hammond, 2000; Rockoff, 2004).
Existing studies on teacher attributes have, however, reported contradictory findings. Teacher attributes such as educational attainment, years of teaching experience, and area of certification have been reported both as significant and non-related factors. Xin and his colleagues (2004) found that teacher attributes have no impact on mathematics achievements and argued against using teacher credentials as the standard of selection on the teacher market. They did, however, concede that some problems existed in their data analysis process due to the limitations of the data. Goldhaber and Brewer (1996) found that teachers certified in science and mathematics had a positive influence on student performance scores, but not in History and English. The Darling-Hammond (2005) group studied 4th and 5th grade classrooms and found that certified teachers consistently produce stronger student achievement gains than do uncertified teachers. A study by Mandeville and Liu (1997) assessed the interaction effect of teacher mathematics preparation and the thinking level of 7th graders in their performance solving mathematics problems. Based on this study, teachers have an important influence on the development of students' high-level mathematics thinking skills, but an insignificant influence on low-level mathematics thinking tasks. Sweetland and Hoy (2000) also reported a positive association between school characteristics and student achievement on state test. According to their study, academic emphasis has a strong influence on teacher behavior and student achievement. They also reported that academic emphasis, reasonable goals set by teachers, teachers' beliefs in their students' ability to achieve, or an orderly learning environment, are "significant predictors of between-school differences in student achievement in both mathematics and reading" (p.697).

With higher grade students, teacher preparation and certificate type had a generally positive effect on students’ mathematics learning outcomes. Despite such variations in teacher test scores, a number of studies stated that teacher experience positively affects student achievement (Goldhaber & Anthony, 2007; Jepsen, 2005). A study by Nye and her colleagues (2004) also supports, but not significantly, the impact of teacher experience and/or education on student achievement. Comfort et al (2000), however, found a positive relationship between years of teaching experience and teachers’ degree and student achievement.

**Teacher Instructions and Students’ Achievement**

Even though a teacher may have strong characteristics and high qualifications, those aspects may not match the importance of a teacher’s instruction. Research shows that teachers differently implement tasks, which affect student engagement in different ways (Henningsen & Stein, 1997). Whether a teacher uses teacher directed/prescribed or student-centered instruction, their actual teaching approaches may vary. However, it is necessary to examine which forms of instruction lead to an improvement in student achievement. Examples of such forms come from a teacher’s contribution to mathematics achievement, effective instructional strategies, or homework activities (Ai, 2002; Henningsen & Stein, 1997).

Studies on instructional activities focus on various aspects: different types of classroom practices aimed at improving mathematics education; specific types of instructional tasks aimed at maintaining student engagement; the use of problem-centered classrooms aimed at developing mathematics concepts and operations; learning activities at home; and different types of activities, such as worksheets, experiments, and classroom discussion (Henningsen & Stein, 1997). Other examples include: encouraging active student engagement with challenging problems; allowing sufficient time for students to wrestle with problems and to record their solutions; promoting discussion among children as they determine various ways to solve problems; and expecting and encouraging students to explain and justify their solutions to other children in the class. These
are all considered as factors that influence student achievement (Thornton, 1995). Previous national and international studies on instructional practices, demographic variables, and their relationships to student achievement are based on data from NAEP and the Third International Mathematics and Science Study (TIMSS), which dealt with 4th, 8th and 10th grades. However, only a limited number of studies considered the relationship between teacher qualification, instructional practice, and student achievement in mathematics with young children. This is possibly due to the shortage of data that link student test scores to the characteristics of their teachers (Guarino, Hamilton, Lockwood, & Rathbun, 2006).

Other Factors Affecting Students’ Achievement

There has been continuing interest in identifying factors that affect the improvement of mathematics education. Some studies focus on student-level factors, such as individual family issues, home resources, gender, race, and socio-economic status (SES) (Broeck et al., 2003; Comfort et al., 2000; Ma, 2005; Okpala et al., 2001; Williams & Jacobsen, 1990). Affective and cognitive factors for students are always considered by educators (Ai, 2002; Higbee & Thomas, 1999; Wilkins & Ma, 2002). Parental and peer influence on students are reported as factors with a consistent relationship to growth in mathematics achievement (Hall, 1999; Okpala et al., 2001; Wilkins & Ma, 2002).

The research done on the influence of school governance or policy related factors on student mathematics achievement has shown mixed results. It seems that the results of these studies show fluctuations and changes in the effectiveness on student achievement in mathematics. Such differences in results may be interpreted by the combinations of factors related to school governance or policy with other variables, such as: students’ backgrounds, their experiences outside of school, and teacher attributions, which are all closely interrelated (Teddle & Reynolds, 2000).

Methods

The ECLS is a nationally representative longitudinal study that follows a sample of U.S. children enrolled in 1,000 kindergarten programs from kindergarten through Grade 5. The ECLS uses a multistage sample, which represents different socioeconomic and racial-ethnic backgrounds. The ECLS began in 1998 and concluded in 2004; 1998–1999 (Kindergarten), 1999–2000 (Grade 1), 2001–2002 (Grade 3), and 2003–2004 (Grade 5). Data on children’s cognitive, social, emotional, and physical development were collected in the fall and in the spring from students, parents, teachers, and schools. Data about the children’s home environment, educational practices at home, the environment at school and in the classroom, and classroom curriculum and teacher qualifications were collected from children, families, teachers, and schools (http://nces.ed.gov/ecls/). In this study, we used the data on 3rd grade students attending public schools in the four geographical locations, who were assessed in mathematics in the spring of 2002. The data were further filtered to exclude cases for which data were recorded with negative number codes (that indicate lack of relevant information or respondent’s refusal to submit information). These data were used to estimate the degree to which variables of interest – teacher attributes (certification, qualifications, experience, etc.), pedagogical methods and tools (discussion time, group activities, use of worksheets, computers, etc.), and student attributes (reading scores, SES, home-environment, etc.), among others – were associated with student achievement in mathematics.

A preliminary correlation analysis revealed both statistically insignificant as well as significant correlations between the selected variables. Factor Analysis with Varimax rotation was employed to extract factors from the correlated set of variables. Using factor loadings that were at least 0.6, factor scores were constructed. These factors along with other independent variables were then used in linear regression procedures to estimate the degree to which they were associated with student achievement in mathematics.

**Results**

Until now, findings of various regressions of student achievement scores in mathematics showed a number of statistically significant relationships with teacher-, school-, and student-level factors. The ANOVA test result (Table 1) shows that there is a significant relationship between students’ mathematics scores and variables including teacher qualification, instructional methods, gender, race, SES, and student reading scores.

Table 2 shows significance of the extracted factors on mathematics achievement scores. The p-values show that third graders' mathematics achievement scores were related to the amount of time spent discussing mathematics. This included talking to the class about their mathematical work, discussing solutions to mathematics problems with other children, and working out and discussing mathematics problems that reflect real-life situations. Also, the more often and the longer students do mathematics in class, whether as an entire class, in small groups, or individually, the higher their achievement scores were. However, teacher use of the traditional way of solving problems, testing through quizzes or manipulatives, was not significantly associated with student achievement scores. The amount of time they spend on measurement, fractions, and skill development also did not show any significant associations with student achievement in mathematics.

Variables related to the self-reported teacher attributes were aligned with categories in Guarino et al's NCES report (2006) – 3rd grade teaching experience in years, certification level (full vs. less than full), employment status (full vs. part time), degree status (receipt of a master's degree), and the number of courses taken in mathematics teaching (0 to 6 or more courses). As can be seen in Table 3, the teacher attributes, such as their certificate type, whether they teach reading courses or mathematics courses, their main assignment at school, or years they taught this grade are not significantly associated with student achievement in mathematics.

The study also analyzed the relationship between students’ attributes and their mathematics achievement scores (Table 4). We find that students reading scores, gender, SES, race, and primary home language are strongly associated with their mathematics scores. We also used Pearson’s correlation to investigate the influence of other variables on students’ mathematics achievement scores. In particular the study analyzed factors related to students scores in reading, parental involvement, student’s extracurricular activities, and use of computers.

Partial results of the analysis are presented in Table 5. As can be noted, mathematics scores are strongly correlated to their reading and general knowledge scores. Factors on parental involvement such as how often parents attend open house, PTA/PTO, and/or school events have small but statistically significant correlation coefficients with mathematics achievement scores. However, how often parents contacted the school or how often parent-teacher conferences occurred were not significantly correlated. Further, student mathematics achievement scores were significantly correlated, albeit with small correlation coefficients, with their non-subject related extracurricular activities, such as if they volunteered, visitations to the library or a museum, attend a play, concert, or show, and participation in athletic events. Visiting the zoo or aquarium, using a home computer, or the frequency of a child’s computer use did not show significant correlation with their mathematics achievement. As can be seen in Table 5, variables statistically associated with mathematics scores were also significantly correlated with students reading scores and general knowledge scores.

**Discussion**

The research questions addressed in this study ask whether or not instructional practices and teacher attributes are related to student achievement scores, as well as what other variables influence on student achievement in mathematics. The findings show that organizational factors have more impact on student achievement than do content-specific factors. Spending more time on mathematics and discussing mathematics were positively associated with mathematics achievement. While we may now assume the significance of time spent for mathematics and mathematics discussion, we are reluctant to do so with other instructional factors (e.g., manipulatives, problem solving, and mathematics skills). This result seems to imply that students may learn better by understanding or through the process of meaning making. That is, after learning concepts or skills with various instructions, student may need time to process and internalize their learning especially through discussions. This suggests the need for a more detailed study of frequency and duration of other forms of instruction and the use of discussions.

The available data do not show how much time teachers actually spent on mathematics skills, problem solving or manipulatives and the combined approaches between those instructions and discussions.

* Correlation is significant at the 0.05 level (2-tailed)

This study also provides us insights on the effects of different types of parental involvement: parental participation in open house, PTA/PTO, school events, or parent teacher conference.

Although the importance of parental involvement in student achievement has been pronounced, some studies have not agreed on the effect of types and frequency of parental involvement on students’ achievement (Desimone et al. 2004; Ho & Williams, 1996). We assume that there is a need of considering multiple aspects of diverse parent populations such as language, culture, etc. Specific student factors such as visitations to concerts, museums, etc., participation in extracurricular activities, etc., have significant influence on mathematics achievement scores. It is possibly due to students’ learning motivation developed from such activities (Stefan, 2004).

The findings show that a teacher’s experience teaching 3rd grade impacted on student achievement, whereas no direct relationship was found between courses teachers took or their employment status, and student achievement in mathematics. Unfortunately, the survey questions were not specific enough to discern whether or not a teacher’s mathematical pedagogical and content knowledge are associated with student achievement. Based on our results regarding teacher certification type, a more focused and in-depth investigation ought to be done, especially on the question of subject-specific training, such as the time a teacher spends learning mathematics, what they learn or how they were taught. According to Rivkin et al. (2005), the effect of teacher qualifications decreases during the first 3-5 years in the classroom, because a novice teacher’s teaching skills improve around the 5th year. However, the effect of teacher experience on student achievement may vary due to teacher qualities or abilities (Kukla-Acevedo, 2008).

The NCES collected the 5th grade data in 2004 and the 8th grade data in 2007 to see how the same group (Kindergarten Class of 1998-99) of student progressed through 8th grade. It would be beneficial for teacher educators to see how instructional approaches and teacher attributes influence student mathematics achievement in middle school by analyzing the 5th and 8th grade data.

ENGAGING SECONDARY STUDENTS AND TEACHERS IN PROFICIENCY-BASED ASSESSMENT AND REASSESSMENT OF LEARNING OUTCOMES

Kathleen Krier
21st Century partnership for STEM Education
kkrier@21pstem.org

According to a recent report published by The Urban Institute, nearly 1.3 million of the roughly four million ninth graders attending public schools each year will fail to graduate (Swanson, 2005, pg. 8). The Consortium on Chicago School Research (CCSR) concluded that students maintaining at least a B average in their 9th grade year have more than a 95% chance of graduating from high school. Conversely, 9th grade students with less than a C average have a greater likelihood of dropping out of school than of graduating. Clearly, 9th grade is a pivotal year for students. The PARLO study targets 9th grade students taking Algebra 1 or Geometry and will research the efficacy of a system that emphasizes students attainmenting “proficiency or better” on a limited set of high-value, standards-based learning outcomes. Rather than using a traditional letter grade system, PARLO establishes a new proficiency-based approach to learning and assessment. If a student does not attain proficiency on an outcome, he/she will have subsequent opportunities (reassessment) to learn the material that he/she has not yet mastered and demonstrate proficiency. For the purposes of this study, the definition of proficiency consists of three degrees of mastery: proficient (P) when a student grasps the major concepts taught, not yet proficient (NYP) when he/she demonstrates minimal understanding and high performance (HP) when he/she demonstrates an almost flawless understanding of the learning outcome. Learning outcomes are an explicit description of “what a learner should know, understand, and be able to do as a result of learning” (Bingham, 1999, p.4). Proficiency levels along with explicit learning outcomes help to provide teachers with coherent evidence of student mastery.

This study employs a cluster randomized trial of 44 schools. The schools will be assigned to either a: (1) treatment group using the PARLO system, or (2) control group in which students are taught and assessed using a traditional model. Randomization will be done at the school level to simulate a naturalistic setting where an entire school employs this type of assessment system. The research questions under investigation are: (1) Does the use of PARLO lead to increases in students’ achievement and engagement in mathematics? (2) Does PARLO lead to increased student interest in pursuing advanced mathematics courses and/or STEM content? (3) Will teachers’ regular and sustained use of PARLO foster changes in teachers’ conceptions about: (a) how students learn mathematics, and (b) the capacity of students to achieve proficiency?

RECONCILING STUDENT THINKING AND THEORY: THE DELTA LEARNING TRAJECTORY AND THE CASE OF TRANSITIVITY

Ayanna Franklin  
NSCU  
adfrankl@ncsu.edu

Zuhal Yilmaz  
NCSU  
zylimaz@ncsu.edu

Jere Confrey  
NCSU  
Jere_confrey@ncsu.edu

An important aspect of the learning trajectories (LT) construct is their dual theoretical and empirical nature (Confrey et al., 2009). While literature and theoretical perspectives are the basis of LTs, empirical data are necessary to ensure their validity through “iterative cycles of empirical testing and theoretical revision and refinement” (Duncan, 2009, p.607). The Diagnostic e-Learning Trajectory Approach (DELTA) LT validation process began with a synthesis of research articles. Through conducting clinical interviews and teaching experiments, a task design matrix with proficiency levels was created and outcome spaces were written based on student interview behaviors. Both pilot and field test items were created to assess these levels. Finally, rubrics were developed based on an examination of all responses to the field test items. Each step of this validation process led to revisions and refinements of the LT.

This poster presents the process by which the DELTA research team validated a LT for equipartitioning. Each level of the trajectory describes the development of young children’s fair sharing of collections to adolescents’ formalization of the partitive fractional quotient construct. Through analyzing data from clinical interviews and pilot item responses, this poster charts our progress in achieving greater clarity in how children’s abilities to fairly share a single whole using multiple methods relates to their emerging understandings of the equivalence of non-congruent parts. It describes how analyses of pilot item responses revealed multiple ways that children argued for equivalence between two figures, including composition/decomposition and transitivity. These observations were incorporated into a revised LT and additional items were field tested. An analysis of responses to these items during rubric construction revealed that multiple methods are significant if students can justify them and recognize transitivity within and across figures. Each cycle of revisions helped the team to infer about students’ thinking and resulted in an incorporation of those inferences in the LT. Ultimately, validation takes time but yields a more robust description of how children’s ideas develop.

USING PORTFOLIO ASSESSMENT IN MATHEMATICS COURSES FOR ELEMENTARY TEACHERS

Sandra Berry
IPFW
berrys@ipfw.edu

This poster display will present all aspects of the portfolio assessment program including course requirements, logistics, sample tasks, rubrics, student work and journal prompts. The intent of using this strategy in these content courses is to indicate to students clearly what is valued in their learning. As Clarke suggests: "It is through our assessment that we communicate most clearly to students which activities and learning outcomes we value" (Clarke, 1989 p.1).

As the students participate in the sequence of courses and create their portfolios they realize that what is expected and what is valued is correct solutions of the problems posed, but more importantly providing evidence of their understanding of the “Big Ideas” in the course and how the problems relate to those ideas. Clear and complete communication is stressed using appropriate mathematical vocabulary and terminology.

Portfolio assessment is not without it’s challenges and concerns and these will be shared and discussed. Evidence gathered from four consecutive years of portfolios will also be shared. This evidence indicates that students are focusing on their thinking and understanding of the mathematics content ideas rather than simply expecting to get a correct answer or do the right procedure. There is a shift toward self-assessment and improved communication and use of appropriate mathematical terminology.

- “YES, AND...”: HOW GROUPS BUILD IDEAS IN THE COLLECTIVE
  Jo Towers, Tina Rapke, Tony Pascuzzo, Lyndon C. Martin .................... 461
In a recent paper (Martin & Towers, 2009) we introduced the notion of improvisational coactions as a process through which mathematical ideas and actions, initially stemming from an individual learner, become taken up, built upon, developed, reworked and elaborated by others, and thus emerge as shared understandings for and across the group. We suggested that improvisational coactions are a specific kind of interaction, but with particular characteristics. In this paper we both illustrate and elaborate on the distinction between these two ways in which a group can work together and highlight the different kinds of mathematical understandings that emerge from these.

Introduction

The research reported in this paper forms part of our ongoing research program concerned with the nature of mathematical understanding and how it might be theorized and characterized. In recent years our specific focus has been the phenomenon of collective mathematical understanding—the kinds of learning and understanding we may see occurring when a group of learners work together on a piece of mathematics. We have characterized the growth of collective mathematical understanding as a creative and emergent improvisational process and illustrated how this can be observed in action (Martin, Towers, & Pirie, 2006; Martin & Towers, 2009; Martin & Towers, 2007; Towers & Martin, 2009). Here we present data that help to illuminate a distinction between interaction and improvisational coaction.

Theoretical framework

Our research draws on theoretical framings from two main perspectives—mathematical understanding (particularly the work of Pirie & Kieren, 1994) and the study of improvisational group performances in jazz and theatre (e.g., Berliner, 1994; Sawyer, 2003). While on the surface the phenomena of mathematical understanding and group improvisation may appear strange bedfellows, our initial explorations of the nature of collective mathematical understanding (Martin & Towers, 2009; Martin & Towers, 2007; Martin, Towers, & Pirie, 2006) have suggested that the fields of jazz and theatre improvisation have much to offer theoretically to an advancement of our understanding of how interacting groups coalesce on particular ideas that move the action (be it jazz or mathematical problem-solving) forward.

Improvisation is broadly defined as a process of “spontaneous action, interaction and communication” (Gordon Calvert, 2001, p.87). It is a collaborative practice of acting, interacting and reacting that emphasizes participants’ “ability to integrate multiple, spontaneously unfolding contributions into a coherent whole” (Ruhleder & Stoltzfus, 2000, p. 186). Improvisational theorists (Becker, 2000; Berliner, 1994; Sawyer, 1997, 2003) have proposed particular characteristics of the improvisational process and we have adapted and elaborated these in the context of collective mathematical understanding (Martin, Towers, & Pirie, 2006). In a recent paper (Martin & Towers, 2009) we developed the idea of improvisational coactions and its relationship to the growth of mathematical understanding at the level of the group. We chose the
term *coaction* as a means to describe a particular kind of mathematical action, one that whilst obviously in execution is still being carried out by an individual, is also dependent and contingent upon the actions of the others in the group. Thus, improvisational coacting is a process through which mathematical ideas and actions, initially stemming from an individual learner, become taken up, built upon, developed, reworked and elaborated by others, and thus emerge as shared understandings for and across the group, rather than remaining located within any one individual.

**Methodology and methods**

We worked with a number of student teachers who were in their first year of a two-year Bachelor of Education degree program at a university in Canada. They were preparing to be elementary school teachers, and none of those participating were, at the time, specializing in mathematics. The volunteer students were invited, during a series of lunch breaks, to be videotaped as they worked on some mathematical problems. They were encouraged to form their own groups of three or four and to choose tasks from a booklet supplied, which contained nine tasks covering different areas of mathematics ranging from “Fractions, Decimals and Percentages” to “Mathematical Argument” (Teacher Training Agency, 1998). The task booklet was produced in the United Kingdom with the intention of helping elementary teachers determine their development needs in mathematics. We chose this set of tasks for this study as we felt they offered an appropriate level of challenge to the student teachers, and were also presented in a way that would stimulate discussion and collective action. The main purpose of the data collection was to allow us to elaborate the theoretical notion of improvisational coactions through exploring it in greater depth than we had previously, and thus we deliberately chose tasks and participants that would allow us to do this.

The analysis of the video data drew on the approach proposed by Powell, Francisco, and Maher (2003). This is a seven stage process involving (1) simply viewing the tapes in their entirety; (2) describing the video-data through writing brief, time-coded descriptions; (3) identifying ‘critical events’ with regard to our interest in improvisational coaction; (4) transcribing relevant excerpts of data relating to these critical events; (5) analyzing and coding of the critical events using our existing definition and description of improvisational coactions together with elements of the Pirie-Kieren Theory; (6) identifying and constructing a storyline to “discern an emerging and evolving narrative about the data” (Powell, Francisco, & Maher 2003, p. 430); and (7) composing narratives, and for us the linking of those narratives to characteristics of coaction to further develop our theoretical notion of improvisational coactions.

**Results**

In this paper we are only able to share a few brief excerpts from the video data of two groups of students. However, some of our comments that follow are drawn from the analysis of the larger data set, and not merely these short transcripts. The first group has three students known here as Mary, Shauna, and Kay. The second group, while retaining Mary and Shauna, has Kay replaced by Hillary (this was not a deliberate part of the research design, but a result of Kay being absent).

*Extract One*

The students in the first group (Mary, Shauna and Kay) have chosen the following task from the booklet, and are trying to determine what the correct answer should be:
Children were asked to find the original cost of an item which had been reduced in a sale by 15% to £850. One child did the following calculation:

\[
\frac{850 \times 15}{100} = 122.50 \\
850 + 122.50 = 977.50
\]

Describe why the child has arrived at an incorrect solution and calculate the correct answer.

Just prior to the extract below, the students have spent a few minutes playing with the question. Initially they thought the child had calculated the £122.50 correctly, but that they should have subtracted this. However, they then realised that the child had incorrectly found 15% of the sale price. Kay has pointed out to the group that 85% equals £850 and that they need to calculate what 100% would be. We join the group as they begin working on this:

1 Kay: I’ve got to write it down in order to…[she looks for a pencil in her bag]
2 Shauna: You can write on there.
3 Kay: I’ve got to see it. I’m a visual learner. I can’t do it all in my head. [she starts writing out the calculation]
4 Shauna: Neither can I but I have no idea what to write down.
5 Kay: One hundred equals…[talking as she writes]
6 Mary: You know what, all we have to say is why she didn’t come to the correct answer, well we calculate the correct amount.
7 Shauna: Yeah.
8 Kay: Eighty-five equals. Eight-fifty. Eighty five x equals…[she is still writing]
9 Shauna: It looks like the child’s done a great job [she looks at Mary]. I would have done the same thing. Because you just go…
10 Mary: I remember doing these and that’s how…
11 Shauna: Usually like if a person’s gets it wrong thing it’s because they go by the information that’s in the question.
12 Kay: Okay. A thousand pounds is the answer [she looks up but not at Mary or Shauna].
13 Mary: Oh. Yeah?
14 Shauna: Instead of what’s on…
15 Kay: I would figure a thousand pounds would be the answer. Now does that work?
16 Shauna: But that’s like pretty close to that. Like, did you round up? [they are looking at Kay’s written work]
17 Kay: No.
18 Shauna: Okay.
19 Shauna: So but are they going to be using x’s at this age?
20 Mary: We don’t know what grade this is.
21 Shauna: Like what age is this?
22 Kay: That’s just how I would do it.
23 Mary: A thousand. So what’s fifteen percent of a thousand?
24 Kay: Okay, so in order to work backwards, fifteen percent of a thousand would be hundred and fifty. [Mary and Shauna are watching Kay as she explains to them]
25 Mary: So it’s not quite.
26 Kay: Fifteen percent of one thousand is one fifty so if you take a thousand minus one fifty you get eight hundred and fifty and therefore it’s right.
Although all three students are talking and contributing throughout this episode, there is not a sense of collaborative mathematical working taking place. Kay sets out her need to write down the calculation she is performing and then proceeds to articulate this as she works (lines 5,8,12,15). Shauna and Mary do not engage with her mathematical working—instead there is something of a conversation between them about the problem generally. They seem to be simply waiting for Kay to finish and to tell them the answer. When she does this, there is no great surprise from Mary (line 13) who seems happy to accept Kay’s solution. Kay’s question (line 15) seems posed to herself rather than to the group and does not seem to invite (or receive) a response. Although Shauna questions her a little (line 16 - thinking that the answer is merely the incorrect solution rounded up – suggesting she doesn’t really follow what Kay has done), Kay dismisses this saying “that’s just how I would do it” (line 22). There is an attempt by Mary (line 23) to engage the group in checking the answer but Kay quickly gives just the answer, followed by the final statement of “therefore it’s right” with no suggestion that she needs the group to agree with her.

Extract Two

In the next two extracts the second group (Mary, Shauna and Hillary) have chosen a task that requires them to classify a number of triangles drawn on 9 pin geoboards by their side length properties and to label them as equilateral, scalene or isosceles. There is a short pause as they seem to consider where to start:

[Shauna looks at Mary, who nods back.]

27 Shauna: It’s all coming back to me.
28 Hilary: I don’t remember scalene or isosceles.
29 Shauna: Isosceles is this, okay? [She is drawing.] Where two are equal?
30 Mary: Yeah.
31 Shauna: Equilateral is when they’re all equal?
32 Hilary: Hm hm...
33 Shauna: And scalene is?
34 Mary: They’re all wonky?
35 Hilary: This must be scalene. [Pointing to triangle in Figure 1.]
36 Shauna: Okay.
37 Hilary: When it has one, one sss...[pause]
38 Mary: One longer?
39 Shauna: Isos, eq and scale. So the scale, none of them [the sides] are equal?

Although the initial statement of Shauna (line 27) suggests that properties of triangles and their associated names are not new to them, none of the three students seems immediately able to recall and restate the definitions for the three different kinds of triangles. No one student is able to offer a complete definition and instead the three students each offer what can be characterised as partial fragments of an image for the scalene triangle. Mary talks of it as being “wonky” (line 34), Hilary and Mary both develop the idea of “one longer” side (lines 37 and 38), whilst Shauna extends this idea to the conception of “none of them [the sides] are equal” (line 39). There is a building on what individuals offer, and the image emerging is a function of the discourse and is not simply being articulated by any one student.

Extract Three

Following the extract above, they begin work on the task, and start to label each of the triangles as equilateral, isosceles, or scalene using their definitions. However, they decide that in the case of some triangles they need to measure the sides to be able to determine their type. But they do not have a ruler, and instead turn to examining the relationship between the dots (what the students refer to as pins or dots or pegs) and the sides of the triangles. Just prior to the extract below they have been using a rule they have generated that states that the distance between any two neighboring pins (even diagonal neighbors) is equal, but they are now unsure whether this is right.

40 Mary: I don’t know...

A pause

41 Shauna: But, maybe, yeah...

Another pause

42 Mary: Like, there’s something with it going across there that messes it up. Why can’t we think of it?

43 Hilary: ‘Cos there’s always...

44 Shauna: Okay. I got it, I got it. If it’s like...

45 Hilary: [Laughing] Are you making this up?

46 Shauna: No, I’m just thinking. Say for like a right angle. Okay, it made sense and now I can’t say it out loud [pause]. I think its because this is obtuse, like...

47 Hilary: Because, wait. Oh my goodness, don’t you remember? \(a^2 + b^2 = c^2\)?

48 Shauna: Yeah.

49 Hilary: That means these are not. \(a^2 + b^2 = c^2\). So this cannot be equal to two. This is two squared plus two squared, do you see what I’m getting at here? This isn’t the same distance as this. [She is now talking about the hypotenuse and one other side of the triangle in Figure 2 again.]

50 Shauna: Well, it worked [laughing]. It worked!

51 Hilary: So this is not.

52 Shauna: Yeah, cos you didn’t take the square root.

Just prior to the start of the extract above they have realised that their current image and criteria for classifying the triangles are incorrect. However, none of the three is initially able to offer a new image, idea, or starting point, evidenced by the pauses in speech (lines 40-42). Suddenly though, Shauna interjects, and although she cannot easily articulate her thinking she states what seems to be an important idea “say for a right angle” (line 46). Her recalling of this prompts Hilary, who builds on what Shauna seems to be thinking (even though it was not clearly articulated), to recall Pythagoras’ Theorem, recognizing that it might be appropriate to use in the context of this problem (line 47). This concept is then brought into their current thinking as another image that they can use in determining the type of triangle at which they are looking. The process of finding, recalling and restating Pythagoras’ Theorem is an ongoing one, with individual suggestions and thoughts acting to spur further contributions from the group that collectively build on these.
Discussion

In reference to our first data extract we suggest that while the three students are collaborating and talking together (as they did throughout the whole hour they worked together) a collective understanding does not emerge from this. At a superficial level, the three students do appear to have worked together, and to have participated in the finding of the answer. However it is the nature and form of the collaboration which may (or may not) give rise to the growth of mathematical understanding at the collective level.

We suggest that Mary, Shauna and Kay are interacting rather than coacting and that what we see is a set of individual understandings that, although being compatible with one another, are never truly shared or distributed. There is no sense of collective purpose or any interweaving of partial ideas being offered, picked up and built on by others. In the case of Mary and Shauna this is particularly significant, as we would question whether at the end of the extract their understanding of percentages has grown. Although the ‘group’ has solved the problem we would suggest that Mary and Shauna’s individual understandings are limited and likely to be some kind of memorized, procedural replication of Kay’s approach and method of solving the problem.

Improvisational literature refers to the notion of a “driver” (a dominant role wherein one member of an improvisational group dominates the emerging direction), the presence of which typically flattens and ultimately halts an improvisational performance. Kay acts as the ‘driver’ throughout this extract (though this should not be taken as a criticism of Kay, her mathematics, or her intent) and removes the opportunity or need for the kinds of collective interdependence we see in the second two extracts.

In the second two extracts we see something very different occurring. Here, no one student acts as the driver, instead all contribute to a collective understanding that we see emerging from the interweaving of their suggestions and ideas. We characterize Mary, Shauna and Hillary as improvisationally coacting. There is a sense of unpredictability about the pathways their collective mathematical actions, and emerging understandings, will follow, and it is this that contributes to the improvisational nature of the process. They act on the ideas of each other, building on what is offered to collectively work together in order to have (or even re-have) a useable image. This understanding emerges from the way that the offered ideas are starting to intertwine and be developed through the discourse. There is a sense in the extracts that no one student simply wants (or is able) to tell the others what to do, or to merely state a mathematical idea without expecting some response. Equally, those listening to the idea seem to accept their responsibility to do something with what is offered, and not merely receive it (in the way Mary and Shauna do in the first extract). The way in which the second group is able to interweave fragments of each individual’s knowing, to allow a shared (rather than taken-as-shared) image to emerge from their coactions, is what enables their collective mathematical understanding to grow and ultimately enables them to successfully complete the task.

Conclusion

Our analysis of the extracts above highlights the distinction we wish to make between interaction and improvisational coaction, and the importance of observing how a group collaborates—even when all its members appear to be participating. Coaction emphasizes the notion of acting with the ideas and actions of others as they are offered to the group, and places as much responsibility on those who are positioned to respond to an action as on the originator. Interaction we see as being more of a process of acting on the ideas of another in a reciprocal or complementary way. Such interaction may allow for separate, individual traces of mathematical
understanding to be observed, but groups who work in this way seem to lack the capacity (or responsibility) to build upon and add to the emerging collective image and therefore diminish the capacity for collective mathematical understanding to develop and be observed.

As noted earlier, in the first extract we remain concerned about whether Mary and Shauna’s individual understanding has grown through the observed episode. In contrast, we suggest that collective image making and the growth of collective mathematical understanding were powerful factors in enabling Mary, Shauna and Hilary to be successful in solving the task in the second extract, and also likely to enable their individual understandings to also grow. Groups that improvisationally coact, as in the case of Mary, Shauna and Hilary, have the capacity to work mathematically, and to solve problems, in ways that individually may not be possible.

EXPLORING THE RELATIONSHIP BETWEEN WRITTEN AND ENACTED CURRICULA: THE USE OF MATHEMATICAL WORDS

Jill Newton
Purdue University
janewton@purdue.edu

This paper reports on part of a study that examined the relationship between written and enacted curricula. The purpose of the study was to investigate the use of a discursive framework to explore fidelity of implementation focused on the mathematics presented in the curricula. Both quantitative and qualitative differences in mathematical word use in the curricula were revealed. In particular, opportunities for objectification and using a wide variety of types of fractions were more present in the written curriculum. Here, I focus on the use of “fraction” and fractions themselves to provide an example of the utility of the framework.

Introduction

Since the publication of the first set of standards by the National Council of Teachers of Mathematics (1989) and subsequent development of curricula to support their vision, there have been calls for evidence that the standards and their associated curricula are improving student learning. An important factor in assigning credit or blame for student mathematical learning to the standards or curricula involves documenting the extent to which these curricula are being used in classrooms in ways “faithful” to their original intent. It is only after some level of fidelity of implementation has been established that credit or blame can be assigned. In two key documents that examined studies of these curricula’s effectiveness (National Research Council, 2004; Senk & Thompson, 2003), the need for attention to implementation was strongly emphasized. Researchers have documented the enactment of curricula in a variety of ways, including asking teachers which chapters have been completed, observing classrooms for evidence of standards-based practices, and collecting textbook-use diaries from students and teachers (e.g., Tarr, Chavez, Reys, and Reys, 2006). What seems absent from these methods is attention to the mathematics presented in the written curriculum and that which is enacted in the classroom (i.e., the enacted curriculum).

In this paper, I present a small part of a study in which I examined the relationship between the written and enacted curricula in one classroom. The purpose of the study was to investigate the usefulness of a discursive framework for revealing the mathematics. I argue that a detailed analysis of the mathematical discourse revealed relationships between the written curriculum and what a teacher and her students enacted in the classroom.

Theoretical Framework

In this study, I conceptualize the written and enacted curricula as discursive texts, and define mathematics as discourse about mathematical objects and mathematical learning as a change in participation in mathematical discourse. This allowed me to compare the curricula using a discourse analytic framework, the Commognitive framework (Sfard, 2008). Commognition (created by merging communication and cognition) treats communication (interpersonal exchange) and cognition (intrapersonal exchange) as two forms of the same phenomenon. It was
developed to emphasize the close relationship between these two processes. Commognition suggests a detailed analysis (i.e., a search for patterns) of the use of discursive features of mathematics, including (1) Mathematical Words, (2) Visual Mediators, (3) Endorsed Narratives, and (4) Mathematical Routines. Mathematical words include those that signify mathematical products (e.g., triangles) and processes (e.g., multiplying). Visual mediators are artifacts created for the primary purpose of mathematical communication, including but not limited to algebraic symbols, diagrams, and graphical representations. Narratives include any text, spoken or written, which is framed as a description of objects, of relations between objects or processes with or by objects, and which is subject to endorsement or rejection (i.e., being labeled true or false). Finally, routines are repetitive characteristics of mathematical discourse. A comparison of these features of mathematical discourse in the written and enacted curricula provides information about the fidelity of implementation of the curricula as one would expect to find a relationship between these features in the textbooks and the classroom.

One phenomenon that is particularly sensitive to this type of analysis is objectification. Objectification is defined as “a process in which a noun begins to be used as if it signifies an extradiscursive, self-sustained entity (object), independent of human agency” (Sfard, 2008, p. 412). The process consists of two closely related sub-processes: reification and alienation. Reification is the replacement of talk about processes with talk about objects and alienation is the use of discursive forms that present phenomena in an impersonal way, as if they were occurring of themselves, without the participation of human beings. These two processes, when taken together indicate that what was previously something to “do” becomes a discursive “object”. Mathematical and scientific discourses are particularly dependent upon objectification for their successful evolution. The objectification of fractions occurs when an individual reifies the division of one into four equal parts into an object (that can be marked as “1/4”, “0.25,” etc.) and “encapsulates” three of these one-fourths into a single entity, “3/4”. Objectification in school mathematics is more important today than ever as more students are expected to take advanced mathematics courses and therefore to operate on a larger domain of numbers.

Methods

I used Connected Mathematics 2 (Lappan, Fey, Fitzgerald, Friel, & Phillips, 2006) as the written curriculum for this study, in particular, a five-day Investigation, Multiplying with Fractions, included in Bits and Pieces II: Using Fraction Operations (the second of three Units in grade 6 that address fractions). When “Investigation” is capitalized in this paper, I am referring to this particular Investigation. The union of the teacher guide and the student guide served as the written curriculum. The enacted curriculum analyzed for this study took place in a sixth grade classroom in a rural community in the Midwest on five consecutive days in October 2006. The class was heterogeneous in mathematical ability (i.e., the students were not tracked). The teacher of this particular class was a veteran Connected Mathematics teacher. She had used Connected Mathematics for 13 years, attended and conducted professional development for Connected Mathematics, and verbally endorsed the curriculum. The union of student and teacher discourse, both oral and written, served as the enacted curriculum.

In the larger study, the written and enacted curricula were compared in terms of the four mathematical features included in the Commognitive framework. However, in this paper, I focus only on a comparison of the mathematical word use, and even more specifically, on the use of “fraction.” This includes any derivatives of the word (e.g., fractions, fractioning) and fractions themselves (e.g., “two thirds”, “\(\frac{2}{3}\)).

Findings

Uses of “Fraction” in the Curricula

Four common categories of the use of “fraction” and its derivatives (e.g., “fractioning”) emerged from the written and enacted curricula, including fraction as a number, a part, an adjective, and a verb. Table 1 provides examples of each category of use in the curricula.

<table>
<thead>
<tr>
<th>Category</th>
<th>Written Curriculum</th>
<th>Enacted Curriculum</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number</td>
<td>“The strategy introduced in the Getting Ready involves changing the form of mixed numbers and whole numbers so students can operate in the same way as when both factors are fractions.” (TG, p. 75)</td>
<td>S: “One thing I don't get is, you know how when we said eight times seven and we showed like the picture. Like, that wouldn't work with fractions, would it?” (Day 2)</td>
</tr>
<tr>
<td>Part</td>
<td>“What fraction of the goal does Nikki raise?” (SG, p. 36)</td>
<td>S: “She, it said what fraction of the pan she bought, and she would buy two sixths of the pan because if you split these into thirds you'll get two sixths.” (Day 1)</td>
</tr>
<tr>
<td>Adjective</td>
<td>“Sometimes, they have to find a fractional part of another fraction.” (SG, p. 32)</td>
<td>T: “You can buy any fractional part of a pan of brownies and pay that fraction of twelve dollars.” (Day 1)</td>
</tr>
<tr>
<td>Verb</td>
<td>-----</td>
<td>T: “Maybe you're going to have a picture of something and be fractioning off parts or whatever.” (Day 4)</td>
</tr>
</tbody>
</table>

1. Dashes (i.e., “-----”) indicate that the category of use of “fraction” is not present in the designated curriculum.
2. “TG” indicates the Teacher Guide and “SG” indicates the Student Guide.

I distinguished between the “number” and “part” categories by determining which word (i.e., “number” or “part”) could replace “fraction” in each sentence. Even though “fraction” is used as a noun in both of these categories, when “fraction” is used as “part,” it is used only in specific contexts.
types of phrases (e.g., “fraction of the whole pan”). Therefore, it is only when “fraction” is used as a number that it is objectified and discussed as if it has a life of its own. The fraction as number example from the written curriculum refers to fractions as factors and factors are objects in their own right. In the fraction as number example from the enacted curriculum, the student is comparing fraction multiplication to whole number multiplication which reifies “fraction.” In contrast, the other examples use “fraction” and its derivatives as processes or descriptors which does not fulfill the reification requirement of objectification. Figure 1 summarizes the relative frequency of each category in the curricula.

“Fraction” as number is the most common use of “fraction” in both the written and enacted curricula; however, its use as number represents nearly three-fourths of the uses in the written curriculum compared to slightly more than half in the enacted curriculum. “Fraction” as part is more common in the enacted curriculum than in the written curriculum (42% compared to 15%) which indicates that “fraction” and its derivatives are objectified more often in the written curriculum than in the enacted curriculum.

Next, I examined the use of fractions in the written and enacted curricula. Figure 2 summarizes the relative frequencies of proper fractions, improper fractions, and mixed numbers in the curricula.

The relative frequency of the appearance of each type varies substantially. For example, proper fractions represent 57% of all fractions present in the written curriculum compared to 83% in the enacted curriculum, whereas mixed numbers represent 35% of all fractions present in the written curriculum compared to just 13% in the enacted curriculum. This may indicate that in this Investigation, students have more experience with proper fractions and less experience with improper fractions and mixed numbers than intended by the authors of the written curriculum. In terms of objectification, the extension from multiplication of fractions to include improper fractions and mixed numbers may facilitate reification (and therefore objectification) by problematizing the “part of part” discursive pattern. For example, it is possible to speak about \( \frac{1}{6} \times \frac{3}{4} \) as \( \frac{1}{6} \) of \( \frac{3}{4} \) (i.e., part of a part) indefinitely. Therefore, if only proper fractions are provided as examples, the reification of fractions may never happen. However, it is much more...
problematic to speak about “\( \frac{7}{6} \times \frac{3}{4} \)” as “\( \frac{7}{6} \) of \( \frac{3}{4} \).” This problematizing is important because it may facilitate the reification of fractions.

The five most common proper fractions in the written and enacted curricula are the same (i.e., \( \frac{1}{2}, \frac{2}{3}, \frac{1}{3}, \frac{1}{4}, \frac{3}{4} \)). In fact, even their order of prevalence is the same. When taken as a whole, these common fractions make up 42% of all proper fractions that appear in the written curriculum and 70% of all proper fractions included in the enacted curriculum. This statistic indicates that students are having less exposure to a variety of proper fractions than the authors intended.

![Graph showing frequencies of fractions in written and enacted curricula]

**Figure 2. Relative frequencies of the total number of appearances of proper and improper fractions and mixed numbers in the written and enacted curricula**

As mentioned previously, reification of fractions is dependent upon the encapsulation of fractional parts (e.g., four one-sevenths) into one number (e.g., “\( \frac{4}{7} \)”). Evidence of such reification in association with proper and improper fractions and mixed numbers is rare in the enacted curriculum because nearly all fraction discourse is of the form “\( X \) of \( Y \)” where \( X \) is a fraction (e.g., two thirds) and \( Y \) is either another fraction or a contextual object (e.g., brownie pan). Examples such as the ones presented here are ubiquitous throughout the five days:

**Example 1 (Enacted Curriculum).**
S: “Because he wants to buy one half of the pan that is two thirds full.” (Day 1)

**Example 2 (Enacted Curriculum).**
T: “One third of a half, right? So what are you starting with, if you have one third of a half, what are you starting with?” (Day 3)

This prevalence of “\( X \) of \( Y \)” is also found in the written curriculum in the first problems of the Investigation (Days 1-3); however, the last two problems (Days 4-5) contain less of this use.
In both the written and enacted curricula, estimation discussions seem to facilitate the objectification of fractions. For example, the following problem from the written curriculum provides such opportunities:

**Example 3 (Written Curriculum).**  

Getting Ready for Problem 3.3  

Estimate each product to the nearest whole number 

\[
\frac{1}{2} \times 2 \frac{9}{10} \quad 1 \frac{1}{2} \times 2 \frac{9}{10} \quad 2 \frac{1}{2} \times \frac{4}{7} \quad 3 \frac{1}{4} \times 2 \frac{11}{12}
\]

Will the actual product be greater than or less than your whole number estimate?

Here, the question asks “Will the actual product be greater than or less than your whole number estimate?” Numbers are “greater than or less than,” therefore, the use of these words promotes the objectification of fractions. This type of language is used in several places in the written curriculum in association with estimation. Another example is included here:

**Example 4 (Written Curriculum).**  

“\( \frac{9}{3} \) is 3 and \( \frac{1}{2} \) of 3 is \( 1 \frac{1}{2} \), which is greater than 1.” (TG, p. 62)

Again in Example 67, \( 1 \frac{1}{2} \) “is greater than” 1 seems to imply the reification of “\( 1 \frac{1}{2} \)” as a mathematical object in its own right rather than as a whole number (i.e., 1) and a fraction (i.e., \( \frac{1}{2} \)). This is not the case for all estimation problems in the written curriculum; however, it is notable that such instances are common in the written curriculum in association with estimation.

Some language used in association with estimation in the enacted curriculum also indicates the possible reification of fractions. The following statement is made by a student that is rounding up \( 2 \frac{9}{10} \) to 3:

**Example 5 (Enacted Curriculum).**  

S: “Because if I was going to round up the nine tenths like Graham did so” (Day 4)

“Rounding up” is language associated with numbers. That is, \( 2 \frac{9}{10} \) (and \( \frac{9}{10} \) itself) seems to be used here as a number. Another example comes from a student multiplying \( 4 \frac{1}{2} \) by 1:

**Example 6 (Enacted Curriculum).**  

S: “Well I think you’d have to times it ’cause one times any number is always itself, so I think it’d be about four and a half because” (Day 4)

---

This student states explicitly that $4 \frac{1}{2}$ is a number and therefore multiplying it by 1 would “be about four and a half.” The next excerpt, taken from the same day indicates the complexity of determining whether or not reification has occurred. The Question being discussed is “$\frac{1}{2} \times 2 \frac{9}{10}$.”

**Example 7 (Enacted Curriculum).**

(1) T:  Could you help me with an estimate? If I said I was going to get one half of two and nine tenths, Graham, how could we think about estimating that answer?

(2) S1:  Well, nine tenths, that's close to a whole, so -

(3) S2:  One.

(4) S3:  Yeah, so

(5) T:  So what, Graham?

(6) S2:  Nine tenths is close to a whole.

(7) T:  Okay. So you could round that up into a whole and then two would be a three.

So you would call this [points to $2 \frac{9}{10}$] about three?

This excerpt is interesting because the student seems to be reifying “$\frac{9}{10}$” because he says “nine tenths is” in Line 6. This is in contrast to saying “nine tenths are” in which the plural verb is used because the nine is plural. In addition, the teacher uses “round that up” in Line 7 which also tends to be used in cases where a fraction is reified because numbers are rounded up. The complexity comes from these indications of reification combined with the use of “whole” in Lines 1, 5, and 6 by both the teacher and the students. Discourse indicative of reification would use “one” instead of “whole” to indicate that “$\frac{9}{10}$,” because it is a number, should be compared to another number.

**Discussion**

The question addressed in this discussion is, “What does an investigation of the mathematical words in the written and enacted curricula allow us to see?” The analysis revealed several potentially significant differences. First, “fraction” is more often used as a number in the written curriculum than in the enacted curriculum (72% of uses compared to 53% of uses). In the enacted curriculum, 42% of the uses of “fraction” were as a part compared to only 15% in the written curriculum. This is important because opportunities for students to use fraction as a number facilitates students’ objectification of fractions. Second, 83% of all fractions in the enacted curriculum are proper fractions compared to 57% of the fractions in the written curriculum. The remainder are improper fractions or mixed numbers. Third, the five most common fractions represent 42% of all proper fractions in the written curriculum compared to 70% in the enacted curriculum. The second and third points, when taken together, indicate that students are likely not receiving opportunities to use the wide variety of fractions and fraction types provided in the written curriculum. Finally, the “X of Y” discursive pattern is used
extensively on all five days in the enacted curriculum and only on the first three days in the written curriculum. Although this discursive pattern likely serves students well as they develop meaning for fraction multiplication, the fact that the pattern continues throughout the Investigation suggests that students are not be given opportunities to move beyond talking about fractions as parts to fractions as numbers in the context of multiplication. These four examples of mathematical differences were made obvious using the Commognitive framework and likely would not have been brought to light using common methods to document curricular fidelity of implementation.

The claims in this paper are made with several caveats. First, this analysis compares the written text with an enactment of the written text (one of infinitely many possible enactments); this should be kept in mind when reading these statements as some results may be attributed to this difference in curricular form. Second, similarity (and difference) here is through my eyes only. That is, another person (e.g., a teacher, a textbook author) using their own lens may see things quite differently. Finally, the evidence for my claims is gleaned from five days of the written and enacted curricula. That is, none of my statements can be generalized either to the written curriculum as a whole or the enacted curriculum as a whole. Rather, they highlight insights gained through the use of this framework regarding the relationship between the written and enacted curriculum on these five days that may be of interest to teachers, curriculum developers, and mathematics education researchers.

INTELLECTUAL WORK: THE DEPTH OF MATHEMATICAL DISCOURSE AND ITS RELATIONSHIP TO STUDENT LEARNING

Jessica Pierson Bishop

ianwhitacre@yahoo.com

In this paper we consider the transformative use of language at the micro-level of classroom action – how teachers and students respond to one another moment-by-moment and the resulting knowledge constructed in those exchanges. We focus on a theoretically significant construct of discourse, intellectual work, in order to describe the levels of intellectual work in teacher and student discourse and to determine how differences in intellectual work are related to learning. Using techniques of discourse analysis combined with HLM, we found that although intellectually demanding discourse is rare, there is a large pay-off for student learning when it is present.

Introduction

We take as our premise that learning occurs in interaction. And one of the primary means of interaction in classrooms is discourse; thus, our focus is the mathematical discourse of teachers and students and the relationship of these discourses to student learning. Like Vygotsky, we view language as a mediational tool that can fundamentally transform the potential for action and make new kinds of meaning and understanding possible in classrooms (Vygotsky, 1986; Wertsch, 1991). In this paper we consider the transformative use of language at the micro-level of classroom action – how teachers and students respond to one another moment by moment and the resulting knowledge that is constructed in those exchanges.

By nature of the institutional authority of their position, teachers play a large role in determining discursive norms, but they alone do not determine patterns of interaction. Because of the reciprocal, dependent and unpredictable nature of discourse, teachers and students together co-construct these context-dependent ways of engaging in classrooms. Ways of responding and interacting are negotiated, internalized, and eventually become recognized ways of doing things in the localized mathematics communities we call classrooms. As in any community, classroom events develop a sense of coherence over time where certain types of discourse moves are expected and employed as standard routines of behavior. Through these familiar and repeated patterns of interaction, learning occurs. Thus, differences in discourse patterns (e.g., consistently requesting justifications instead of answers only) can lead to differences in learning.

We are interested in a particular theoretically significant construct reflected in classroom discourse – the amount of intellectual work required of students (Hiebert & Wearne, 1993; Pierson, 2008; Stein, Grover & Henningson, 1996; Vygotsky, 1978; Webb, Nemer & Ing, 2006). Intellectual work reflects the cognitive work set in motion and required of students within a given turn of talk. Higher levels of intellectual work extend thinking and include discursive moves such as providing justifications, examples, conjectures, explanations, and challenges; making connections across representations; generating problems and scenarios (contextualizing); or requesting these activities from students.

Intellectual work can be thought of in terms of what cognitive activities students are asked to (and do) engage in during real-time, classroom conversations. Over time, if students routinely make sense of mathematics, struggle with complex problems, reason for themselves, generate

multiple solution paths, and communicate their understandings, the potential for deeper mathematical understanding increases. Higher levels of intellectual work are invitations to do exactly this, to engage deeply with the processes and content of mathematics.

Our research sought to describe the levels of intellectual work in teacher and student discourse and to determine whether and how differences in intellectual work were related to students’ mathematics achievement. Specifically, the research questions guiding our study were:

1. What levels of intellectual work are observed in seventh-grade mathematics classrooms?
2. What is the relationship between the intellectual work reflected in students’ responses and the intellectual work required by their teachers?
3. What is the relationship between the level of intellectual work in teacher and student discourse in a curricular unit on rate and proportionality and seventh graders’ learning of mathematics as measured by a validated pre- and post-test?

Methods

Participants and Setting

This study is part of a larger program of research, Scaling Up SimCalc, which investigated the efficacy of a 3-week curricular unit on rate and proportionality using the SimCalc™ Math Worlds technology (see Kaput, 1994) as it was taken to scale across Texas. The broader experimental study investigated the impact of a technology-rich curriculum combined with focused professional development on student learning. Overall main effects were statistically and practically significant showing that students in SimCalc classrooms learned more than their counterparts in the control classrooms (p < .0001 and a student-level effect size of .63; see Roschelle, Shechtman, Tatar, Hegedus, Hopkins, Empson, Knudsen & Gallagher, in press).

In our study, we analyzed the discourse moves of 13 teachers and approximately 250 students in seventh-grade mathematics classrooms as they implemented the SimCalc technology and curriculum. All students took a pre- and post-test that assessed basic understandings of rate and proportionality as well as more complex and conceptually difficult understandings including the interpretation of piecewise linear graphs of motion and the relationships between graphical, algebraic (written symbols) and tabular representations of motion. We selected a lesson in the middle of the SimCalc Math Worlds curricular unit and videotaped 13 teachers teaching the same lesson. The corresponding transcripts and video footage along with the pre- and post-test scores provide the data corpus for this study.

Coding Scheme

Operationalizing the intellectual work present in moment-to-moment discourse moves is not straightforward. In a broad sense, students can a) give (or be given) information to make sense of (give moves) or b) request information or, more likely, have their teacher request information from them (demand moves). In give moves, the speaker’s role is to do the work of making connections, supplying information, selecting relevant responses, and evaluating the correctness of ideas. Discourse moves in the demand category offer this role to another (typically the student) as the speaker’s role shifts from knowledge source to facilitator. The final outcome of discourse routines relying on give versus demand moves is largely the same, an increase of the group’s common knowledge, but the responsibility and division of labor in achieving it is different. Our coding scheme for intellectual work takes into account the distinction between give and demand moves as well as the cognitive action required of the participant. We define three levels of
intellectual work with relevant examples in Table 1 below (see Pierson, 2008 for a more detailed description of the coding scheme).

<table>
<thead>
<tr>
<th>Table 1. Intellectual Work Coding Scheme</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Demand</strong></td>
</tr>
<tr>
<td><strong>Low:</strong> Moves that provide basic information such as reading values off graphs/charts, performing calculations, or requesting these activities from others.</td>
</tr>
<tr>
<td><strong>Potentially High:</strong> Moves where claims or conjectures are requested or provided but evidence and justifications are not provided; moves include generating problem scenarios for given graphs, interpreting graphs of motion and making conjectures, or requesting these activities from others.</td>
</tr>
<tr>
<td><strong>High:</strong> Moves facilitating engagement in mathematical argumentation and justification, engaging with another’s thinking in a sophisticated way, or requesting these kinds of activities from others.</td>
</tr>
</tbody>
</table>

Using this coding scheme, we coded each transcript turn by turn indicating the level of intellectual work present, whether the move was a give or a demand, the speaker, and the mathematical correctness of the statement (note that demand moves were not coded for correctness). To establish reliability, a random sample of 10% of the transcript exchanges were selected and coded independently. Interrater agreement was 89%. (Note: Although we present a finalized coding scheme, it was developed and refined through an iterative process, drawing both from the data itself as well as findings from relevant literature.)

Quantitative Analyses and Hierarchical Linear Modeling

Because of the nested nature of the data set and the fact that student test scores were not independent, we also analyzed the data using hierarchical linear modeling. For each measure of discourse (both teacher and student discourse) we specified and ran a two-level hierarchical linear model on student post-test achievement scores, nesting students within classrooms. We constructed each model using the appropriate classroom discourse measure of intellectual work as a predictor at the classroom level and pre-test achievement scores as a predictor at the student level. This allowed us to test the nature and strength of the relationship between teacher and student intellectual work and student achievement.

Findings

A Profile of Teacher and Student Intellectual Work Across Classrooms

In this section we report the results from the analysis of intellectual work of both teacher and student discourse. Figure 1 on the following page aggregates frequency counts for the various categories of Give and Demand moves across all classrooms showing the total number of teacher demand moves, teacher give moves and student give moves for each of the three levels of intellectual work. In these 13 classrooms, we see that low-level give and demand moves dominate the discourse, that teachers rarely demand high levels of intellectual work, and that
students provide high levels of intellectual work infrequently (see similar findings in Kawanka & Stigler, 1999; Stein, Grover & Henningson, 1996; Webb et al., 2006). 

The Relationship Between Teacher and Student Discourse Moves

To better understand if and how the intellectual work reflected in student discourse was related to patterns in teachers’ discourse, we focused on exchanges where a teacher demand move was followed immediately by a student give move. For each teacher we categorized his or her demand moves into one of three categories – Low, Potentially High and High. Within each of these three levels of Teacher Demand we identified and then counted the type of student give move that followed. Table 2 below aggregates counts of demand-give pairs across the data set.

<table>
<thead>

</tr>
</tbody>
</table>

Essentially we see that low demands lead to low gives, potentially high demands lead to potentially high gives, and high demands lead to high gives (see bold cells). To test this relationship more robustly using statistical methods, we first disaggregated these frequency counts for each teacher. In other words, we counted the number of student give moves within each category of demand moves for every teacher. In other words, we counted the number of student give moves within each category of demand moves for every teacher. Table 3 provides an example for one teacher.

</tbody>
</table>

Based on these frequency counts we then calculated the average Student Give level for each category of teacher demand (see the last column in Table 3). To have a meaningful metric we used a weighted average, weighting student give moves as follows: Low Gives were weighted as 0, Potentially High Gives were weighted as 1, and High Gives were weighted as 2. We chose this metric because it accounts for both the quality and quantity of student give moves. For the classroom in Table 3 the average Student Give level following a Potentially High Teacher Demand move is given by the calculation

$$\frac{16(0)+13(1)+1(2)}{16+13+1} = .5.$$  

In other words, the student is equally likely to reply to a teacher potentially high demand move with either a low level give (weight of 0) or a potentially-high give (weight of 1); the average student response lies in between a low give and a potentially high give. Figure 2 visually displays the average Student Give level for each Teacher Demand Level along with the mean Student Give Average across all 13 classrooms.

**Figure 2. Student Give Weighted Average By Teacher Demand Level Across Classrooms**

Notice that the average level of intellectual work for a student response is more variable across classrooms as the level of teacher demand increases. The 13 data points for Demand Level Lo are tightly clumped between 0 and .25, meaning that when a teacher asks a low-level question, students generally respond in kind. However, when teachers ask questions requiring more intellectual work, students respond in a variety of ways indicated by increased variation in the average student give moving left to right. Teacher demand moves act as a ceiling of sorts, limiting but not completely determining the depth of intellectual work in student responses. Moreover, given the relative infrequency of high demand teacher moves (occurring in less than 3% of teacher moves, or 35 times out of 1200 total teacher demands), one would expect larger variance simply due to the small sample size of high demand teacher moves.

We followed this analysis with a MANOVA to specifically test the relationship between teacher demand and student give pairs. This analysis revealed a statistically significant, positive relationship (p<.0001) between Teacher Demand Level and average Student Give Level across the 13 classes. Thus, a teacher’s Demand Level does predict the average student Give Level.
The Relationship Between Discursive Patterns and Learning

To test the nature and strength of the relationship between discursive patterns and student achievement, we created two metrics – one to measure the level of intellectual work present in the teacher’s discourse and another to measure the level of intellectual work presents in students’ discourse moves. The metric for teacher discourse is the ratio of high and potentially high demands to low demands. We did not include teacher give moves because variation in teacher give moves did not appear to systematically explain variation in student learning. (r = .055).

The metric for student discourse is a weighted average considering both the clarity and correctness of student responses as well as the level of intellectual work. The weighting was as follows: All low-level give moves were weighted 0 regardless of correctness or clarity. Potentially high give moves that were unclear or incorrect were weighted 1. Potentially high give moves that were correct were weighted 2. High give moves that were unclear or confusing were weighted 3. High give moves that were incorrect or technically correct but lacking detail were weighted 4, and high give moves that were correct were weighted 5. Because student questions were so rare we did not include student demand moves as part of this weighted average. The scatter plots and the corresponding regression equations in Figure 3 display the relationship between average gain score and intellectual work in student and teacher discourse.

Figure 3. Scatter Plots of Teacher and Student Intellectual Work by Mean Teacher Gain Score

To test for the relationship between intellectual work and student achievement, we examined the coefficient for the group-level (i.e., classroom level) intellectual work slope in both HLM models. The teacher discourse model yielded a parameter estimate that was positive and marginally significant (γ₀₁ = 6.82, p = .09); the student discourse model parameter estimate was also positive and marginally significant (γ₀₁ = 13.35, p = .11). Though not statistically significant, we report these findings because 1) they approach significance with a relatively low number of classrooms (level-two units) and therefore low power, and 2) practically speaking, the results are significant. The associated increase in a class’s average post-test score with a corresponding increase of .2 in the intellectual work of teacher and student discourse is 1.36 and 2.66 points respectively (out of 18 total). Recall that the teacher discourse metric is a ratio of high-level demand moves to low-level demand moves. In practical terms, if teachers can ask just one more
high or potentially high-level question for every 5 low-level questions, the predicted increase in
their class’s average post-test score is roughly 8%. (Note that the mean demand ratio across all
teachers was .20: for every 5 low-level demands there was one high or potentially high demand.)

In addition, we also found patterns in our data related to equitable achievement when
inspecting the coefficient for the group-level pre-/post-achievement slope. Consider, for example,
the scatter plot in Figure 4. Each student can be represented by an ordered pair where the x-
coordinate represents his or her pre-test score and the y-coordinate represents the corresponding
post-test score. Ordered pairs of the same shape represent all students in one classroom; thus
Figure 4 displays student achievement data for two classrooms and their regression lines. The
variable of interest is the pre/post-test achievement slope.

![Figure 4. Scatter Plot and Regression Lines for Student Pre/post Scores
in Two SimCalc Classes](image)

Some classrooms have steeper slopes and some have flatter slopes. In other words, pre-test
scores are stronger determinants of achievement in some classrooms, which manifests in larger
pre/post achievement slopes (e.g., see the circles and the solid regression line in Figure 5). Some
claim that more equitable classrooms are those in which the pre/post achievement slope is closer
to 0. In other words, all students achieve equally regardless of their prior knowledge. Our HLM
analyses revealed that 1) the patterns of intellectual work at the classroom level helped to explain
variation in pre/post achievement slopes, and 2) that these discourse moves were positively
related to more equitable classrooms. The coefficients in the teacher and student discourse HLM
models were negative and statistically significant (teacher intellectual work: $\gamma_{11} = -.88, p=.017$;
student intellectual work: $\gamma_{21} = -1.52, p=.04$). In other words, classrooms with higher levels of
intellectual work moderated the effect of prior knowledge on student learning. An increase of .2
in teachers’ (or students’) intellectual work metrics corresponded to decreases in their class’s
pre/post achievement slope of .18 (or .3). Interestingly, intellectual work seems to play out as a
factor in more equitable classrooms by decreasing the impact that pre-test scores have on post-
test achievement.

Conclusions and Implications

In response to our research questions and based on the findings from the analyses we draw
the following conclusions.

---

American Chapter of the International Group for the Psychology of Mathematics Education. Columbus, OH: The
Ohio State University.
1. Low levels of intellectual work in both teacher and student discourse persist despite resources (curriculum, technology, professional development) providing ample opportunities for teachers and students alike to explore deep mathematical ideas. The classroom practices of the teachers and students in this sample seemed to be typical of most middle school mathematics classrooms. Therefore, the low levels of intellectual work observed are likely present in other classrooms. This motivates questions of why these discursive features are relatively rare in seemingly typical classrooms and leads us to re-examine our tacit models of teaching.

2. Using a multivariate analysis of variance we found that the intellectual work of teachers’ demand moves are predictive of the level of intellectual work of students. In other words, teachers usually get what they ask for.

3. Correlational analyses and hierarchical linear modeling revealed a marginally significant, positive relationship between the intellectual work of teacher and student discourse and student learning of rate and proportionality. Specifically, the HLM model predicts an 8% and 15% increase in a class’s mean post-test score (an increase of 1.36 and 2.66 points out of 18 total) with a corresponding increase of 20% in teacher and student intellectual work metrics. Additionally, classroom communities with higher levels of intellectual work moderate the effect of prior knowledge on student learning – an increase of 20% in intellectual demanding teacher and student discourse corresponds to decreases in the class’s pre-post achievement slope of .18 and .3 (p<.05).

In general, we found that classroom discourse and normative interaction patterns can guide and influence student learning in ways that both improve and impede achievement. There is tremendous and often unrealized power in the ways teachers talk with their students. We also found that classrooms with high levels of intellectual work are positively related to student learning. However, in order to more fully understand the relationships between intellectual work and student learning we need more data, especially in classrooms with good mathematical discourse. In closing, we are not proposing that there is one “right” model for classroom discourse. The key is for teachers to continually grow, refine, reflect and change – becoming a student of their students. This is a process that continues throughout a career.

References

Although there has been extensive scholarship about the importance of teaching with multiple strategies in the elementary grades, there has been relatively little discussion of what teaching with multiple strategies would or should look like in the middle and high school levels. This paper begins our exploration of this practice by addressing the following questions: (1) Why do middle and high school teachers think that mathematics instruction should include a focus on multiple strategies?; (2) What attitudes and concerns do middle and high school teachers have about teaching multiple strategies for solving mathematics problems?; and (3) How do middle and high school mathematics teachers report teaching with multiple strategies in their classrooms? We examine these questions through interview data collected from experienced middle and secondary mathematics teachers.

Introduction

The practice of teaching children multiple strategies for solving mathematics problems has been recommended in many recent mathematics education policy reports in the US, including the National Council of Teachers of Mathematics' (NCTM) Curriculum Focal Points (National Council of Teachers of Mathematics, 2006) and the National Research Council’s (NRC) Adding it Up (National Research Council, 2001). Indeed, the idea that students benefit from generating, comparing, and reflecting on multiple solution methods has been a central precept of mathematics reform pedagogy for at least the past 20 years (Silver, Ghousseini, Gosen, Charalambous, & Strawhun, 2005). For example, Silver and colleagues note that, “It is nearly axiomatic among those interested in mathematical problem solving as a key aspect of school mathematics that students should have experiences in which they solve problems in more than one way” (Silver et al., 2005, p. 288).

Although there has been extensive scholarship about the importance of and implementation of this practice in the elementary grades, there has been relatively little discussion of what teaching with multiple strategies would or should look like in the middle and high school levels. Should middle and high school mathematics teachers provide instruction in multiple strategies, or are the benefits of this instructional approach limited to the elementary grades? Are there differences in the ways that this practice can and should be implemented in middle and high school classrooms, as compared to elementary classrooms?

This paper begins our exploration of the practice of teaching students multiple strategies for solving mathematics problems, in the context of a professional development institute whose goal was to encourage middle and high school algebra teachers to think more deeply and carefully about the use of multiple strategies in their instruction. The paper addresses the following questions: (1) Why do middle and high school teachers think that mathematics instruction should include a focus on multiple strategies?; (2) What attitudes and concerns do middle and high school teachers have about teaching multiple strategies for solving mathematics problems?; and (3) How do middle and high school mathematics teachers report teaching with multiple strategies.
in their classrooms? We examine these questions through interview data collected from experienced middle and secondary mathematics teachers.

**Teaching with multiple strategies in the elementary grades**

Research on the practice of teaching with multiple strategies has been conducted almost exclusively in the elementary grades. Projects such as Cognitively Guided Instruction (CGI) played an early and important role in drawing elementary educators’ attention to the issue of multiple strategies (Carpenter et al., 1998). Research on CGI prompted elementary school teachers to think more carefully about students’ invented strategies, and encouraged the acceptance of multiple strategies for solving problems in elementary classrooms. Case studies of effective implementation of CGI and related programs describe teachers prompting students to solve problems in two different ways, to compare the similarities and differences between multiple methods, and to discuss and justify why various solution strategies may yield the same answer (Carpenter et al., 1999). Overall, there appears to be a consensus among researchers that there is a developmental appropriateness to accepting multiple solution strategies from young children, in that children are encouraged to begin solving problems using the intuitive mathematical knowledge that they have developed prior to entering the classroom, and to progress to strategies that are increasingly complex and abstract for the same sorts of problems.

In addition to describing models of effective instruction with multiple strategies, the research literature on multiple strategies in the elementary grades has furthermore identified ways that a focus on multiple strategies can go awry. In particular, a commonly identified problem is that attempts to teach with multiple strategies take the form of mere “serial sharing,” where students share and present multiple strategies but the teacher does not draw mathematical connections between them (Ball, 2001). Here students miss the crucial opportunity afforded by the presentation of the multiple strategies to investigate, compare, and justify diverse mathematical solutions, methods and algorithms. Without these connections, the pedagogical value of presenting multiple strategies is unclear (Ball, 2001).

**Multiple strategies in middle and secondary school**

While there has been substantial research regarding teaching with multiple strategies in the elementary grades, there has been significantly less thinking about this practice at the middle and high school levels. In fact, it is not always clear what a focus on multiple strategies means in the secondary grades. For example, should algebra students learn more than one way to solve linear equations and proportion problems? Should students be asked to invent, share, and compare multiple strategies for solving quadratic equations?

In summary, the ubiquitous practice of teaching students multiple strategies for solving mathematics problems has not been given as much attention in middle and high school, and thus merits further exploration. In this paper, we begin to examine this practice by analyzing middle and high school teachers’ views about the use of and value of multiple strategies. We focus in particular on the teachers’ initial views, before they participated in our professional development.

**Method**

In this section, we provide a brief description of the professional development project which provided the context for this study. We then describe the types of data collected, and the process by which the data were analyzed.
Setting
The context for this study was a one-week professional development workshop held in July 2009. The goal of the workshop was to prepare participating teachers to implement a set of researcher-developed curriculum materials in their Algebra I courses. These curriculum materials were developed as part of an NSF-funded research project whose goal was to 'infuse' multiple strategies into Algebra I courses.

Participants
The workshop participants were 13 experienced Algebra I teachers from nine middle and high schools in the Boston metropolitan area, representing a mix of urban and suburban schools. Eleven of the teachers taught in public or charter schools, and the other two teachers were from private schools. The mean number of years of teaching experience for the thirteen teachers was 10 (range 3 to 25). Teachers were recruited through print and e-mail advertisements seeking experienced Algebra I teachers who wanted to explore new techniques for teaching algebra.

Data Sources
The data analyzed in this study were collected in introductory interviews that were conducted with the teachers as the first activity of the first day of the workshop. Teachers were interviewed individually; all interviews were audio-recorded and later transcribed. The interviews were conducted by the authors, as well as by other trained research assistants. The interview was semi-structured; we began with a series of pre-determined questions but asked follow-up questions as appropriate. In particular, the teachers were asked about whether they felt it was useful to expose students to multiple strategies while teaching math, what they believed the advantages and disadvantages were to this approach, and whether and how they used multiple strategies in their current teaching. Teachers were also presented with several specific mathematics problems, and asked what strategies they would teach students to use for each of these problems. Each interview took approximately 30 minutes to complete.

Analysis
After transcription was complete, multiple researchers independently listened to the interviews and identified statements that were relevant to the research questions. Meetings were held to discuss emergent themes in the data, after which we revisited the transcripts to confirm or challenge these emergent themes. Finally, meetings were held to discuss tentative findings and evidence supporting these findings.

Results
Our analysis of the interviews sought to answer the following questions: (1) Why do teachers think it is important to teach multiple strategies in middle and secondary school mathematics?; (2) What attitudes and concerns did teachers have about teaching with multiple strategies?; and (3) How did teachers report using multiple strategies in the classroom?

Why is it important to teach with multiple strategies?
During the pre-interview, all thirteen of the teachers indicated that they believed teaching with multiple strategies was useful. When teachers were asked what the advantages were of teaching with multiple strategies, their answers fell into four categories (in describing these categories, we adapt terminology introduced by Leikin and Levav-Waynberg (2007)): (1)
success-oriented, in that this instructional practice affords multiple entry points into a problem for students who learn differently; (2) understanding-oriented, in that teaching with multiple strategies facilitates the development of a deeper understanding of mathematics; (3) affective, in that this practice increases qualities such as student enthusiasm and interest; and (4) efficiency-oriented, in that knowledge of multiple strategies helps students to solve problems more quickly or efficiently. Table 1 indicates the types of responses that each teacher provided; note that some teachers’ responses fell into multiple categories. We describe each of these types of responses below.

Success-oriented responses. In explaining why they believed teaching with multiple strategies was important, most teachers responded that teaching with multiple strategies could provide multiple entry points to a given problem for students with different learning styles. In the pre-interview, ten of the thirteen teachers cited this as a primary advantage of teaching with multiple strategies. These comments from Tamara and Bernadette were typical of these responses:

I think some students will think, "This method, I get it," like that. These students over here, they’ll like the other method. And so if you give more than one method, you probably have a better chance of reaching a greater number of students (Tamara).

Everybody’s brain is different, so if you only teach it in one way, you’re going to miss some kids. So the more ways you give them to access it, the more likely the majority of them are going to get it . . . So, the more the merrier, basically (Bernadette).

In such responses, teachers frequently indicated that they believed teaching with multiple strategies could improve their likelihood of “reaching” a greater number of students by showing each student at least one strategy that he or she could understand.

Understanding-oriented responses. A second, and much less commonly cited reason for the importance of teaching with multiple strategies was that learning multiple ways of solving a problem could help students develop a deeper understanding of mathematics. Four of the thirteen teachers mentioned this as an advantage. In a comment typical of these teachers, Robert noted, “I
think if you can look at two sides, and make a decision of, hey, you know this doesn’t work because of this, then you know what you’re doing.”

*Affective-oriented and efficiency-oriented responses.* Two additional reasons for teaching with multiple strategies were given, although each was cited by only one teacher. A single teacher, Naomi, cited affective reasons when describing the advantages of teaching with multiple strategies, saying that learning with multiple strategies could help students become “much more enthusiastic and upbeat, more engaged, more interested in learning, just more into it.” A second teacher, Nina, was the only teacher to cite speed and efficiency as reasons for teaching with multiple strategies. She explained that learning multiple strategies could help students to use faster and more efficient approaches when problem-solving.

*What attitudes and concerns did teachers have about multiple strategies?*

Teachers were also asked what they saw as the potential disadvantages of teaching with multiple strategies, and what concerns they had about exposing students to multiple approaches to solving math problems in their classrooms. Their concerns fell into three general categories: (1) *risk of student confusion*; (2) *motivational concerns*; and (3) *teacher constraints* (such as lack of class time and the large quantity of material in the curriculum to be covered). Teachers’ responses are summarized in Table 2 and discussed in more detail below.

</table>

*Risk of student confusion.* The most common concern cited by teachers was that they would risk confusing some students by showing them multiple strategies for solving problems. Ten of the thirteen teachers mentioned this concern in some form, with six of these expressing concern that low-achieving students specifically could become confused.

*Motivational concerns.* A second possible disadvantage of teaching with multiple strategies cited by teachers, expressed by five teachers, was student motivation. These teachers cited their students’ preference for generating an answer rapidly and correctly, and what they perceived as their students’ aversion to thinking in greater depth about a problem.

*Teacher constraints.* The third category of concerns cited by teachers regarding teaching with multiple strategies was teacher constraints, such as lack of class time, the large quantity of material in the curriculum to be covered and the need for more preparation time. Two teachers mentioned such concerns.
How did teachers report using multiple strategies in the classroom?

All of the teachers in the study reported that they used multiple strategies in their teaching. Yet rather than indicating that they taught with multiple strategies as a matter of course, most teachers indicated that they used this approach only for certain topics, under certain conditions, and as time permitted. Most teachers indicated that any class discussions about the multiple strategies would be brief and would focus on student preferences. Regarding class discussions of multiple strategies, most teachers stated that any such discussions would be brief and would center around student preferences. Kelley was typical of those teachers who did appear to have a routine for conducting class discussions about multiple strategies; her routine involved polling students as to which method they preferred:

I’ll do one [method], then do the other. And I’ll ask them, “Okay, who likes this method?” And then we’ll call this Andrew’s method. “Who likes this method?” And we’ll call that Kayla’s method. And then for homework, I’ll ask the kids, “Which method do you like, Andrew’s or Kayla’s?” And then I’ll go over it with the method they liked better. (Kelley)

While Kelley did have a routine for talking about multiple strategies, the discussion was not particularly substantive, extending little beyond a show of hands for students’ preferred methods. Furthermore, most teachers said that their class discussions would not address the question of whether one solution strategy was better than another, but rather that they would tell students to use whichever strategy they preferred. Teachers thus emphasized that they would discuss multiple strategies in terms of student preferences, rather than with regard to considerations such as evaluating which strategy worked better for different problems.

Discussion

Implications for mathematics teaching and research on mathematics teaching and learning

A key question that this study sought to explore was the extent to which teaching with multiple strategies may differ in middle and high school from teaching with multiple strategies in the elementary grades. Indeed, the substantial differences between middle and high school compared with the elementary grades, both in terms of students' development and mathematical knowledge and in terms of the content that is taught, might lead us to ask whether teaching practices that are advocated for in elementary grades are not as applicable in the middle and secondary grades. Our data speak to this issue, particularly in the ways that our teachers' views on multiple strategies did and did not align with elementary teachers' views taken from the literature.

On the one hand, the middle and high school teachers who participated in our study did not express the views about multiple strategies that are widely present and held at the elementary level, namely that teachers should accept multiple strategies from students as they progress from intuitive to more abstract methods in a developmentally appropriate progression. Nor did the middle and high school teachers express the view commonly held at the elementary level that the key pedagogical value of presenting multiple strategies is that it allows students to investigate, compare, and justify diverse mathematical solutions, methods and algorithms.

On the other hand, the middle and secondary teachers that participated in our study expressed some ideas about the value of teaching with multiple strategies that we would likely never expect to hear from elementary teachers on this topic. For example, some of the teachers in our study
cited speed and efficiency as reasons for teaching students multiple strategies for solving problems; such concerns with speed would unlikely be found at the elementary level.

How can we interpret this disconnect between what elementary teachers say about teaching with multiple strategies and what secondary teachers say? One interpretation might be that the secondary teachers are essentially wrong. In this view, the discussion taking place and the teaching practices being enacted at the elementary level could be considered much further along in terms of adoption and implementation of reform practices, while the secondary grades remain largely traditional in terms of practices and curricula (particularly outside of middle school). By this interpretation we might presume that perhaps in time, teaching and learning mathematics in secondary school will more closely resemble what happens in elementary schools. In this view, it appears that perhaps the disconnect between the views expressed at the elementary and secondary levels may be a temporary artifact of where we are in the development of reform-oriented practices at all levels.

In support of this idea that we are in a transitional period, it is interesting to note that the main reason secondary teachers give for why they think it is important to teach with multiple strategies is essentially that if one keeps showing students more and more ways of looking at something, eventually something will make sense to each student. This is essentially a muddled view of the reform rhetoric from elementary school. As noted above, this is in fact quite different from the reasons why we teach multiple strategies in elementary school, namely in order to support students’ developmental progression and to help them to justify, compare and investigate different strategies. In fact, this view that multiple strategies should be taught so that at least one method can be found that appeals to each learner seems to emerge more directly from the research on learning styles, for which many scholars argue there is limited evidence (Pashler, McDaniel, Rohrer, & Bjork, 2008).

Alternatively, perhaps the disconnect between what elementary and secondary teachers say about teaching with multiple strategies may be due to the fact that there are important differences in the mathematics and in students at the elementary versus at the secondary school level that indicate that certain practices are appropriate for one group and not as appropriate for the other. In secondary school, students are generally more comfortable with abstraction, and the strategies that they learn are more complex. The role of invention of strategies does seem quite different at the elementary versus at the secondary level. For example, we would not likely expect that secondary school students would invent new strategies for solving complex problems, such as solving a quadratic equation, in a reasonable amount of time, and even if they could do so, one might question whether the students would get the same value from this exercise as elementary students do from invention.

A complementary argument might proceed as follows: perhaps rather than arguing that some practices are good for elementary but not for secondary and vice versa, instead it might be the case that a practice is good for both but for different reasons. There may still be important reasons for teaching multiple strategies in secondary classrooms, but they perhaps are not the same as the reasons for teaching multiple strategies in elementary school. Perhaps while in the elementary grades teaching with multiple strategies has the goal of building on students’ intuitive knowledge in a developmentally appropriate way, in secondary school teaching with multiple strategies may have the goal of helping students to develop a more connected understanding of mathematics, and to develop fluency in mathematics by becoming more flexible and adaptive problem solvers.
In either case, our research indicates that secondary teachers clearly articulate different goals for teaching with multiple strategies than those found in the literature on teaching with multiple strategies at the elementary level. The issue merits further exploration, to think carefully about whether teaching with multiple strategies in some form is useful for secondary students and, if so, what goals this practice might be seeking to address.

A primary limitation of this study is that we did not observe teachers’ actual classroom practice, but looked only at their descriptions of their practice. It would be useful to observe teachers’ practice in order to see how they implement a multiple strategies approach with students.

Conclusions

Providing instruction with multiple strategies introduces a new challenge to teaching. At the middle and secondary school level, where limited research has been done on what teaching with multiple strategies does or should look like, the challenge is even more pronounced. Teachers’ limited idea of the primary benefit of teaching with multiple strategies, that it can offer a greater number of students an “entry point” into a problem, may be interfering with their likelihood of conducting substantial class discussions. For instance, teachers who believe that the primary purpose of multiple strategies is to find a strategy that “works” for every student may feel satisfied ending the discussion once it appears that all students have found some approach that they can use to begin a problem. Yet a discussion limited to this scope does not afford students opportunities to engage deeply with the multiple methods, to probe the similarities and differences among them, to consider why and in what contexts they work, and to think about and justify which strategies they would choose to use in various situations in the future. In light of the National Research Council’s (2001) goal that students should be able to utilize multiple approaches and adaptively select strategies appropriate to diverse types of problems, a discussion about multiple strategies whose main goal was merely to ensure that more students could use any single strategy does not seem adequate.

Teachers’ interview responses revealed that they generally held positive views of teaching with multiple strategies and had the desire to incorporate multiple approaches in their teaching. All of them were indeed attempting to do so. Yet their descriptions of how they were utilizing multiple strategies in their classrooms indicated that they lacked routines and scaffolding to engage students in substantial thinking about multiple approaches. These findings suggest that providing teachers with curriculum materials that routinely present multiple methods for solving problems as well as specific guidance for conducting rich classroom discussions may help middle and secondary school teachers to realize the potential learning associated with multiple strategies for their students.

THE EFFECTS OF USING PREDICTION FOR MATHEMATICS CLASSROOM DISCOURSE

Lisa Kasmer

Ok-Kyeong.Kim@wmich.edu

The value of utilizing prediction questions in mathematics classrooms has been recognized as a potential instructional tool helping students make sense of the mathematics they learn. In this paper we describe how the use of prediction questions helped classroom discussions on related mathematical ideas, by comparing a class using prediction questions to a similar class where no such questions were asked. The results suggest that the prediction questions allowed the students the opportunity to interact with the related mathematical ideas, connect to previous learning, and become more engaged and thoughtful in the classroom discussions.

Introduction

We found that prediction is a useful teaching and learning tool for many purposes (e.g., instructional tool, Kim & Kasmer, 2009; means for motivation, Kasmer & Kim, in press b; conceptual understanding and reasoning, Kasmer, 2008; Kasmer & Kim, in press a; Kim & Kasmer, 2007). In this paper, we will compare the qualities and nature of discussions on mathematical ideas between two middle school mathematics classes (treatment and control), taught by the same teacher, using the same curriculum. The only discernable difference was the use of prediction questions during the launch segments of the treatment class. We will highlight how using prediction questions impacted classroom discussion in terms of the kinds of ideas shared, thinking encouraged, and connections attempted. In this study, prediction is defined as reasoning about the mathematical ideas of the lesson prior to instruction by using previous knowledge, or connections to related concepts.

Literature Review

Prediction is considered a valid construct within reading and science instruction. In terms of reading comprehension, prediction questions were found to support knowledge acquisition (Palinscar & Brown, 1984). Other researchers concur that predicting affords students opportunities to connect previously learned knowledge with the new knowledge they encounter. (Duffy, 2003). Prediction also has been found to benefit student learning in science education. Furthermore, Gunstone and White (1981) found the model they developed, Predict-Observe-Explain (POE), to secondary school students to be an important instructional practice to help students make sense of physics concepts. The POE model is used to assess students’ understanding by requiring students to perform three tasks. Initially, students must predict the outcome of an event and justify their prediction; students then describe what they see happen, and finally they reconcile any conflict between their initial prediction and the observation. POE has been found to be an effective model in helping students make sense of complex scientific ideas.

The effectiveness of using prediction in the teaching and learning of mathematics has recently been investigated. Battista (1999) established the benefits of students making predictions in geometry lessons. When students resolved the discrepancies between their predictions and actual answers, they were able to build more useful mental models for
mathematical ideas. Lim, Buendía, Kim, Cordero, and Kasmer (in press) also suggest that predictions presents opportunities for both students and teachers to become aware of their misconceptions or ill-formed ideas. Prediction also aligns with other reasoning aspects such as generalizing, abducting, conjecturing, and visualization (Lim et al, in press).

In Kasmer’s (2008) study, where prediction questions were incorporated into the launch of algebra lessons, overall results suggest prediction is a relevant and valid construct with respect to enhanced conceptual understanding and mathematical reasoning. This study demonstrated that prediction provides students opportunities to connect and refine their existing knowledge and reported positive results in developing understanding. The study also revealed that these students exhibited a higher level of engagement compared to a similar class where prediction questions were not used. When predictions were used, students were engaged in sustained conversations that were created by a culture precipitated by the inherent risk free virtue of prediction questions as within the nature of predicting is the absence of certitude. These students had an opportunity to think about the question and record their responses, and as a result were confident in their responses and motivated to share and listen to others’ responses.

This paper focuses on the comparison of the nature of a classroom discussion between two classes by using data collected at the midpoint of an 8-month longitudinal study. In doing so, we analyze the kinds of mathematical ideas and reasoning present during the classroom discussion, by using the frameworks described in the following section. We also analyze students’ prediction responses in terms of these frameworks, in order to explain possible attributes that influenced the discussion in the treatment classroom.

Conceptual Understanding and Reasoning Frameworks

For the purpose of this study and analysis of data, two frameworks were developed, although it is understood that conceptual understanding, and mathematical reasoning are not mutually exclusive entities. However for the purpose of data analysis these constructs were treated separately. The conceptual understanding framework [CUF] was developed by incorporating ideas found in the current research related to conceptual understanding (e.g., Hiebert & Carpenter, 1992; National Council of Teachers of Mathematics [NCTM], 2000) and the
Connected Mathematics Curriculum that the classroom used (Lappan, Fey, Fitzgerald, Friel, & Phillips, 1998).

Conceptual understanding is based on the premise that as the number of connections among ideas and concepts increases, so too does the understanding (Hiebert & Carpenter, 1992). The conceptual-understanding indicators of the CUF (see Table 1) are embedded through the curriculum and align with the NCTM’s (2000) Principles and Standards for School Mathematics [Standards]. These indicators were used as a framework for data analysis in seeking qualitative evidence of the existence of differences between treatment and control classes relative to classroom discourse and opportunities to interact with the conceptual understanding indicators.

The mathematical reasoning framework [MRF] resulted from synthesizing constructs from the Standards (NCTM, 2000), TIMMS Assessment Frameworks and Specifications (Mullis, Martin, Smith, Garden, Gregory, Gonzalez, Chrostowski, & O’Connor, 2001), and the Connected Mathematics Project (Lappan, Fey, Fitzgerald, Friel, & Philips, 1998). The MRF framework is comprised of five reasoning indicators, which were utilized to highlight student-reasoning processes and analyze the data (see Table 2). The mathematical reasoning framework is global in nature, and speaks to all grade levels and mathematical content. The conceptual understanding framework specifically aligns with middle school algebra.

Methods

Participants

Two classes taught by the same teacher were selected for the purpose of this study: one class for treatment where prediction questions were purposely posed, and the other class as a control group where there was no exposure to purposely-posed prediction questions. All students in this school are randomly assigned to each of their core class periods. In addition, selection of courses
in this school does not affect classroom composition as the master schedule dictates the class periods during which core academic courses were offered and all students are required to participate in music and foreign language classes. As a result, the classrooms were considered homogeneous. Indeed, results from an Independent-Samples, \( t \) test produced no significant differences relative to the mathematics scores on the state test (Michigan Educational Assessment Program) between the treatment and control groups (\( t_{38} = .77, p < .448 \)). Similarly, no statistically significant difference in reading scores between the treatment and control groups (\( t_{38} = -0.07, p < .941 \)) were apparent.

Data Collection

For this particular aspect of the study, data sources included student written prediction responses (treatment class), teacher interviews, teacher journals, and video segments along with corresponding transcripts (treatment and control classes).

Prediction responses. The classroom teacher posed prediction questions exclusively to the treatment classroom during the launch of each problem in the linear and exponential units. These prediction questions implicitly reflected the mathematical content of the problem, without revealing the essence of the problem. The teacher presented the prediction questions in conjunction with the launch of the investigation. Students recorded in writing their individual responses to each prediction question the teacher posed. The teacher elicited student responses, without commenting on the accuracy of the prediction. Students were also encouraged to comment on others’ ideas. The prediction questions and student responses were revisited during the summary segment of the lesson. Students’ written prediction responses were collected from the treatment group at the completion of each lesson where prediction questions were posed during the linear and exponential unit. These artifacts documented characteristics of the nature of these responses for the units of study. The teacher posed the prediction questions to the treatment class while launching the problems during the units of study. For this analysis we looked at classroom video and the corresponding prediction responses (\( n = 19 \)) from one particular lesson of study.

Classroom videotapes. A total of 9 video observations were made during the instruction of the treatment class, and 5 video observations during the control class. The videos analyzed for this particular paper were drawn from the midpoint of the longitudinal study. In these two video observations, students encountered exponential growth patterns for the first time. Prior to this problem students had studied linear relationships for 6 weeks. Students explored the growth of paper ballots as they are repeatedly cut in half. The problem context was:

Alejandro is making ballots for an election. He starts by cutting a sheet of paper in half. He then stacks the two pieces and cuts them in half. He stacks the resulting four pieces and cuts them in half. He repeats this process, creating smaller and smaller pieces of paper (Lappan, Fey, Fitzgerald, Friel, & Philips, 1998, p. 5).

A prediction question posed in the treatment classroom was: “If Alejandro makes 10 cuts; can you predict how many ballots Alejandro might have? What is your reasoning?” Students provided written responses to this question before exploring the problem context, and discussed their predictions and rationale as well as related mathematical ideas as described earlier.

Teacher interviews and journals. Interview data were collected prior to the treatment, at the conclusions of the linear and exponential units of study. The purpose of these interviews was to gather information with respect to the teacher’s portrayal of the possible benefits of prediction questions, validate her journal entries and potentially illuminate related issues which may have

---

arisen from viewing the video data. The classroom teacher submitted electronic journals weekly. These journals captured the main mathematical ideas taught during the week, the teacher’s perception of the effectiveness of the prediction questions, and provided an opportunity for the teacher to share any concerns she may have about the study.

Data Analysis

Analysis of data comprised of coding the students’ written prediction responses with respect to conceptual understanding (CUF) and mathematical reasoning (MRF) (treatment class) and coding the transcripts of classroom discussion for alignment with conceptual understanding (CUF) and mathematical reasoning (MRF) indicators (treatment and control classes). Video data were transcribed. We used each student statement as a unit of analysis, and coded to a CUF or MRF. In situations where no alignment between the student statement and the CUF or MRF was evident, no code was assigned to the statement.

The teacher interviews were transcribed and presented to the teacher to confirm the transcriptions’ accuracy and credibility. Interview transcriptions were read to become aware of the teacher’s perception of the efficacy of prediction questions in her classroom, and any notable differences she expressed between the treatment and control classes. This teacher artifact was read a number of times in order to uncover surfacing common themes and categories relating specifically to differences between student discussions and student engagement.

The electronic journal entries sought to reveal information related to possible beneficial outcomes of using prediction questions regarding teaching practices, student discussion and student engagement. Analyzing the teacher’s journal validated interview responses and provided affirmation and clarification of teacher practices viewed in the classroom-videotaped segments. A similar method to the interview analysis was employed for this data artifact.

Results

In this section, we describe the results of the analysis of the two classrooms’ discussion segments, using the data drawn from one particular lesson. However, these results are indicative of the differences between the treatment and control classes throughout the entire study.

To compare the qualities and nature of discussions on mathematical ideas an example of a classroom discussion centered on the same mathematical idea is presented in Figure 1. This vignette illuminates the opportunities students were provided with to interface with the conceptual understanding and mathematical reasoning indicators. This highlighted example, as described earlier, was the students’ initial work with exponential relationships. In this problem students probe the effect of repeated cutting in half on the total number of sheets of paper. While in this particular example, the treatment class discussion transpired during the prediction phase of the lesson, the control class discussion occurred during the summary portion of the lesson. For the control class, there was no prior discussion before students began the problem. The teacher read the problem to the students, and they began working in small groups. It appeared that the prediction questions provided students in the treatment class an impetus and focus for classroom discourse, whereas the control class discussion was centered exclusively on the student-generated results of the problem.

It is evident that students in the control class had limited exposure to the potential mathematical ideas that were inherent in the problem but failed to surface in the discussion. Students in the control class merely discussed the results of the problem, and touched upon the two different perspectives of doubling. In fact, the teacher drew the conclusion for the students.
(“So you guys are looking at the cut [the number of cuts] to double, and you guys are looking at the ballot to double, there’s the difference”). The control class discussion demonstrated 4 occurrences of CU1 (represent patterns in tables, graphs, words, and equations) and 3 occurrences of R3 (analyzing and evaluating a problem situation is defined as making information from the problem useful for solution). No other conceptual understanding or reasoning indicators were exhibited in this discussion. That is, conceptual understanding and reasoning indicators were minimally activated. The interactions during the control class were dominated by the teacher, and students’ participation was limited.

Conversely, students in the treatment class, to a greater extent were afforded more opportunities to think about, discuss the mathematical concepts of the lesson and extend their thinking. The treatment class discussion demonstrated 7 occurrences of CU1, 5 occurrences of CU2, 2 occurrences of CU3, 1 occurrence of CU5, and 2 occurrences of CU6. With respect to the reasoning indicators 5 occurrences of R2, 2 occurrences of R3, and 3 occurrences of R4 were evident. Moreover, the treatment class conversation expanded the scope of the intended mathematics of the problem. In particular, the specific objectives of the problem were to begin to understand the effect of repeated doubling. The treatment class students also thought about whether this situation (repeated cutting of paper in half) was a linear relationship or something else, although this was never explicitly asked of students to consider in the problem context. The discussions in the treatment class can be characterized as more dynamic compared to the discussion of the control class.

It appeared as though the prediction questions provoked and contributed to a more vibrant discussion on rich mathematical ideas beyond merely getting the answer to the given problem, which provided the conceptual understanding and mathematical reasoning indicators to emerge. In fact, various conceptual understanding and reasoning indicators were present in students’ written responses to the prediction question, which is evidenced in the following prediction responses as examples.

If he has one piece of paper and cut it in half he has 2 parts. 10 x 2 = 20. 20 ballots.
Yes, I can predict the amount. If there are 2 halves (sic) and you cut them again, you will double that amount 2 x 10.
2,048 ballots. Because every time you put something in half you get twice as many. You will keep going up twice as much as the number before it.

Both responses were coded as CU1, CU6, R2, R3, and R4. However, reasoning in these responses illuminates two different arguments, leading to revisiting the concept of linearity. Such an opportunity to synthesize thinking prior to the discussion triggered various aspects of the conceptual understanding and reasoning indicators to help students build connections, and bring these ideas to the discussion. The statements put forth by the students made during these discussions reflected the thinking that students were afforded the opportunity to conceptualize by responding to the prediction questions.

The teacher interview and journal data also suggested from the teacher’s perspective that the prediction questions did indeed provide the students with opportunities to interact with the conceptual understanding and mathematical reasoning indicators. These opportunities she felt, contributed to more rich discussions and provided her with a focus to help drive the discussion. The teacher also believed that the students in the treatment class appeared to be more motivated and more engaged in the mathematics of the lessons.

<td>T: How many of you think it’s linear, other than it’s doubling</td>
<td></td>
<td>S4: Doubling it</td>
</tr>
<tr>
<td>CU1, 2</td>
<td>S5: It’s not linear because it’s multiplying by the same number, because each time you cut you’re multiplying by the same number it’s squaring</td>
<td>CU1</td>
<td>T: So how is that doubling it is different from Parker’s doubling?</td>
</tr>
<tr>
<td></td>
<td>T: So you think instead of doubling it’s squaring,</td>
<td>R3</td>
<td>S5: You’re doubling it from the last number instead of the number of cuts</td>
</tr>
<tr>
<td>CU2, 3</td>
<td>Will, what do you think?</td>
<td></td>
<td>T: So you guys are looking at the cut to double -, and you guys are looking at the ballot to double, there’s the difference.</td>
</tr>
<tr>
<td>R4</td>
<td>S6: There’s no constant [rate]</td>
<td></td>
<td>At this point students begin working on the ACE problem for homework</td>
</tr>
<tr>
<td>CU1, 3,</td>
<td>T: There’s no constant, so there’s no pattern you think</td>
<td></td>
<td></td>
</tr>
<tr>
<td>R2</td>
<td>S7: If you graphed it, the line would get steeper every time</td>
<td></td>
<td></td>
</tr>
<tr>
<td>R2, CU1,</td>
<td>T: So you looked at it from a graphing point of view, saying that it’s not going to look like a straight line</td>
<td></td>
<td></td>
</tr>
<tr>
<td>CU2</td>
<td>S8: Every time you ripped the paper, it’s doubling what you had before and that’s increasing what you have from before. That’s the reason I don’t think it’s linear</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Conclusion**

In order to make predictions students must think about important mathematical ideas imbedded in the problem context. The prediction questions helped students draw on prior
knowledge and build connections among mathematical ideas. Furthermore, these prediction questions allowed students in the treatment class to explicitly and implicitly interact with the conceptual understanding and mathematical reasoning indicators. This precursory thinking contributes to more rich discussions that are built upon the ideas that students bring to the table. As evident in the comparison of the two classrooms’ discussions, prediction questions enabled students to think about related mathematical ideas, rather than mechanically solving the problem. By doing so, prediction questions provoked a dynamic student discussion on mathematical ideas in the process of thinking, not necessarily as an ending product or conclusion.

In this paper we highlight three generalizable brokering moves that can function as a mechanism for the social production of meaning. These brokering moves, which were identified through analysis of classroom videorecordings from an undergraduate course in differential equations, facilitated the emergence of a complex and sophisticated inscription known as a bifurcation diagram. The three brokering moves we detail each involve different types of efforts to influence the degree of continuity between communities: the broader mathematical community, the local classroom community, and the various small groups that make up the local classroom community. The analysis highlights how various members of the class can function as brokers, with the teacher playing a unique role as a member or peripheral member of all three communities.

Introduction

A pressing concern in mathematics education is to reveal processes by which inquiry-oriented classrooms enable learners to explore and develop their own reasoning powers while simultaneously connecting them with the collected wisdom and conventions of the discipline (Cobb & Bauersfeld, 1995; Lampert, 2001). A teacher’s role in this process is one that often comes with considerable tension. For example, in her work with elementary school students, Ball (1993) posed the tension in the following way: “How do I create experiences for my students that connect with what they now know and care about but that also transcend their present? How do I value their interests and also connect them to ideas and traditions growing out of centuries of mathematical exploration and invention?” (p. 375). Research in inquiry-oriented undergraduate mathematics classroom reveals similar tensions regarding the role of the teacher and other students in the social production and uptake of ideas (e.g., Wagner, Speer, & Rossa, 2007).

In this report we address the aforementioned pressing concern by identifying the brokering moves of the teacher and some students in an undergraduate mathematics class that functioned as a mechanism for the social production of meaning. From an individual cognitive point of view, there are well-established mechanisms that describe how individuals build ideas. From a social point of view, however, mechanisms that describe how ideas are interactively constituted are less developed, especially at the undergraduate level. Such mechanisms are significant because they address the complex job of teaching and specify teacher moves that promote the social construction of meaning (Rasmussen & Marrongelle, 2008).

In his seminal work on communities of practice, Wenger (1998) highlights how brokering has the potential to “cause learning” by introducing into one community elements of practice from a different community (Wenger, 1998, p. 109). We adapt Wenger’s work to the classroom and consider three different communities: the broader mathematical community, the local classroom community, and the various small groups that make up the local classroom community. The brokers in these communities are the teacher and specific students in the class. A broker, by definition, is someone who has membership status in more than one community. For example, in our case the teacher is a member of the broader mathematics community, the
classroom community, and a peripheral member of each of the small groups that make up the classroom community.

**Methods**

Data for the analysis is drawn from classroom videorecordings collected during a 15-week classroom teaching experiment (Cobb, 2000) conducted in an undergraduate differential equations course. There were 30 students in the class, roughly split between mathematics and engineering majors. The brokering moves we identified came from a retrospective analysis of videorecordings from two cameras during three contiguous class sessions. We focused on these three sessions because we recognized that something powerful happened in terms of student learning on these days and we wanted to characterize it. Maher and Martino (1996) refer to such occasions as “critical events.” Such events involve conceptual leaps or significant mathematical progress and hence demand attention and explanation. In our case, the significant event was student reinvention of a bifurcation diagram.

We began analysis by creating complete transcripts of each class session. We then engaged in an iterative cycle of examining the data and writing detailed summaries of the events that transpired. Through this process and reflection on the literature, we refined our understanding of the phenomenon under consideration and characterized the students’ mathematical progress in terms of the emergence and evolution of a classroom mathematical practice (Rasmussen, Zandieh, & Wawro, 2009). Further analysis of the data resulted in identification of various brokering moves that facilitated the emergence and evolution of this classroom mathematical practice. Subsequent synthesis of the various brokering moves resulted in identifying three main types of brokering moves.

**Results and Discussion**

We refer to the three broad categories of broker moves as creating a boundary encounter, bringing participants to the periphery, and interpreting between communities. Each of these brokering moves is exemplified in the following paragraphs.

**Creating a Boundary Encounter**

A boundary encounter refers to direct encounters such as meetings, conversations, or visits between communities. Any boundary encounter will involve boundary objects. Boundary objects refer to objects that serve as an interface between different communities. A broker, by virtue of his or her membership in more than one community, is in a position to bring forth boundary objects that can facilitate encounters between communities. Wenger’s examples of boundary encounters all entail direct meetings, conversations, or visits between communities. We adapt this notion to also include indirect encounters between communities. For example, except in rare cases, it is not feasible for direct encounters between the broader mathematics community and the classroom community to occur. Instead, the teacher as broker can offer indirect opportunities for the classroom community to encounter the broader mathematical community. The teacher can do this by offering opportunities for students to engage in the broader discipline practices of modeling, symbolizing, defining, algorithmatizing, or proving (Rasmussen, Zandieh, King, & Teppo, 2005; Schwarz, Dreyfus, & Hershkowitz, 2009). Such encounters allow for the possibility of participation in the authentic practice of mathematics, and hence provide occasions for the local classroom community to indirectly encounter the broader mathematics community.
We highlight two exemplary instances of “creating a boundary encounter” from our analysis. The first example is between the local classroom community and the broader mathematics community, while the second example is between the classroom community and one of the small groups. Our first example focuses on the teacher as broker in his role of selecting and constituting tasks. Because the teacher is a member of both the broader mathematics community and local classroom community, he is in a position to recognize characteristics of tasks that are likely to be productive for enabling newcomers to engage in the discipline practices of mathematics, such as modeling and symbolizing. In the first example, the teacher recognized that a particular task (which we refer to as the fish.com task) might function as a boundary object because he could use the task to engage students in creating a new differential equation to fit a revised set of assumption. In this way, the students indirectly encountered the mathematics community via modeling.

After creating a modified differential equation, the way in which the teacher constituted the remaining portion of the task was crucial in actually creating a further boundary encounter. In particular, the teacher constituted the task in such a way that it opened up the possibility for students to engage in symbolizing. Specifically, the teacher invited students to develop a report to an imagined audience, rather than requesting students to recommend a specific numerical answer. Constituting the task as a report to the new owners, without prescribing what form this report was to take, allowed students to develop their own inscriptions. Thus, the modified differential equation and task to develop a report functioned as a boundary object because it provided the classroom community an opportunity to encounter the mathematics community via participating in the discipline practice of symbolizing.

The second example comes from our analysis of Lorenzo and Kenneth’s presentation of their work on the fish.com task. In inquiry-oriented classroom settings, it is fairly common for particular small groups to present their work on a problem to the entire classroom community. Such presentations represent the opportunity for a boundary encounter between one small group and their local classroom community. In our experience, not all such small group presentations realize this opportunity. For example, a small group presentation that simply reports back to the class what their group did without a substantive exchange of ideas and interpretations leaves the interface between communities somewhat empty. In order to fulfill the potential for a boundary encounter, there has to be some boundary object that leverages differences between the communities and actions by brokers to encourage an exchange of ideas and interpretations between communities.

The report by Lorenzo and Kenneth included an inscription that the class had never encountered. This inscription, which was the product of Lorenzo and Kenneth’s own creative efforts, was a graph of equilibrium values, $P$, versus constant harvesting values $k$. A portion of their report that shows this graph is shown in Figure 1.

![Graph of equilibrium values versus harvesting rate](image)

**Figure 1. A graph of equilibrium values versus harvesting rate**

The $P$ versus $k$ graph presented by Lorenzo and Kenneth’s small group functioned as a boundary object because this particular inscription was entirely new to the rest of the class and was the center of a substantive exchange between Lorenzo’s group and the whole class. As they presented their report, Lorenzo and Kenneth functioned as brokers as they carefully explained how to mathematically interpret their novel graph of $P$ versus $k$.

Kenneth and Lorenzo’s presentation positioned them as brokers between their small group and the larger classroom community. Their small group also included the teacher as a peripheral member. This is noteworthy because while their carefully explained mathematical connections opened the door for the classroom community to interface with their new inscription, it was the teacher who pushed the door open even further. In particular, the teacher used their presentation to make explicit a connection to a previous small group presentation and to raise questions about how to further interpret the novel inscription. As our two examples of the more general brokering category of creating a boundary encounter illustrates, this particular type of brokering move sets up the opportunity and conditions for the boundary encounter to be realized. Our remaining two categories of brokering moves exemplify different ways that encounters between communities are realized.

**Bringing Participants to the Periphery**

Broker moves in the second category—bringing participants to the periphery—help or encourage participants to move toward another community along a continuum. This is in contrast to the first category in which participants were set up to encounter the other community in a way that highlighted some difference or discontinuity. In the preceding examples the broker’s role was to create the opportunity for participants to engage with a boundary object (task, inscription) that was relatively new to them. This set up a boundary encounter in the sense of being an encounter between discontinuous, distinct communities—those who would already know how to engage the task versus those who would not or those who had created and interpreted an inscription versus those who had never seen it before.

In comparison, bringing participants to the periphery is about moving along a continuum between communities. We tender two examples of this category of brokering move. Our first example of bringing participants to the periphery highlights the interplay between the local classroom community and the mathematical community. During Lorenzo and Kenneth’s presentation the teacher layered what is called a flow line (or phase line) on top of the student generated $P$ versus $k$ graph (see Figure 2). Flow lines were familiar inscriptions to these students and were used in Lorenzo and Kenneth’s novel $P$ versus $k$ graph.

**Figure 2. Layering a flow line on the P versus K graph**

The teacher then handed over responsibility for layering the flow lines to Kenneth, in a move that allowed the students to take ownership of the embellished graph. The initial layering of a...
flow line was a brokering move by the teacher that served more as the creation of a boundary encounter. This initial step introduced a new interpretation to the $P$ versus $k$ graph that brought it closer to the mathematical community’s notion of a bifurcation diagram. The initial introduction of something completely new in this way is a brokering move the presents a discontinuity. However, as the teacher encouraged Kenneth to make further interpretations of phase lines for the $P$ versus $k$ graph this became more of a process of encouraging Kenneth, and the class with Kenneth as their representative, to reason and symbolize in ways that were more consistent with the broader mathematics community.

For example, in Figure 3 we see Kenneth adding additional flow line to their $P$ versus $k$ graph. As Kenneth did this, he stated that you could drop a phase line “anywhere” on the graph, and chose to do so for $k = 6$.

Kenneth: Yeah, if you were to drop, like, a phase line on top of the graph anywhere, like if we were to drop one here [draws a vertical line at $k = 6$, see Figure 3] you’d see that increasing in there [draws an upward facing arrow on the line just drawn inside the parabola], decreasing there [draws a downward facing arrow on the line above the parabola], decreasing there [draws downward facing arrow on the line below the parabola].

As this short transcript illustrates, Kenneth’s addition to the graph highlights how a graph of $P$ versus $k$ can have meaning for regions inside and outside the parabola. The intended meaning of such inscriptions is now much more in line with the expectations of the broader mathematical community. In this way, Kenneth and the rest of the class have been drawn into the community of mathematics.

Our second example of bringing participants to the periphery highlights brokering moves between the local classroom community and smaller groups within this community. The class sessions we analyzed contained many examples of the teacher acting as a broker to encourage members of one community to engage ideas of another community or for members of one community to explain their ideas more fully to another community. In this way the teacher is requesting that participants move toward another community through a continuous periphery. For example, after Brady (student presenter prior to the presentation of Lorenzo and Kenneth) had completed his initial explanation, the teacher said, “Brady, let’s pretend that I’m an owner and I make a lot of money, and I’m an executive, but I’m not so sophisticated with tables and stuff. So I need some help understanding that table that you’ve got up there.” This request for clarification asked Brady to extend the ideas of his group in more detail and more clearly to the rest of the classroom community. A few minutes later after further explanation from Brady, the
teacher asks the class, “So that’s a question to you all—does that explain what his table is? If you’re the owners, are you understanding what he’s, what information he’s provided?” In this way the teacher requests the members of the classroom community to engage in the ideas of Brady’s group and thus bring themselves toward the periphery between Brady’s group and the classroom community.

Interpreting Between Communities

As the label for this category implies, interpreting between communities is a brokering move in which brokers facilitate the understanding of one community regarding how ideas are construed, notated, related, or labeled by another community. In comparison to the first brokering category, creating boundary encounters, this third type of brokering move occurs when a broker takes specific steps to fulfill or realize the opportunities that the creating boundary encounter moves offered. We provide two illustrative examples of this particular brokering category. The first example involves brokering between the local classroom community and Lorenzo and Kenneth’s small group. In the second example the brokering takes place between the local classroom community and the broader mathematical community.

Our first example of interpreting between communities comes from an episode in which Lorenzo responds to a student’s question about a graph $dP/dt$ versus $P$ shown in the case when the parameter $k$ is greater than 12.5. Lorenzo’s response to this question went well beyond an answer to the particular question. In particular, Lorenzo, acting as a representative for his small group, elaborated how the case where $k > 12.5$ fit with the other cases and how their group understood various connections to their novel $P$ versus $k$ graph. This explanation was significant because it served the purpose of framing how others’ analyses could be interpreted in terms of one or more of these cases.

Lorenzo continued connecting his group’s work to that of the others by explicating various relationships for the case when $k = 12.5$. Specifically, Lorenzo pointed to the vertex of the $P$ versus $k$ graph (see Figure 4a) and explained that, “If you take $k$ to be exactly 12.5...these two graphs of equilibrium solutions meet at this point here.”

![Figure 4. Making connections to the graph of P versus k when k=12.5](image)

Here Lorenzo made an explicit connection to their algebraic equations for $dP/dt = 0$ and their novel graph of $P$ versus $k$. Lorenzo continued his explanation by purposefully linking the $P$ versus $k$ graph to two other inscriptions with which the class was more familiar. As he pointed to the node on the flow line (Figure 4b), he stated, “and you have only one equilibrium solution.” He immediately connected this to a $dP/dt$ versus $P$ graph when he stated, “You can also see how if you graph $dP/dt$, that, uh, your population is going to be decreasing all the time except at one point,” as he pointed to the vertex of the parabola (Figure 4c). Lorenzo was careful in his
pointing, and through this care, he linked the inscriptions together by explaining how to construe the same information from three different graphical inscriptions.

We see Lorenzo’s pointing as a type of linking gesture that facilitated his efforts to interpret between communities. Linking gestures are often used to “provide conceptual correspondences between familiar and unfamiliar entities” (Nathan, 2008, p. 376). Here we see that Lorenzo was able to provide conceptual correspondences from what his classmates were already familiar with to a new, unfamiliar inscription through a careful use of pointing gestures. In relating what was familiar to the class to what was unfamiliar, Lorenzo’s use of linking gestures facilitated his efforts to interpret between communities.

Our second example of interpreting between communities highlights the teacher’s unique brokering role as the only person who is a member of both the broader mathematical community and the classroom community. Given this unique position, it is the teacher who can (re)interpret the mathematical ideas that are emerging in the local classroom community in terms of the conventional or formal terminology used by the broader mathematical community. In this way, the teacher can infuse formal terminology into the discourse of the classroom community.

In our second example of interpreting between communities, the teacher inserted the conventional term “bifurcation” by using linking gestures to connect the familiar with the unfamiliar. One of the most familiar inscriptions for the classroom community was that of the $P$ versus $t$ graphs. The term bifurcation was unfamiliar to the classroom community, however the fact that the structure of the solution space is different for different $k$ values was becoming increasingly familiar for students. In Figure 5, we see the teacher use a series of gestures that link the changing number of equilibrium solutions to the term bifurcation. In particular, the teacher extended his hands and forearms in a parallel manner to portray the parallel equilibrium solutions on the $P$ versus $k$ graph, and then he brought his hands and forearms together (Figure 5c), at which point he explained that the “technical” term for the parameter value at which there is a change in the number of equilibrium solutions is “bifurcation value.”

Through these moves, the teacher explicitly introduced the conventional or formal term “bifurcation” at a point in the classroom discussion when it served the function of labeling an idea that was an emerging part of students’ mathematical reality. We see this as a noteworthy departure from teaching that often starts lessons with formal or conventional terminology because it enables students to see themselves as capable of participating in the cultural practice of mathematics.

**Conclusion**

In this report, we introduced three generalized broker move categories: creating boundary encounters, bringing participants to the periphery, and interpreting between communities. Each

---

of these brokering categories highlight the view that teaching and learning mathematics is a cultural practice, one that is mediated by and coordinated with the broader mathematics community, the local classroom community, and the small groups that comprise the classroom community. Because these categories were developed out of two days of classroom data, we make no claim that these categories are exhaustive. Furthermore, we contend that both the course content and the timing of the data observed influenced the categories’ formulation. Thus, we expect that observing other data sets would result in the creation of additional broad categories or in the facilitation of a sharper definition of the existing categories through the creation of subcategories. It is to this end—observing more data sets for the expansion of the categories as well as for a sharpening of the existing categories—that we anticipate a direction for future research.

DEVELOPING MULTIPLICATION FACT AUTOMATICITY THROUGH GAMES

Tiffany Byrd
Washington State University
tbyrd@wsu.edu

Jo Olson
Washington State University
jolson@wsu.edu

This research study examined the effects of using games to help students gain multiplication fact automaticity. This study compared two fourth-grade classrooms in which one played multiplication games and the other did not. An independent-samples t test indicated that the games had a positive effect on students’ learning of multiplication facts. Case study analysis revealed that games helped students develop more sophisticated strategies for figuring out hard to remember facts. These strategies included geometric images, relationships between factors and products, double counting, and the use of related facts.

Introduction

Memorizing multiplication facts has long been a part of elementary school. However, many students seem to have trouble with the automaticity, automatic recall of facts. According to Caron (2007), “That multiplication table, ten by ten columns that we insist with good reason our students learn between third and fourth grade remains a mystery to some” (p. 278). Multiplication fact recall creates a solid basis which students use to further their mathematical thinking as they mature into middle and high school. Indeed, without the ability to quickly retrieve multiplication facts, students cannot perform higher-level tasks such as finding common multiples when adding fractions or solving algebraic equations (Woodward, 2006).

Games are one way to motivate students. Intermediate grade students specifically enjoy games in which they must find and use a strategy to win. At the same time that they are having fun and strategizing, students are also developing a conceptual understanding of patterns and number facts (Olson, 2007). Games in the classroom create an opportunity for students to learn from their peers by comparing their strategies to become better players. Different game choices will likely appeal to multiple intelligences since students are able to choose the game they feel is the most beneficial to them and are encouraged to use those games to achieve automatic recall of multiplication facts. The purpose of this study was to determine the effectiveness of using multiplication games to aid students in multiplication fact automaticity as well as determining how the games helped students develop their mathematical thinking.

Literature Review and Theoretical Framework

Elementary school students are asked to memorize their multiplication facts is so that they can use them as a basis to solve more complex problems (Kilpatrick et al., 2001; Smith & Smith, 2006). The constant reliance on counting fingers, especially for larger products, gets in the way of using more sophisticated strategies for finding the answers to difficult-to-remember facts. Knowing the basic computational facts is theorized to free the brain from figuring out the fact to using the fact in more sophisticated (Donovan, Bransford, & Pellegrino, 2007; Kilpatrick et al.; Woodward, 2006). Students need begin with a conceptual understanding of multiplication before they can have a firm grasp of their multiplication facts (Smith & Smith, 2006). Students can better retain information when it holds meaning for them. Some suggested strategies to help students gain a conceptual understanding include (a) sharing their strategies, (b) using manipulatives, (c) creating problem-solving situations in which students must use multiplicative
reasoning, (d) playing games, and (e) carefully sequencing learning activities (Isaacs & Carroll, 1999).

When students communicate their thinking in mathematics, it leads to higher-level learning (Chapin, et al., 2003). Classroom atmospheres should encourage such communication. Students retain more information when they are excited about it and can relate to it. Therefore, it is the teacher’s responsibility to provide opportunities for their students to make personal connections to new learning and to give students time to share those connections (Gallenstein, 2003). In addition, Cooke and Buchholz (2005) and Olson (2007) found that providing students with materials, such as games, to explore and asking them mathematical-related questions about their interactions with those materials can generate participation in mathematical discussions. When students are excited to learn, they are more likely to participate in mathematical discussions. Finally, facilitating mathematical discussions allows the teacher to focus on the individual learners in the classroom and use that new knowledge to guide further instruction (Fuson, et al, 2005).

Methods

A quasi-experimental design (Creswell, 2008) using mixed methods were used to investigate whether games support students’ learning of math facts. Quantitative analysis allowed us to determine whether the games had a positive effect on student learning. The two groups of students were Author 1’s fourth grade students, one from 2008-2009 and the other from the 2009-2010 school year. Qualitative methods using a case-study design with constant comparative and matrix analysis allowed us to describe how games supported students’ learning of multiplication facts.

Context and Participants

Greenwood Elementary School (pseudonym) in the Pacific Northwest was in a mixed neighborhood comprising of an upper middle class neighborhood and a low income housing complex. Math fact automaticity was a school-wide goal: 85% of the students would correctly answer 100 facts within 5 minutes by the end of 2009-2010 school year. The participants in this study included two fourth-grade classrooms taught by Author 1. Class A was from the 2009-2010 school year and Class B was from 2008-2009. The students in both classes were randomly assigned a school administrator and then the third-grade teachers balanced the student groups for students with learning disabilities, behavior management plans, high abilities, and English language learners. The demographics of the two classes were similar. We selected three low-scoring students (Trenton, Mandy, and Alyse) who did not qualify for special services for case study analysis.

Intervention

Students in Class A (2009-2010) were asked to study multiplication flash cards at home and they played three multiplication games (Akers, et. al., 1997) a minimum of three times a week. Students in Class B (2008-2009) were also asked to practice multiplication flash cards at home and were given weekly timed tests to determine student growth.

Three multiplication games were used. The first, Product Tic-Tac-Toe, helped students to learn their facts because only a small set of facts was focused on, which helped them gain conceptual understanding by grouping related facts (e.g., 3, 6, 9). Students found the answers to the same problems more than once. This repetition helped them to gain better fact fluency. The
second, The Factor Game, further supported the development of a conceptual understanding by creating an opportunity for students to investigate a number and its factors. In turn, this helped them learn their facts by focusing on the actual factors of products. Students were challenged to find all of the factors of given products rather than just a few. The third, Array Flashcards, helped students to learn their facts by providing them with a visual representation of each of the facts they found hard to learn. This visual representation was used to support students who intuitively think about mathematics from a spatial sense rather than numbers and their relationships (Akers et al., 1997).

**Product Tic-Tac-Toe.** Product Tic-Tac-Toe is a game in which students use a pre-made tic-tac-toe card. Figure 1 shows an example of a tic-tac-toe card for students who are working on their 3’s, 6’s, and 9’s. Each square contains the product, or answer, to a multiplication problem using the factors below the table.

![Figure 1. Tic-tac-toe card for students working on 3’s, 6’s, and 9’s](image)

To begin, player 1 places a paper clip on one factor below the game board. Player 2 places a second paper clip on another factor below the game board and then puts a marker on the number within the table that represents the product of the two factors. Player 2 then moves only one paper clip to a different factor and then puts a marker on the number representing the product of those two factors. The students continue playing until one of them has three products in a row or a draw is declared.

**Factor Game.** The Factor Game is one in which students are given a board with products, and each student takes a turn selecting a product on the game board (Figure 2). The partner then finds all of the factors for the selected product and earns those points.

![Figure 2. Factor Game board for use with factors 0 through 6](image)

Using the game board in figure 2, Player 1 might choose 30 and earn a score of 30. Player 2 identifies the factors of 30 including 1, 2, 3, 5, 6, 10, 15. The sum of these factors becomes his/her score, 42. Then, Player 2 chooses a product and Player 1 selects the remaining factors for their respective score. Once a number has been chosen as a product or a factor, it can no longer be used by either player. The game continues until all factors on the board have been used. The winner is the player with the highest score.

**Array flashcards.** Students choose the multiplication facts that were the hardest for them to remember. Using centimeter grid paper, students cut out arrays that represented each

Chapter 5: Classroom Discourse

multiplication fact that was difficult to recall. Students wrote the multiplication problem on one side of the array and the answer on the other side. Then, students either practiced independently or quizzed each other on these facts.

Data Collection and Analysis

To determine whether there were significant differences in the number of facts students could recall between Class A and Class B, pre- and post-test design was used. Students in both classes were given a pre-test in September consisting of 40 randomly selected single-digit multiplication facts with factors between zero and ten to assess their automaticity. The post-test was given in November and consisted of the same 40 facts. The difference between the pre-test and post-test was used to indicate growth. An independent-samples t test was conducted to evaluate the difference between the mean growth of the two independent groups, Class A and B.

Three data sources were collected to describe how students used the multiplication games and their game preferences. The case-study students were interviewed three times using a semi-structured protocol (Creswell, 2008), daily field notes were made, and students wrote reflections on their learning and game preference. Field notes included detailed descriptions of students while they were engaged in the games, their conversations with each other, and whole-class discussion. Analysis of these data included constant comparative methods to collapse the data into meaningful categories. Matrix analysis allowed for cross-case comparisons to generate aspects of games that supported students’ memorization of facts.

Results and Discussion

An independent-samples t test indicated that the games had a positive effect on students’ learning of multiplication facts, α<.05, t(48)=2.05, p=.046. The number of facts that students learned in the class A (M=26.56, SD=15.59) was significantly higher than the students who did not use games (M=18.32, SD=12.77). A weak effect size (0.16) may be the result of using the games for nine weeks and the small number of students (26) in each class. After nine weeks of playing the games, the case students showed growth. The number of facts that Alyse knew increased by 10%, Trenton’s growth was 38%, and Mandy’s growth was 35%.

Before beginning the study, the case-study students were asked which facts were the easiest for them to remember. All three of the students found the 10’s facts were the easiest. Trenton said, “They were easy because all he had to do was look at the number and add a zero to the end of it to find the correct answer.” Alyse said she could count by tens easily so it didn’t take her long to find the solution. Mandy agreed that she could also add ten to a number quickly to find the answer. Next, we asked the students which facts were the hardest for them to learn or remember.

1 Trenton  Nines. I just don’t know them very well.
2 Alyse  Nines. We never really did them last year. I remember a few, but that’s it.
3 Mandy  Eights. I don’t know them at all.
5 Author  What do you do to help you learn the facts that are hard for you?
6 Trenton  I count in my head. Like, ten times five. I can draw ten circles and put five in each, or I can use my fingers.
7 Alyse  I count on my fingers or use counters. It’s easier to remember that way.
8 Mandy  I count with counters.
It was obvious from our conversations with these students that they needed more exposure to their math facts. Nines seemed to be a main problem (lines 1 & 2). This was not a big surprise to us as many students find it hard to find multiples of nine. Clearly these three students were relying heavily on their fingers and/or counters to use repeated addition to find the answers to multiplication problems (lines 6-9). When students used repeated addition, there are two mechanisms to count.

The first can is referred to as *count all* (Carpenter, Fennema, Franke, Levi, & Empson, 1999). Students use the count all mechanism when they create the required number of groups with a corresponding number of objects in each and then count all of the objects. For example, when multiplying $3 \times 4$, a student may draw 3 groups of 4 tick marks on his paper. Then he counts each tick mark, disregarding the groups. The second, *double counting*, is a mechanism in which a student counts individual items in a group simultaneously with the number of groups (Steffe, 1994). If a student were multiplying $3 \times 4$, she may count 1, 2, 3, 4 on her left hand and then hold up one finger on her right hand signifying that she counted one group of four. Then, closing her left hand, she continues counting 5, 6, 7, 8 moving one finger with each number. After counting eight, another finger on her right hand is straightened. Following the same procedure of counting and extending a finger, she reaches 12 with three extended fingers on her right hand. Here, the student kept track of the number of groups with her right hand and on her left hand she counted individual objects in the group. Vergnaud (1988) suggested that this double counting was fundamental to multiplicative reasoning, essential for more sophisticated thinking. These three students relied on repeated addition in which they counted all.

The first game that Author 1 introduced was Multiplication Tic-Tac-Toe. She explained the rules and asked a student to play with her in front of the class. Trenton immediately gave Author 1 advice for one of her next moves, demonstrating his understanding of winning strategies through these suggestions. His enthusiasm was hard to contain with his exclamation, “Oh, I get it!”

After playing the game for several weeks, Trenton described his game strategy. “I put the paperclips on numbers so that I could get numbers on the board. If there was a number I wanted, I tried to get the paperclips to equal that number.” Through his explanation does not clearly articulate how he made his decision, it is clear that he is thinking about different combinations of products that he can make using the factors. While engaged in this thinking, he also recognized that some products could be created in more than one way and indicates a growing level of mathematical thinking. Likewise, Alyse was beginning to select factors to make particular products. She explained, “I had to see what was available on the board and then think what I could do with it. Like if 12 was available, I would try to get the paperclips to 6 and 2 so I could equal it.” In contrast, Mandy focused her attention on blocking rather than trying to get three-in-a-row by claiming the needed product first. A more sophisticated blocking strategy for larger game boards would be to avoid putting a clip on a factor that could be used to create the needed product.

The second week, Author 1 introduced the class to The Factor Game. Again, the excitement was high. This game proved to be more challenging; students had to know the factors of a number in order to be the most successful in the game. However, this did not seem to detour the students from wanting to play. Mandy, Trenton, and Alyse used their fingers to skip count to see if a number was indeed a factor of the product that had been chosen and developed strategies which varied in sophistication while playing.

Mandy’s strategy was to select the highest product on the board. She reasoned that she could boost her score quickly. However, she did not realize that sometimes the highest product could give her partner more points. For example if she chose 24, her partner could identify the factors 1, 2, 3, 4, 6, 8, 12 giving them a score of 36 points. Trenton noticed that prime numbers have only one factor on the board, so he developed the strategy of selecting primes. Alyse struggled to identify factors and found the game laborious. However, she gained an insight; some numbers have more factors than others.

The third week, Author 1 demonstrated the construction of array flashcards. She explained, “You needed to make flashcards for the facts that were hardest to remember.” To Author 1’s surprise, the three case-study students happily made arrays for the facts that they did not know. Even though they had more arrays to construct than their classmates, these three students were busy counting squares, drawing arrays on grid paper, cutting them out, and writing the corresponding multiplication sentence. Alyse, Mandy, and Trenton said that they liked using array flash cards because they knew they needed help with certain facts and it was nice to have a set of cards devoted to only those facts. Alyse eagerly explained that she enjoyed the challenge of memorizing them and couldn’t wait to weed out the ones she had memorized. Only Mandy explicitly used the size of the rectangles as a clue. She explained, “I knew that the bigger rectangles had bigger answers, so sometimes that helped me.”

After teaching the three games, Author 1 noticed that the three students were still counting on their fingers and was curious how the games supported their learning.

11 Alyse   I really like them. I like the array flashcards. I made them for my nines. It helped me to count out the squares [on the rows] and find the right answer.
12          
13 Trenton I like the Tic-Tac-Toe because I’m getting better at it. It helped a lot with my twos, fives and tens. I got to move up to the green card! (The green card was made for practice with threes, sixes, and nines.)
14          
15          
16 Mandy   I like Multiplication Tic-Tac-Toe. When I see the numbers over and over again, it helps me remember them. And I know if I got one wrong because the number is not on the card.
17          
18          

Alyse preferred array flashcards and seemed to use the geometric shape to help her remember the facts. She also recognized that the rows on the arrays represented repeated addition interpretation of multiplication (line 12), indicating a growing conceptual understanding of multiplication. Clearly, Trenton and Mandy preferred Multiplication Tic-Tac-Toe (lines 13, 16). They had a better grasp of their facts and were beginning to recognize the relationships between factors and their products. Trenton recognized patterns between related facts and was able to advance to another set of factors (line 14). Both Trenton and Mandy recognized the value of repetition in gaining multiplication fact automaticity (lines 13 & 16-17). Mandy based her answers on the related facts on the board, indicating that she recognized relationships between factors and related products (lines 17-18).

Twenty of the 26 students said they use their fingers or pictures to count up to the answer with repeated addition. The other 6 students used a related fact to build the unknown pair. Trenton knew the multiples of 2, 5 and 10. When he multiplied 8 x 3, Trenton first found 5 x 3 and then used repeated addition by counting on his fingers to complete his answer. Speaking to

himself he might think, 5 x 3 is 15, so I need 3 more groups of 3. That would be 15, pause 16, 17, 18; then 19, 20, 21; then 22, 23, 24. This strategy shows the use of a related fact and double counting. Each pause signified a count of the number of groups. In recent research (Xin, et. al.; Zang, et. al., 2009) on the development of students’ with learning difficulties, double counting was found to be an intermediary step essential to transition students from repeated addition relying on fingers to more sophisticated reasoning strategies. It is clear that Trenton was using a more sophisticated strategy than his initial use of counting all. In Author 1’s classroom, five other students also used more sophisticated reasoning that relied on both double counting and the commutative property. They would begin with 2 x 3 = 6 and then would then double the answer, which would result in a 12. Next, they would double the answer a third time, resulting in the answer of 24. Mathematically they broke the 8 into its prime factors and then used the commutative property. Symbolically this process is represented as follows: 8 x 3 = [(2 x 3) x 2] x 2. We theorize that Trenton was on the cusp of developing this strategy in November and that the other two case study students will also advance their thinking by using the double counting process as the school year progresses. The six students who used related facts seemed to have a firmer conceptual understanding of their multiplication facts than the rest of the class since they were able to draw upon knowledge of facts they already knew.

Conclusions

The results of this study suggest that the use of multiplication games did in fact help students to gain automaticity. As noted by Olson (2007), students enjoy the challenge of finding ways to win games while also developing a better conceptual understanding. The games helped the students learn more multiplication facts and there was evidence that one of the case-study students developed a more sophisticated counting strategy. Students enjoyed playing the games and placed greater importance on learning their facts.

Students eagerly learned the rules of the games each time they were introduced and hurried to play the game themselves. Many students in Class A wanted to practice their multiplication facts at home and this desire indicates that learning them was important. They wanted to play the games at a faster pace and also win. The students in Class A identified four ways that they practiced facts at home: (a) computer games, (b) array flash cards, (c) problems written on paper by a parent, and (d) the traditional flash card. In contrast, many students in Class B reported that they really did not practice their multiplication facts at home. As noted by Diaz-Lefebvre (2004), when students believe an activity like learning multiplication facts are important, they are more likely to engage in the necessary practice. Students in Class A were highly motivated to practice their facts because they were excited by the games.

The games helped all of the students in class A develop a better conceptual understanding of multiplication as shown through the diagrams that they drew and use of double counting when they used repeated addition. They were beginning to use more sophisticated strategies that relied on relationships between the different multiples and factors. Students in Class B were asked to memorize the facts in a context that was void of meaning and importance. They saw little to no connections between the fact and the different representations. As suggested by Diaz-Lefebvre (2004), students who do not have a deeper understanding of material are at a loss for retaining it.

Multiplication games had a positive effect in the fourth-grade classroom. Such games can be incorporated into any classroom by merely setting aside a small amount of time each week to devote to the games. It was clear that the amount of time spent playing the games was truly beneficial to students. Without making strategies explicit when teaching the games, the students

---

relied on their own critical reasoning skills. This forced them to think on a higher level than simply using flashcards. This higher level thinking paired with a conceptual understanding may help students achieve greater success in mathematics in the future. Additional research is needed to determine the long term effect of gaining mastery of facts through games and other activities that build conceptual understanding on students’ later achievement in mathematics.

EXAMINING SOCIOCULTURAL CONTEXTS OF CLASSROOMS TO FOSTER
STUDENT MATHEMATICAL DISCOURSE AND LEARNING

Melva R. Grant
Old Dominion University
mgrant121@gmail.com

Mathematics learning and teaching are optimized in classrooms when reform-oriented culture (ROC) is present. This report presents a case study that illustrates how ROC manifested and influenced mathematical Discourses in one sixth-grade classroom. The data was drawn from a study that addressed the question: How do classroom interactions influence mathematical Discourses? The study used interpretive methodology for analysis. One finding was that classroom boundary interactions either enhanced or hindered mathematical Discourses dependent upon sociocultural context alignments. An implication of this research is when “effective” learning and/or teaching strategies are identified, “effective” implementation may require paying close attention to sociocultural context alignment.

Introduction

In the past, mathematics education reform has been articulated in terms of content (NCTM, 2000), curriculum and assessment (NCTM, 1989), and teaching (NCTM, 1991); and in each of these standards documents are descriptions of sociocultural elements of mathematics classrooms and advice for transitioning classrooms from traditional to reform-oriented culture (ROC). For this study, sociocultural elements include all classroom interactions related to learning and teaching. The purpose of this investigation was to examine classroom interactions closely using a perspective that would offer insights into how mathematical Discourses (more than talk, engagement, and participation) influenced learning and teaching. This report offers a glimpse into a study (Grant, 2009) that examined how classroom interactions influenced mathematical Discourses related to learning and teaching.

The research study took place in a large urban Midwestern school district in the United States. The participants were from three sixth-grade mathematics classrooms from two different schools from within the school district and included teachers, students, and Mathematics Coaching Program (MCP, Erchick & Brosnan, 2005) instructional coaches. The study examined interactions from each classroom and then compared the three classrooms to illuminate the findings to address the research question: How do classroom interactions influence Discourses related to mathematics learning and teaching?

Methodology

The overarching method for the investigation was case study including comparative case study analysis (Stark & Torrance, 2005). Data sources for this study included videotaped mathematics instruction (~1,350 minutes), survey responses from teachers and students, and audiotaped interviews with teachers and coaches. NVivo 8 (QSR International, 2008) qualitative analysis software was used to support the data analysis.

The theoretical model used in this study was inspired by relational perspectives developed by Cobb and several colleagues (2002) The mathematics teaching and classroom practice literature (e.g., Franke, Kazemi, & Battey, 2007) suggested that classroom learning requires social and cultural interactions. A significant problem for the investigation was determining what

sociocultural elements to target when studying mathematics classroom interactions. The theoretical model used in this study addressed this issue and focused the observation and analysis using three key constructs – classroom culture (social norms and practices), Discourse (more than talk, participation, engagement, and community), and relationships (that support opportunity for learning). These constructs were prominent in both the relational perspectives of Cobb and colleagues and the mathematics teaching and classroom practice literature.

The theoretical model offered a point of view that was beneficial for interpreting or making sense of the complexities of interactions that occur in a mathematics classroom (Yackel & Cobb, 1996). This theoretical model and the classroom practice literature led to defining a hierarchically organized set of codes that were used to focus the classroom observation and analysis on specific sociocultural elements of the mathematics classrooms targeted in the study.

Data analysis included both descriptive statistics and interpretive analysis (Erickson, 1986). The theoretical model was used serially – each of the three theoretical constructs in turn was used as a lens to code all of the data from each classroom (i.e., the hierarchically organized codes were assigned to specific data). In other words, all data were reviewed and coded at least three times, one pass for each construct. Then descriptive statistics were generated to describe the data and analysis quantitatively – categories with the highest density coding by construct were identified, then inferences were made and those sufficiently warranted by the data across all constructs led to claims and findings.

The study presented three case studies, one for each classroom, and a cross case analysis by construct was done to further elucidate the findings. This paper presents one of the findings that emerged from the study, but was limited in scope in an effort to be concise. The case study and analysis in this paper is from one classroom (Eva) and focused on only one construct (classroom culture).

The classroom culture construct focuses on social norms and processes related to interactions within mathematics classrooms; examples of the hierarchy and codes follow: a) cultural influencer – teacher expectations; b) mathematical process – connections; c) sociomathematical norm – student explaining; and d) social norm – listening.

Findings

One of the major findings from the study was that some classroom interactions enhance while others hinder mathematical Discourses related to learning and teaching; and the sociocultural contexts within the classroom appear to determine whether Discourse emerges or not. These types of classroom interactions that depend on sociocultural contexts are called boundary interactions. Several examples of boundary interactions are described within the case study.

The following case study and discussion are presented to demonstrate how boundary interactions manifest in practice. Three examples of classroom interactions are presented. The sociocultural context alignment in each situation described in the case enhanced the mathematical Discourse. The discussion that follows the case suggests alternative sociocultural context alignments for the boundary interactions that would likely hinder the mathematical Discourse. The alternative sociocultural context alignments were inspired by data from the study.

Eva’s Mathematics Classroom

Eva taught sixth-grade mathematics for 90 minutes three times each day during this investigation. During the observation period, all of the mathematics topics in Eva’s classroom
were related to fractions. Eva’s class included a diverse group of students. The class was comprised of slightly more males (12) than females (8), a diverse representation by race or ethnicity included a balance of Black (8) and White (8) students, and there were biracial (2) and other (2) racial or ethnic students. On average, there were 20 students present on each of the observation days.

Eva described this class as a good class, but not her best. During the initial pre-observation interview, Eva described her instructional style as one that was “organized” and “structured” (Feb. 20, 2009). Observation data validated her description; instruction followed a pattern. First, students completed bell work (two or three problems related to the previous day’s mathematics) as Eva circulated the room observing student work, answering questions, and taking notes (sometimes written) of who did what and how. Next, Eva reviewed the bell work in a whole-class format that included students’ explaining taking 30-45 minutes of the 90-minute instructional period. Then, students engaged in activities, usually in small cooperative groups of two to four followed by students’ sharing solution strategies. During the last 5 to 10 minutes of class, Eva articulated a summary review of the days’ mathematics or presented new mathematical ideas. This instructional pattern was consistent with little variation on the observation days.

Given Eva’s admission of being structured and organized, it was not surprising that the normal desk configuration in her classroom was straight rows facing front. Each day I observed her classroom, prior to children entering the room, she spent time straightening the rows and preparing supplies for children’s ready access or for easy distribution at the appropriate time during instruction. However, when she wanted students to work cooperatively, students reorganize desks to accommodate the collaboration and Eva’s oversight ensured a timely transition. At an appropriate time following cooperative activity or before leaving Eva’s classroom, students returned desks to their original positions.

Classroom Interactions on the Boundary

In Eva’s classroom, there were several instances when classroom culture enhanced Discourses and other instances when it served to hinder them. Classroom interactions that hindered Discourses included: a) fact or procedural reproduction; b) low-level questioning; and c) negative social norms. Conversely, classroom interactions that enhanced Discourses included: a) mathematical connections; b) student explaining; and c) listening and respect. Additionally, there were boundary interactions – classroom interactions that sometimes enhanced and at other times hindered Discourses depended on related sociocultural contexts such as: a) collaborative sense making; b) communications; and c) teacher explaining (see Table 1 column 1). These sociocultural contexts were boundary interactions in Eva’s classroom, but I cannot conclude they would manifest as boundary interactions in other classrooms.

Boundary interactions listed in Table 1 enhanced mathematical Discourses when sociocultural contexts aligned with enhancers such as those in column two. Conversely, boundary interactions hindered the mathematical Discourses when sociocultural contexts aligned with saboteurs such as those in column three. For example, in Eva’s classroom for the boundary interaction teacher explaining (column one) the mathematical Discourse was enhanced when the sociocultural context alignment supported students’ sharing ideas (column two). Conversely, for the boundary interaction, collaborative sense making (column one) the mathematical Discourse was hindered when the sociocultural context alignment included students tasks without choices (column three).

Table 1 is not an exhaustive representation of boundary interactions and sociocultural context alignments that enhanced or hindered Discourses in Eva’s classroom. These boundary interactions and sociocultural context alignments may be valid for other mathematics classrooms, but more research with a broader scope is needed before such conclusions can be made.

There were glimpses of reform-oriented culture (ROC) within Eva’s classroom. One example of ROC occurred when two students’ perceived they had an opportunity to share an authentic idea based upon their independent thinking. These two boys had each autonomously thought about comparing fractions conceptually instead of using one of the procedural approaches that had been the focus for instruction over the last several days. The students were asked to compare three fractions \(\frac{3}{4}, \frac{3}{5}, \text{ and } \frac{3}{12}\) and order them from least to greatest. The following classroom snapshot is a descriptive vignette that summarizes the interaction processes.

**Classroom Snapshot 1 – Listening and Revoicing**

Eva began the class discussion of the bell work by inviting two boys to share their thinking. Eva discovered the two boys’ approach as she circulated the room assessing student work and understanding. The boys explained their thinking and approach without Eva interrupting or correcting errors in their explanations. At the end of each explanation and throughout the mathematical Discourse related to the bell work, Eva congratulated each boy. She revoiced what each boy had explained after both explanations were done.

In this vignette, the boundary interaction is communication and the sociocultural context alignment that enhanced the Discourse is students sharing ideas. Eva created the opportunity for student sharing. The two boys’ articulated rationale was that each fraction had the same numerator and different denominators, thus all that was needed was to compare the relative sizes of the pieces by using the denominators. The students’ sharing led to a broader class discussion and analysis than perhaps would have otherwise emerged had the Discourse been limited to comparing fractions using only the two procedural approaches the class had been practicing. The ensuing Discourse included students’ generalizations about relationship between the magnitudes of denominators and the size of the pieces and the importance of assuming all fractions were based on an equivalent whole.

A second example of a boundary interaction is collaborative sense making and the sociocultural context alignment that enhanced the Discourse is a task with choices. The instructional segment started with Eva asking students how to show \(\frac{7}{10}\) using a pictorial representation of a fraction bar. Several students contributed and described what to do as Eva drew on an overhead projector. Eva asked, “So, I’ve got \(\frac{7}{10}\) but I have 100 squares. How would I divide this up?” and the following interaction ensued:

---

**Classroom Snapshot 2 – Developing fraction representations**

**Eva:** [waits ~10 seconds, repeats the question several times as she waits, and more students raise their hands] Student A1?

**A1:** You can make boxes of ten.

**Student:** no [shouting out]

**Eva:** So, I'd have to make boxes of ten. You're right. What do I know about the boxes of ten Student A1?

**A1:** Um

**Eva:** They need to all look how?

**A1:** The same.

**Eva:** They all need to look the same. A1, So, could I go like 1, 2, 3, 4, 5 and could I make my boxes of ten like this? [drawing 5 X 2 rectangular arrays on the overhead displayed grid paper]

**A1:** Yeah

**Eva:** You bet I could. How else could I make them? Student A2?

**A2:** You could take one like, one set of ten, like a row [gesturing with her hands as she speaks] and color it in.

**A3:** What if you took one bar [10 of the 100-square grid] and colored in 7?

The task called for students to create a pictorial representation of a fraction and yielded two different approaches and an interesting question (Line 12). This student’s question was a clarifying question that enhanced the Discourse by encouraging more collaborative sense making to emerge after the initial task was completed. The fraction being represented, \( \frac{7}{10} \), could have been easily done using a row of 10 blocks; however, the nature of the task, representing the fraction on a 10X10 grid likely encouraged the student to seek clarity. Nonetheless, students’ collaborative sense making Discourse was enhanced because the student’s question led to the class having to consider whether the proposed pictorial representation met the criteria of the original task. Using Bloom’s taxonomy, the original task was a knowledge question, but the student’s question was an evaluation question; the Discourse was enhanced.

The third and final example of a boundary interaction is teacher explaining (as implicit telling) and the sociocultural context alignment that enhanced the Discourse is student comparing mathematical approaches.

**Classroom Snapshot 3 – Reflecting and Evaluating a Mathematical Procedure**

**Eva:** by 4's

**Students:** 4, 8, 12, … [Counting by 4's up to 48].

[Students are unenthusiastic, and lose synch. Eva writes on the overhead sighs, and then runs out of space]

**Eva:** Do we have to count like this? Seriously guys, what would be the easiest way to do this? We'll be counting forever. What's an easier way to do this Student A?

**Student A:** You know how we put the numbers at the bottom and circle them? Instead of going through the whole thing.

**Eva:** OK. OK. Student G?

**Student G:** Factor tree

**Eva:** Guys? Factor tree. Awesome. I would say factor tree. You're probably gonna spend less time than if you do it the other way. Let's try it? Let's try factor tree.
Eva appeared to have contrived a situation that caused students to reflect and evaluate the efficiency of a mathematical approach by commenting about running out of space for writing and showing great exasperation during the execution of the mathematical procedure. Her theatrics (Lines 3 & 4), which were not in character for her, were interpreted as teacher explaining, but not telling. She asked in Line 4 if there was a better way to find the least common multiple than counting ALL of the multiples of a number. In fact, Eva asked the question multiple times. This approach had been observed as a way to focus students’ attention and to generate wait time for thinking. The result was several students raised their hands to offer ideas, which evidenced several students’ compared mathematical approaches and enhanced the Discourse related to learning and teaching.

**Discussion**

In the case study, examples of how boundary interactions when coupled with sociocultural context alignments enhanced mathematical Discourses related to learning and teaching. In this section, we will examine how those Discourses might have been hindered by Discourse saboteurs. Consider the first example in Classroom Snapshot 1, the process was described in the vignette, Discourse might have been different had Eva not created opportunities for the two boys to share their ideas for comparing the three fractions. Would the class have had the opportunity to reflect on the size of denominators when the numerators are the same? Additionally, the Discourse included thinking about the importance of the whole and the relationship it plays when comparing fractions. How helpful might it have been for a student harboring a misconception about fractional comparisons to hear three different explanations for comparing fractions conceptually followed by a comparison done procedurally?

In Classroom Snapshot 2, collaborative sense making was the boundary interaction. However, how might the Discourse have differed had Eva simply dismissed the student’s proposed representation as not correct? That is, offered a task with no choice. Instead, the task was designed to accommodate “What if” questions and students were encouraged to decide whether the representation was appropriate given the task; the task afforded choices. Consider task options that are presented as choices that in practice are not. For example, suppose Eva had provided several representations for students to select the one that was correct. The cognitive rigor of the task must be considered if collaborative sense making is desired. The task that was the focus for this example was not especially rigorous for a sixth-grade class, but the pedagogical approach of valuing and using all students’ input enhanced the Discourse.

In Classroom Snapshot 3, teacher explaining was the boundary interaction, even though the teacher explanation or telling was implicit. How might the Discourse been different had Eva explained explicitly that they needed to use a different approach? She could have simply told the students that what they were doing was inefficient and they could get the solution faster by using one of the procedural approaches they had been practicing, i.e., offered a prescribed solution. When Eva created wait time by asking and re-asking questions, had she not, would the same number of students raised their hands to offer their ideas about the question? Additionally, how effective are mathematical Discourses when students choose not to participate?

Eva’s teaching actions appeared to be more aligned with developing integrated mathematical knowledge than sharing correct answers. Her sociocultural perspective was aligned toward reform-oriented culture (ROC), which led her to encourage students to share their authentic thinking and ideas. Eva invited and encouraged students to act this way as evidenced by the opportunities she afforded them during instruction independent of whether or not she finished
her instructional goals for the day. This type of instructional perspective manifested in the emergence sociocultural context alignments that enhanced Discourses toward mathematical inquiry and sharing of ideas, ROC. The classroom culture in Eva’s classroom often led to multiple student approaches for finding correct solutions and mathematical connections; restated, using a traveling metaphor, the journey was valued as much as the destination in Eva’s classroom.

One implication for practice from this study is if expected outcomes fall short for new learning and/or teaching strategies, something to consider examining is the sociocultural context alignment. That is, reflect on classroom interactions and consider adjusting related sociocultural contexts such as creating opportunities for student explaining or revising the task for increased student autonomy before concluding that the new strategy was ineffective.

Conclusions

If a goal of reform is to usher in effective mathematical Discourses related to learning and teaching, then those focused on support and implementation must not lose sight of ROC and reflecting on the alignment of sociocultural contexts that enhance or hinder boundary interactions. Simply stated, ROC is about creating opportunities and space within instructional settings for students to be both learners and teachers as their authentic ideas emerge. However, sociocultural contexts must be appropriately aligned to enable authentic mathematical utterances from students as the norm rather than the exception.

Some reform-oriented learning and teaching strategies appear to be promising, but they often emerge independent of consideration for sociocultural contexts extant in today’s classrooms. As educators, we must forego rigid plans focused on curriculum coverage and/or strategy implementation, and look for opportunities to allow ROC to emerge and infiltrate classrooms. As supporters of teachers engaged in reform implementation, we must be cognizant of and prepared to help teachers transform ROC stifling classroom cultures. As researchers, we must further define and articulate sociocultural nuances related to recommended reform-oriented learning and teaching strategies to support the emergence of ROC within classrooms.

MULTIPLE VOICES IN MATHEMATICS CLASSROOM: AN ANALYSIS OF MATHEMATICS TEACHER’S TELLING

Mi-Kyung Ju
Hanyang University, South Korea
mkju11@hanyang.ac.kr

Traditionally, teacher’ telling was understood as limited to presenting mathematical facts and procedural skills. However, recently, researchers propose to reconsider teacher’s telling to understand its function more fully in the context of teaching and learning mathematics. Adapting this perspective, this research analysed a preservice mathematics teacher’s classroom discourse to show that teacher’s telling functions not only to present mathematical information. More importantly, it was shown that teacher’s telling functions to highlight emerging mathematical voices by diverse agents and position the voices in the context of mathematical argumentation for the collective construction of mathematics. This paper also discussed factors to facilitate the teacher’s telling that celebrates the gift of the diversity in mathematics class.

Introduction

Recent reform movements in mathematics education emphasize teaching and learning of mathematics based on students’ active participation (e.g., Cobb & Bauersfeld, 1995; NCTM, 2000). For the purpose, it is recommended that mathematics teachers be equipped with discursive competence to fulfil their role as a facilitator and orchestrator in class (Chazan & Ball, 1999). The emphasis on discourse roles in teaching and learning of mathematics is predicated upon the ideas that mathematics is social practice. When considering mathematics as social practice, an individual’s practice of mathematics is always revalorized in the context of the communal practice. An individual’s practice of mathematics becomes assigned to a certain position with respect to the culturally shared notion of legitimacy of how to do mathematics. In particular, a teacher plays a role to position individual students’ practice of mathematics by deciding what kind of question needs to be raised to whom, whose argument deserves to be referred to for an extended inquiry, and so on. This suggests that teacher’s discourse functions as an epistemic device, which is defined as the means whereby actors or institutions establish and negotiate the legitimacy of knowledge and of knowledge production (Moore & Maton, 2001). As an epistemic device, teacher’s discourse shapes the practice of mathematics in class by distributing the norms of doing mathematics and assigning a student to a certain position according to the norms. Then, it is of significance to address the features of teacher’s discursive practice that is consistent to the teacher’s roles recommended by reform movements. In this perspective, this research specifically focuses on teacher’s telling to investigate the features of teacher’s telling to create a classroom community where students are positioned as authors of mathematics and as arbiters of what counts as truth in the classroom practice of mathematics.

Theoretical Background

Research shows that telling belongs to a teacher’s major discourse repertoire (Lobato, Clarke, & Ellis, 2005; Smith, 1996). However, the recent emphasis on the constructivist approach to teaching and learning mathematics carries a negative connotation of teacher’s telling. That is, teacher’s telling hinders a student’s active construction of mathematics. This is based on the traditional notion of teacher’s telling which conceptualizes telling as stating information or...
demonstrating procedures. This notion of teacher’s telling reflects the assumptions that mathematics is a fixed collection of definite truth and that teaching mathematics is concerned with transiting the knowledge package from a teacher to a student (Smith, 1996). When mathematics is considered as social practice, the traditional notion of teacher’s telling needs reconsideration since it is confined to only a partial aspect of mathematics.

In fact, Chazan and Ball (1999) criticized that an exhortation to avoid telling oversimplifies the teacher’s role and provides only inadequate guide for teachers. In reform-oriented mathematics class, one of teacher’s roles is to support and sustain intellectual ferment by monitoring and managing disagreement among students in meaning negotiation. Telling is a useful discourse move for a mathematics teacher to provide intellectual resource and to steer students’ arguments. By telling, a teacher may return an issue to the students in class, to appropriate a student’s comments by rephrasing them to other students. Lobato and her colleagues also proposed reformulation of telling as a set of teaching actions that serve the function of stimulating students’ mathematical thoughts via introduction of new ideas into a classroom conversation (Lobato, Clarke, & Ellis, 2005).

Since the 1990s, community of mathematics educators adapted the perspective of mathematics as social practice. In this perspective, mathematics includes not only facts and skills but also intersubjective meanings that emerge through the human engagement in the context of doing mathematics. This suggests that mathematics teaching is not merely a process in which a teacher exports facts and skills. Rather, in class, a mathematics teacher is engaged with students to collectively construct mathematics out of emerging ideas in the context of on-going meaning negotiation. Adapting this perspective, this research analyzed a mathematics teacher’s telling in class to reconsider its didactic function in the context of teaching and learning mathematics and to investigate the features of teacher’s telling to create a mathematics classroom with intellectual ferment.

**Research Methods**

*Setting & Participant*

This research has been conducted in the context of teaching practicum. The analysis focused on the case of a preservice mathematics teacher, Lami, who had participated in the program for three semesters. In teaching mathematics, Lami encouraged students’ active participation into mathematical inquiry to learn mathematics. Lami’s class was organized around problem solving and mathematical communication. Lami developed the tasks based on real world phenomena. The task included a sequence of questions to guide students’ collaborative construction of mathematics. So the questions were not simply concerned with finding the answer to a given task but also with facilitating students’ explanation and justification of their mathematical findings. The students worked on the task collaboratively in small groups of 3-4 and shared their findings in whole class discussion where Lami played a role as a facilitator and orchestrator. As she described in her journal, Lami tried to adapt the social constructivist approach to her teaching and reflected upon her role in classroom discourse through her practicum. Hence, the analysis of her classroom discourse would provide some understanding of the features of teacher’s telling that is consistent to the educational vision of recent reform movements.

*Data Collection & Analysis*

Data for this research had been collected for 3 semesters: from Fall 2005 through Fall 2006. All the class sessions taught by Lami were observed and video-recorded. The video-recordings

---

of her teaching were transcribed for discourse analysis. The classroom discourse analysis focused on Lami’s telling in whole class discussion where she consciously played her role in discourse as a teacher. The preliminary analysis of the transcripts focused on the identification of discourse types that occurred in Lami’s classroom discourses. All the utterances by Lami and the students were separated sentence by sentence and placed on individual cells of the spreadsheet. In the analysis, both form and function of teacher discourse were considered. So after sorting the utterances by the form of a sentence, the functional aspects of utterances were taken into account. Then, content of teacher discourse (i.e., whether the teacher is talking about mathematics or not) were considered.

A coding scheme was primarily developed based on literature review and then refined through multiple passes through the classroom discourse data. The analysis identified 4 types of the teacher’s discourse moves: questioning (Q), telling (T), managing (M), and revoicing (R). All the discourse moves including telling became refined into a set of subcategories since they carried out various functions, which will be described in following section. The codes for the subcategories of the discourse moves were assigned to each utterance. The coded transcripts were analysed both quantitatively and qualitatively. Lami’s reflection journals were collected to validate and supplement the analysis of her classroom discourse.

Findings

Functions of teacher’s telling

Telling is defined as a discourse pattern that Lami used to declare a statement referring to a mathematical content. The analysis showed that Lami’s telling could be distinguished further into subcategories by taking into account of what kind of mathematical content carried. Following table presents the subcategories with the descriptions and the codes.

<table>
<thead>
<tr>
<th>CODE</th>
<th>DESCRIPTION</th>
</tr>
</thead>
<tbody>
<tr>
<td>T1a</td>
<td>Presenting information concerning mathematical concepts, procedures, representation, methods which are detached from a student’s mathematical experience and meaning system</td>
</tr>
<tr>
<td>T1b</td>
<td>Presenting information concerning mathematical concepts, procedures, representation, methods in a way to relate with a student’s mathematical experience and meaning system</td>
</tr>
<tr>
<td>T2a</td>
<td>Explaining the mathematical background of a given task in a way that is detached from a student’s mathematical experience and meaning system</td>
</tr>
<tr>
<td>T2b</td>
<td>Explaining the mathematical background of a given task in a way to relate with a student’s mathematical experience and meaning system</td>
</tr>
<tr>
<td>T3</td>
<td>Referring to a student’s mathematical position</td>
</tr>
<tr>
<td>T4</td>
<td>Referring to a teacher’s own mathematical position such as giving a comment on a student’s mathematical argument</td>
</tr>
<tr>
<td>T5</td>
<td>Evaluating a student’s mathematical claim</td>
</tr>
</tbody>
</table>

Table 1 shows that the function of teacher’s telling can be diversified depending on types of a mathematical content (e.g., information about mathematical concepts or procedures, explanation of a task, a mathematical position of a class participant, and evaluation). Furthermore, teacher’s telling can be categorized according to types of an agent. Specifically, T1a and T2a are telling
moves that convey mathematical knowledge by external beings such as textbooks, professional mathematicians, or, in general, the community of mathematics. On the contrary, T1b, T2b, and T3 carry mathematical knowledge authored by a student. T4 and T5 deliver mathematical knowledge by a mathematics teacher. Thus, this diversification of telling patterns suggests that teacher’s telling functions more than exporting textbook-like knowledge of mathematics. In telling, a teacher highlights emerging mathematical perspectives and locates mathematical positions by diverse agents such as the community of mathematics, a student, and a teacher) to have the floor in class.

Use of Telling for Positioning Diverse Mathematical Voices in Class

Then, how did Lami use these various types of telling moves in her teaching? What does the pattern of use tell about her teaching practice? Table 2 presents the result of the quantitative analysis of the frequency of each type of telling.

Table 2. Frequency of Telling Subcategories (in Percentage)

</tbody>
</table>

Table 2 shows that while T1a and T2a were used slightly more often than T1b and T2b, the frequency of T1b and T2b increases through the period of practicum. While a-type telling refers to knowledge by the external mathematics community, b-type telling refers to mathematical knowledge that is meaningful to students’ own mathematical resource. Thus, it can be inferred that this switch is related to the change in Lami’s position regarding the legitimate source for mathematics practice. For instance, following is an excerpt of a class transcript from the first semester of her practicum:

“**How do you think of the problem? It might be difficult but it is about the number of possible outcomes (T2a). So you have to find how many possible outcomes there are (T1a).**”

In this excerpt, Lami told the students the background principle of the problem and the method to solve it. There was no room left for the students to use their own cognitive resources. Following excerpt is from her reflection journal written in the very early stage of practicum:

“I expected the students to consider all the possible cases and then to choose proper cases. But they seemed to try to find the exact cases without considering the set of all the possible cases. The class couldn’t finish the second question because we ran out of time. I regret that I didn’t tell them to find all the possible cases first” (September 23rd, 2005).

This journal excerpt reflects Lami’s beliefs that are coherent to those in the transcript excerpt assuming that a teacher’s knowledge is the only legitimate source for mathematics practice. However, as she observed the strength of the students’ ways of doing mathematics in her teaching, she became to change her beliefs about legitimate source for mathematics practice and began to introduce the students’ mathematical perspectives in her teaching.
The consistent increase of T3 confirms this change. Since T3 refers to a student’s mathematical position, the increase of T3 suggests that Lami became to place the students’ mathematical resource at a more central position in the classroom practice of mathematics. The use of T3 had gone through a qualitative transformation in the regard that T3 more often accompanied revoicing2 (T3-R) over the practicum. The analysis tells that the frequency of T3-R is 22.22% in Fall 2005, 41.51% in Spring 2006, and 50.00% in Fall 2006. T3-R can be distinguished from T3 in the sense that T3-R highlights not only the mathematical position of a student but also the ownership of the position. Then, what is the function of T3-R in the context of teaching mathematics?

1 Teacher: What is a circle? Q
2 Student 1: A ring. A
3 Teacher: A ring. T3-R
4 Can you express it in more mathematical terms? Q
5 Student 2: 360 degrees. A
6 Teacher: 360 degrees. T3-R
7 That means turning around, right? T3-R
8 How does it turn around? Q
9 Students: A center! A
10 Teacher: A center. T3-R
11 There is a center and then how would you draw a circle with a compass? Q-R
12 Student 3: An identical length. A
13 Teacher: An identical length. T3-R
14 So a circle is what you draw with an identical length around one spot. T1b-R

In this episode, instead of giving the definition of a circle, Lami exploited the students’ notion of a circle through a sequence of questions. T3-R functions to highlight the students’ mathematical ideas that were elicited by the teacher’s questions. Often teacher’s questioning followed T3-R. Lami highlighted an emerging mathematical idea then guided the students to explore another features of a circle by asking a follow-up question. By this pair of Q and T3-R, Lami could make the mathematical trajectory of the students’ mathematical exploration explicit and successfully guide the students to construct the definition of a circle collaboratively.

Another interesting pattern is that the frequency of T4, a telling move that conveys a teacher’s mathematical position, decreased in the beginning but increased in the last semester of practicum. In addition to this quantitative change, there observed that Lami’s way of talking her own mathematical position had been changed qualitatively over the practicum. Following is a transcript excerpt from the first semester:

1 Teacher: Why did they use symbols? Q
2 It is because it is convenient. A

In this episode, Lami raised a question and then she answered it by herself. So her discourse flew like a monologue which does not invite the students’ mathematical voices. On the contrary, Lami integrated her mathematical position with the students’ arguments:

This conversation began with the teacher’s question to request justification that a given triangle is equilateral. Lami raised a series of questions to elicit the student’s mathematical positions and used revoicing in her telling to make explicit the connection among the positions. Finally, she presented the justification which she collaboratively constructed with the students.

The increase in the use of T4 may indicate that Lami became aware of what a teacher can offer to the class. More importantly, Lami seemed to learn how to talk with her students. She actively listened to the students’ mathematical voices as revoicing and negotiated her mathematical position according to the students’ ways of thinking and talking mathematics. Thus, her mathematical position could be well-integrated into the on-going mathematical argumentation in class.

Conclusion

This research began with the question of what the features of teacher telling are to maintain and sustain the intellectual ferment in a mathematics classroom. Based on the analysis of a teacher’s classroom discourse, diverse functions of teacher’s telling were identified. The subcategories of teacher’s telling reveal diverse agents that are involved with the classroom practice of mathematics. Moreover, the pattern of change in ways of telling suggests that positioning is the essential function of teacher’s telling. By positioning diverse agents as legitimate, a teacher decentralizes the practice of mathematics to create classroom community where diverse voices are heard and to extend the territory of current practice of mathematics in class. The analysis of Lami’s reflection journal suggests that a teacher’s beliefs about mathematics need to be changed to acknowledge the voices by the diverse agents and the gift of the diversity in mathematics class. In addition, a teacher’s pedagogical content knowledge is of significance to support all the agents to go through all of way together to the wonderland of mathematics and, most of all to make the journey be a chance to have the travellers open their eyes to the world that they’ve never appreciated before.
Endnotes

1. Pseudonym
2. Revoicing is discourse of reuttering another person’s speech through simple repetition, rephrasing, expansion, and reporting (Forman, et al., 1998; O’Connor & Michaels, 1993).

EXAMINING RELATIONSHIPS BETWEEN TEACHER FACILITATION OF MIDDLE SCHOOL MATHEMATICAL DISCOURSE AND STUDENT PARTICIPATION

Dina Neyman  
University of Delaware  
dina@udel.edu

Amanda Jansen  
University of Delaware  
jansen@udel.edu

Forman (2003) claims that mathematical learning occurs through communication in these communities of practices and that learning is a discursive activity. Investigating and contrasting classroom settings where students appear to participate more and less productively can help us identify instructional practices that appear to be more and less successful with supporting students’ productive participation in mathematics classrooms. What is the relationship between teacher facilitation of classroom discourse and student participation in two middle school classrooms?

For this study, two sixth-grade classrooms from the same school were compared and contrasted to identify how the teachers facilitated student participation and how the students participated in the classroom discourse. Teachers at this school used the Mathematics in Context (2006) textbook series, which are materials that include rich mathematical problem solving tasks that have the potential to foster dialogue among students. Three video recordings from the fall, winter and spring of each classroom were analyzed for this study. Codes were developed through an emergent process.

Students in Classroom A appeared to engage in more sophisticated mathematics classroom discourse, but more students participated in Classroom B. In Classroom A, a mean of 43% of students participated in whole-class discussions by presenting their solutions at the overhead projector and explaining strategies that they used to solve mathematics problems. After they explained their strategies, students responded to questions from 28% of their classmates about why their strategies worked. In Classroom B, a mean of 69% of students participated by responding with non-elaborated answers to procedural questions posed by the teacher. Teachers in each classroom facilitated discourse differently. The results of this study demonstrate ways in which teachers’ explicit and implicit communication of behavioral expectations supported and constrained students’ participation in classroom discourse. One teacher’s explicit behavioral expectations provided students with the opportunity to share their elaborated problem solving strategies with the whole class. The second teacher limited the nature of student participation (but appeared to increase frequency) by asking students to respond to procedural or computational questions.

STUDENT-REPORTED LISTENING IN MATHEMATICAL DISCUSSION

Karl W. Kosko
University of Michigan
kwkosko@gmail.com

Investigations of mathematical discussion tend to focus on student talk or factors contributing to its quantity or quality. However, listening has also been characterized as an important component of student mathematical discussion (McCrone, 2005). Yet, most of the studies on listening in mathematics focus on teachers’ listening to students rather than students’ listening to students. The purpose of the current investigation is to provide an initial look at how student listening relates to their mathematical discussion. The present study asked 78 high school geometry students to complete a survey including questions about the quality of their listening actions, frequency they listened to other students, and the frequency of mathematical discussions. Students’ listening actions (listen) were assessed with four questions on a 6-point Likert scale with higher scores representing “truer” statements. Responses were averaged into a composite score. In order to assess the frequency of other listening and discussion activities, students were asked to rate the following statements on a 4-point Likert scale. Higher scores represent a more frequent activity: Our class has discussions about mathematics (class disc); In math class, I have opportunities to talk about math with a partner (partner); In math class, I have opportunities to talk about math in a small group (small group); When other students are talking about math during class, I listen (listen freq); When we have class discussion about mathematics, I participate (disc. participation).

The indicate positive relationships between listening activity and listening frequency. Listening activity was not found to have a statistically significant relationship with any frequency of discussion, but listening frequency was found to be positively and significantly related to small group frequency and partner frequency, suggesting that mathematical discussions in small groups and partner contexts have a stronger relationship to more frequent student listening than whole class discussions. Therefore, these results provide evidence that having students discuss math in small group and/or with a partner provides a stronger context for student listening than whole class discussions.

This poster presentation draws on data from our ongoing study of the nature of collective mathematical understanding and the role of improvisational theory as a framework for interpreting collective actions in a mathematics classroom (Martin & Towers, 2009; Towers & Martin, 2009). Improvisation is broadly defined as a process “of spontaneous action, interaction and communication” (Gordon-Calvert, 2001, p. 87). It is a collaborative practice of acting, interacting and reacting, of making and creating, in the moment, without script or prescription and draws attention to our capacity to integrate multiple, spontaneously unfolding contributions into a coherent whole—a capacity that may be vital for mathematical sense-making in collaborative groups. We suggest that there are specific characteristics of the improvisational process that have much to offer theoretically to an advancement of our understanding of how interacting groups coalesce on particular ideas that move the action (be it jazz or mathematical problem-solving) forward. In this poster we focus on one of these, the notion of “yes, and...”, to consider the ways in which a group of learners solve a mathematical problem.

The data we offer here feature three preservice teachers (not mathematics specialists) working on the problem of finding a number with exactly thirteen factors. What occurs throughout the session (and is illustrated in the extracts embedded within the poster) is a continual process of the offering of ideas or innovations and the subsequent adding of something new—a process recognized by Sawyer (2001) as “yes, and”—the “First Rule of Improv”—wherein strong improvisers support the emerging ‘storyline’ by accepting the previously offered line and adding to it with their own contribution. Through our analysis we identify the ways in which collective mathematical understanding emerges and grows and suggest that the capacity of the group to repeatedly say “yes, and...” to conceptual innovations is a key element in enabling the group to both work productively on the problem and arrive at a solution.

Xiaoxia Zhang  
Chengdu University, China  
zhangxiaoxia2000@163.com

In this study, a stratified random sample of 4784 sixth graders from a populous province in China was assessed about their computational performance after the implementation of school mathematics reform. The results show that Chinese sixth graders developed their computation skills well with the use of new curriculum materials. However, the results reveal a large gap in students’ computation performance between rural and ethnicity schools and those in cities. The results call for further investigations of possible factors contributing to the performance gap, and to inform possible changes in educational policy and practices to improve elementary mathematic education in rural and ethnicity schools.

Introduction

The development of students’ computation skills is generally valued in school mathematics. Being able to compute quickly and correctly is taken as an essential skill for students in many education systems, and it is often assessed in many cross-national studies of students’ mathematics achievement (e.g., Lapointe, Mead et al. 1992; Mullis, Martin, Gonzalez, & Chrostowski, 2004). However, the tremendous emphasis traditionally placed on students’ acquisition of computational skills has been challenged and subsequently decreased in recent school mathematics reform in many education systems including China and the United States (e.g., Leung & Li, 2010; NCTM, 1989, 2000). Students’ rote acquisition and practice of computation skills is no longer favored. Instead, the development of students’ conceptual understanding and problem-solving ability has been taken as a more important goal. While the proposed changes in school mathematics are generally accepted in many education systems (e.g., Liu & Li, 2010; NCTM, 2000), concerns about possible weakening of students’ computation skills are inevitably mounted. There is no exception for the situation in China, where students’ computation skills have often been valued highly in mathematics education (e.g., Zhang, 2006). Recent change in educational emphases in China provides an interesting case for others to examine and understand possible impacts of school mathematics reform on the development of students’ computation skills.

It is generally documented that Chinese students outperform their counterparts from many other educational systems in international mathematics assessments (e.g., Lapointe, Mead et al. 1992). In these existing international assessments, Chinese students’ mathematics performance was measured mainly with students sampled from economically developed areas. The difficulty in accessing students in remote and/or rural areas often restricted the possibility of getting a well represented sample from the vast student population in China. However, few studies that are available suggested that the quality of school education varies dramatically between urban and rural areas, due to very limited resources and instructional support available for teachers and students in rural schools (e.g., Ma, Zhao, & Tuo, 2004). Simply excluding those students in rural schools won’t provide an accurate picture about the status of Chinese students’ mathematics learning in general, or their computational performance in particular. Thus, this study was
developed to empirically investigate, in a relatively large scale to include different types of schools, the status of Chinese elementary school students’ computation skill development in the current context of school mathematics reform. In particular, the purposes of this study include the following:

(1) Assessing elementary school students’ acquisition and development of computation skills that are required in elementary school education in China;

(2) Investigating possible similarities and differences in students’ acquisition and development of computation skills in terms of school locations and ethnicity.

**Assessing Chinese Student Computation Skills**

*Teaching and Learning Computation Skills in China*

The development of student computation skills has long been taken as an important goal in school mathematics in China. Back in 1963, the nationwide arithmetic teaching and learning syllabus stated clearly that students are expected to firmly master basic knowledge of arithmetic and abacus, and be able to compute correctly and quickly. Chinese teachers also developed various approaches for teaching computation skills that were found to be effective. For example, many teachers combined the teaching of oral computation, paper-and-pencil computation and abacus, and found that this method was effective for developing student computation skills. Over the years, there have been some changes in specific requirements and approaches for teaching and learning computation skills, such as decreasing the requirement of computing with large numbers in 1986 and deleting the requirement of teaching and learning abacus in 2001 (Zhang & Ma, 2008).

The recent curriculum reform in China has led to the release and implementation of new curriculum standards in 2001 (Liu & Li, 2010). In the new curriculum standards, the requirements for teaching and learning computation skills have emphasized developing students’ number sense, students’ conceptual understanding of computation concepts and properties, and their application of computation knowledge and skills. Although fostering students’ computation ability and skills are still important, the requirements in computations with large numbers and computation difficulty have been further decreased. Students are expected to learn multiple computation methods, including oral computation and estimation. The use of calculators is also introduced in teaching and learning elementary arithmetic. Correspondingly, the expectation of developing students’ oral computation skills specified in textbooks has become less specific than previous versions.

*Assessing Student Computation Skills: A Framework*

In order to provide a comprehensive assessment of students’ computation skill development, we propose a three-dimensional framework to characterize and assess student computation skills. The first dimension is from a mathematical perspective. Mathematically, computations with different numbers and symbols are closely related, but they are not the same. For example, the addition of two fractions with versus without the same denominator will require students to follow different procedures, but this will not happen to the case of adding two whole numbers. Student computation skills with whole number addition can not simply be taken as what students can do in carrying out fraction addition. Thus, the assessment of student computation skills requires a consideration of computing with different numbers and symbols.

The second dimension is from a curriculum perspective. Curriculum, as developed and structured to outline students’ learning experiences, specifies the requirements in expected
performances including computations. Different forms of computations are included in the Chinese curriculum, including oral computation, paper-and-pencil computation, and applications in solving problems. Thus, the assessment of students’ computation skills needs to consider different forms of computations.

The third dimension is from a psychological perspective. Although computation itself is a procedural skill, students’ learning of computations now requires more than skill acquisition. Students’ knowing and application of specific computation concepts and skills are also emphasized in school mathematics in many education systems. In this study, the assessment of student computation skills is thus developed to contain such items that help measure students’ understanding and application of specific computation concepts and skills.

**Method**

**Participants**

To assess elementary students’ acquisition and development of computation skills, the study was designed to focus on the population of sixth graders who have learned all different computations required in elementary school education. The assessment was carried out in one populous province in the western part of China (i.e., less developed region in comparison with the coast region). The summary statistics of educational development in that province published in 2003 was used as a guideline in the sampling process. A stratified random sampling procedure was employed to obtain a representative sample of expected 5000 sixth graders from different elementary schools in that province.

In particular, all elementary schools in the province were first classified into 4 categories: urban, town, rural, and ethnicity. The number of students in each type of school across the entire province formed the base for selecting a proportional number of students in each category. The number of students selected from each participating school was restricted to 60 sixth graders per school (with a few exceptions as required by schools). As a result, a total of 73 elementary schools were randomly selected in 4 types of schools from 15 regions across the entire province. A total of 5100 copies of assessment instruments were distributed, and 4784 were collected.

**The Design of Assessment Instrument**

In China, there is no commonly acceptable and used instrument for assessing student computation skills. Because this study aimed to assess student computation skills with the implementation of new curriculum standards, the assessment instrument was thus designed to align with the mathematics curriculum standards in China (Zhang & Ma, 2008). In addition to the aforementioned three-dimensional framework, the design of the assessment instrument also adhered to the following principles:

1. The assessment content should cover basic knowledge and computation skills required in elementary mathematics, including whole numbers, decimals, fractions, solving simple equations, ratio and proportion;
2. The instrument should assess both students’ computational results (correctness) and their skill level (speed and flexibility);
3. The items are designed with a consideration for large-scale assessments.

The combination of these considerations led to the development of the instrument matrix that specifies content and performance requirements: (a) oral and paper-and-pencil computations in addition, subtraction, multiplication, and division with whole numbers, decimals, percent, and fractions; (b) performance dimension includes knowing, simple computation, complex and
mixed computation, computation with flexibility. Based on the matrix, a total of 105 items were developed to assess sixth graders’ computation skills that are required in elementary mathematics curriculum. Moreover, all items were designed to ask students to compute, but not multiple-choice items. The 105 items were grouped into two tests (A and B). Test A contains 35 items that are organized into four groups: oral computations, paper-and-pencil computations, mixed computations, and solving equations with all different numbers. The testing time was limited to 10 minutes. Test A was designed to assess the development of sixth graders’ expected basic computation skills. The level of sixth graders’ computation skill development is differentiated in terms of the percentage of correct computations carried out by students from different types of schools. Test B contains 70 items and completion time is also limited to 10 minutes. Because it is assumed that sixth graders won’t be able to complete all 70 computations within 10 minutes, Test B was designed to assess sixth graders’ computation competence and speed. Students’ computation performance was to be assessed through the percentage of correct computations completed.

Study Procedure

Pilot tests and revisions. To ensure the feasibility of the instruments, pilot testing was used four times. The first three pilot testings were carried out at different types of schools. The students’ performance in solving each computation item was carefully analyzed, and compared with teachers’ evaluation of their students’ expected performance. These pilot testing results were used to adjust the number of computation items included, item difficulty and presentation format. After these adjustments, the fourth pilot testing was carried out at three elementary schools with different achievement levels. The results from the fourth pilot testing helped finalize the test instruments and the procedure for testing administration.

To obtain a measure of the assessment instruments’ reliability and validity, both tests were piloted in randomly selected elementary schools. For the reliability measure, both tests A and B were piloted with a total of 439 sixth graders from nine classes in three randomly selected elementary schools. The reliability estimates (Cronbach’s Alpha) are 0.55 for Test A and 0.76 for Test B.

For the validity measure, 97 sixth graders were obtained from two randomly selected elementary schools in a big city. These sixth graders were tested two times that were two weeks apart. These students’ performance at the end of the fifth grade was also obtained and used as reference criteria. Students’ average performance from these two tests were then obtained and used to calculate criterion-related validity measure. The estimates were obtained as 0.71 for Test A and 0.66 for Test B in one school, and 0.80 for Test A and 0.65 for Test B in another.

Data collection procedure. Using the aforementioned sampling procedure (above section), all participating schools were informed about the purpose of tests and relevant instruction. The Department of Education in that province assisted the data collection to provide special permission for this survey. Because relevant instruction was included for both tests, teachers in participating schools were asked to administrate the data collection. Many graduate students majoring in education at a normal university were also dispatched to different schools to provide on-site guidance. Both tests were administrated at all participating schools within three days at the end of October, 2008.

Data analyses. Only two scores (1 or 0) were used to evaluate students’ computation. While students’ correct computation was given the score “1”, a wrong answer would lead to a score of “0”. All students’ computations were scored by a group of graduate students and teachers. And

the results (either 1 or 0) for each student were then entered into a computer and analyzed using SPSS.

Because China did not have such a large-scale assessment of students’ computation skill development, no existing criteria were available as references to help interpret students’ performance. Thus, an estimate of expected students’ performance was also carried out for Test A. In particular, about 40 experienced elementary mathematics teachers were invited as experts to estimate students’ expected performance. These teachers were selected from different schools located in urban, town, and rural areas in that province. These teachers’ estimations (in fact, many teachers actually tested their students with the instrument) were then used as a possible criterion for the interpretation of our results in this survey: For test A with a total of 35 computation items, students’ performance would be rated as “excellent” with 32-35 correct computations, “good” with 26-31 correct computations, and “satisfactory” with 21-25 correct computations. The overall average percentage of expected correct computations would be at or above 85 percent (i.e., about 29 correct computations).

Results

The survey results show that sampled sixth graders did well in their development of computation skills with the use of new curriculum materials. In general, sixth graders reached the expected performance in elementary school mathematics. The following sections are organized to provide the detailed results to answer our research questions in terms of students’ performance in Tests A and B.

Chinese Sixth Graders’ Acquisition and Development of Basic Computation Skills that are Expected in Elementary School Mathematics – Test A

The development of Chinese sixth graders’ basic computation skills. The returned Test A shows that about 97 percent of all 4784 participating students finished all computation items, and the average number of correct computations is about 31 (30.73 based on computation) out of 35 computation items (i.e., 87.8 percent). Because our sampled experts estimated that sixth graders should have an average of 85 percent correct computations for Test A, the survey result suggested that the development of sixth graders’ computation skills overall (87.8 percent correct) reached such an expectation. Table 1 shows the number (and corresponding %) of sixth graders who were correct on various numbers of computation items.

Based on sampled experts’ estimation, students’ performance on Test A would be classified as excellent with 32-35 correct computations, good with 26-31 correct computations, and satisfactory with 21-25 correct computations. Other data indicate that about 90 percent of all sampled sixth graders performed well (i.e., with 26 or more correct computations) on Test A. 7.4 percent sixth graders had satisfactory performance, whereas 57 percent of sixth graders had excellent performance (i.e., with 32 or more correct computations).

Because Test A required sixth graders to complete 35 computations in 10 minutes, it did place a high requirement on sixth graders to do all computations correctly within the limited time. There is a high percentage of sixth graders (14.4 percent) reached this excellent level of computation performance. Further analyses suggested that these students were mainly from urban or town schools with 15.2 percent and 19 percent sixth graders reached such excellence, respectively. At the same time, there were 179 (3.7 percent) students who did less than 21 computations (i.e., 60 percent items in Test A) correctly. We noticed that these students were mainly from rural schools (146 of 179).

To examine whether sixth graders have specific difficulties in computations, we took a close look at the percentages of students who performed correctly on each computation item. The quantitative results suggest that the majority of sampled sixth graders can do correct computations for all items. Although there are some variations in students’ computation performance across different computation items, it is not the case that sampled sixth graders found any computation item overwhelmingly difficult.

The computation items in Test A were developed to assess students’ basic computation skills with different types of numbers. Further analyses revealed that the development of sixth graders’ computation skills varied in terms of the types of computation skills assessed. In particular, their computation skills showed a decreasing trend from basic oral computations, paper-and-pencil computations, mixed computations, to solving equations. In oral computations, sixth graders did better with whole numbers and decimals than those involving fractions. The results suggest that sixth graders’ oral computation skills were very well developed. Their computation performance was decreased with the increased computation complexity and its combination with other relevant knowledge and skills.

The development of Chinese sixth graders’ basic computation skills across school types.

Because these sixth graders were sampled from four different types of schools, we compared their computation performance in terms of school types. Students’ performance presented a trend of decreased average number of correct computations and increased standard deviations from urban, town, ethnicity, to rural schools. The significance test results indicate that sixth graders from urban and town schools performed significantly better, and with much smaller diversity, than those from rural schools. However, there is no significant difference in students’ computation performance between rural schools and those mainly serving ethnicity populations. Further analyses also indicate that the difference between urban and town schools is not significantly different (Z=1.22, p>0.05). But there are significant differences in terms of the average number of correct computations between town schools and ethnicity schools (p<0.05), and between urban schools and ethnicity schools (p<0.01).

Chinese Sixth Graders’ Computation Speed and Correctness that are Expected in Elementary School Mathematics – Test B

The development of Chinese sixth graders’ computation speed and accuracy. The returned Test B shows that the average number of correct computations is about 36 (36.36 based on computation) out of 70 computation items (i.e., 51.94 percent). Because Test B was designed to assess students’ speed and accuracy in computations with whole numbers, decimals and fractions, it included 70 computation items and sixth graders were not expected to finish all computations correctly in 10 minutes. Nevertheless, there are still 11 (out of 4784) sixth graders who did all 70 computations correctly in 10 minutes. Moreover, if taking correct computations of 50 or more items as “excellent”, the result shows that 9 percent of sixth graders reached this level. If taking

the correct completion of half of Test B (i.e., 35 computations) as “good”, 58.51 percent (2799 out of 4784) students were able to reach this performance level. If taking the correct completion of 25 computations (more than one third of 70 items in Test B) as “satisfactory”, 88.73 percent (4245 out of 4784) students reached this level.

The development of Chinese sixth graders’ computation speed and accuracy across school types. As these sixth graders were sampled from four different types of schools, we also compared their computation performance in terms of school types. Students’ performance presented a similar average number of correct computations between urban and town schools, but a lower average number of correct computations for ethnicity schools and rural schools. In particular, rural schools had the lowest performance with the highest level of divergence among students. The significance test results indicate that sixth graders from urban and town schools performed significantly better, and with much smaller diversity, than those from rural schools. However, there is no significant difference in students’ computation performance between rural schools and those mainly serving ethnicity populations. Further analyses also indicate that students’ performance in Test B between urban and town schools was not significantly different. But there are significant differences in terms of the average number of correct computations between town schools and ethnicity schools (Z=2.315, \( p < 0.05 \)), and between urban schools and ethnicity schools (Z=2.125, \( p < 0.05 \)).

Discussion and Conclusion

Based on students’ performance in Tests A and B, it is clear that sixth graders developed their computation skills well with the use of new curriculum materials. In general, their computation performance met the expectation of elementary school education in China. In particular, over 95 percent of sixth graders had satisfactory performance in Test A computations, and 57 percent had excellent performance. Moreover, the majority of sixth graders could compute quickly and correctly. At the same time, however, there were about 3.7 percent of students who had difficulties in basic computations and they were mainly from rural schools.

While the assessment results reveal a successful story about Chinese elementary students’ computation skill development in general, it also led us to find out that students in rural schools need tremendous help. Students in rural schools not only had less satisfactory performance in computations than those in urban and town schools, but also had the highest level of divergence among rural students themselves. The results indicate the existence of a large gap in elementary mathematics education between rural schools and those in cities, which is consistent with what other mathematics educators observed and reported (e.g., Ma, Zhao, & Tuo, 2004). The consistency suggests that the gap in students’ computation performance between rural schools and those in cities revealed in our assessment is unlikely due to the implementation of new curriculum materials. Nor did the curriculum reform eliminate the pre-existent gap in mathematics education between rural schools and those in cities. In fact, the continued existence of the gap strengthens a call for further efforts to investigate possible factors contributing to the performance gap. Such investigations should help inform what possible changes in educational policy and practices may be needed to decrease such a performance gap.

It is often perceived that ethnicity students may not have equal chances to learn well through elementary school education. The results from this assessment suggest that this is not necessarily the case. Although students from ethnicity schools did not perform similarly well as the dominant ethnicity group of Han students in cities, they actually had slightly better performance than those Han students from rural schools.

The assessment also helped us to learn possible weaknesses in students’ computation skill development. It appears that students experienced relatively more difficulties when computations were related to the use of computation concepts and properties. The results suggest that there is plenty of room for improving students’ computations with more training in thinking and the use of computational properties. As there are also some students who exhibited very strong performance in computations, the results suggest the need to further understand what may help those students develop strong computation skills. Learning from successful students’ performance and related contributing factors can help inform possible instructional changes to improve other students’ computation skill development.

At the same time, because the results are also restricted to students’ computation performance in this assessment, much more research is needed to examine possible connections between students’ computation performance and their mathematical performance in other aspects such as problem solving. Some other questions have also emerged that need further research efforts in the future. For example, how may students’ computation skills relate to the development of mathematics competence in the future? To what extent may the development of students’ computation skills be facilitated or hindered by the new curriculum materials? The findings from this survey not only show the unique value of conducting a large-scale assessment of students’ mathematical performance to inform the status of educational development with current policy and practices, but also serve as a starting point for developing systematic and in-depth education studies of school mathematics.

Leung, F. K. S., & Li, Y. (Eds.) (2010). Reforms and issues in school mathematics in East Asia – Sharing and understanding mathematics education policies and practices (pp. 23-45). Rotterdam, the Netherlands: Sense.
This study utilized teacher’s analysis of student work to reveal teachers’ equity pedagogy perspective. Twenty teachers participated in the study, providing written narrative responses for analyses. Data were coded using research-based equity pedagogy codes, intended to reveal the nuances of the particulars of equity pedagogy. Results indicate that teacher change in terms of equity pedagogy may be identified in ways that allow the mathematics teacher educator and the mathematics education researcher to support the teacher in improving upon particular elements of equity pedagogy. Additional themes emerged which have further implications for pedagogy.

Introduction

The vision of mathematics education, put forth in the NCTM Principles and Standards (2000) captures research-based directional goals of the field in terms of the quality and type of mathematics that should be taught; experiences students should have; the role of the teacher; expected outcomes in terms of student mathematical knowledge, disposition toward mathematics, and fluency with the mathematical processes. The literature of the field supports that the learning with understanding that is envisioned in the Standards and in the work of mathematics educators across the field is a more complex endeavor than merely knowing the “how to do” of mathematics (Heibert et al., 1997). Scholars support this notion by proposing a view of mathematics understanding that includes a broad and integrated interpretation of procedural and conceptual knowledge (Baroody, Feil, & Johnson, 2007; Star, 2005). Toward the realization of goals of learning with understanding, we recognize the role of the teacher in supporting students’ learning mathematics in deep and meaningful ways, in terms of teacher knowledge and teacher pedagogical decisions (Ball, 1993; Ball, Lubienski & Mewborn, 2001; Boaler, 2002; Hill, Rowan & Ball, 2005); and that teachers must deliver high-quality instruction and have ambitious expectations for all students.

We cite these elements of mathematics pedagogy not to suggest that they include of all that the field has to offer. But these elements are examples of what leads to the goal to have all students learn mathematics, and as such are also examples of elements of an equity focus in mathematics pedagogy. But, like learning mathematics, knowing and implementing equity pedagogy is a complex endeavor supported by a rich literature where equity scholars have generated theory and empirical research delineating the importance and potential of equity pedagogy. One of many definitions for equity pedagogy comes from Banks (1996), who defines equity pedagogy as a set of practices that utilizes strategies and instruction that reflect the cultural practices and perspectives known to impact student learning. Given the existence of definition, the abundance of literature supporting elements of equity pedagogy, and the collective set of practices that result from work in the field, we propose that the time is right to consolidate

---

these practices into a tool to help us identify and refine elements of practice, and move practice forward to better support equity goals. In the study we report in this paper, we explore a way to identify and describe elements of equity pedagogy; and we use these descriptions to suggest ways to move a practice toward a more equitable mathematics pedagogy.

**Theoretical Framework**

Over the years, equity has meant many things to many people (Gutiérrez, 2002). A general definition of equity has been given as involving “our judgments about whether or not a given state of affairs is just” (Secada, 1989, p. 68). According to Lipman (2004), equity means “equitable distribution of material and human resources, intellectually challenging curriculum, educational experiences that build on students’ cultures, languages, home experiences, and identities; and pedagogies that prepare students to engage in critical thought and democratic society” (p. 3). The NCTM (2000) names equity as one of its guiding principles, and states, “Equity does not mean that every student should receive identical instruction; instead, it demands that reasonable and appropriate accommodations be made as needed to promote access and attainment for all students” (p. 12).

Researchers and theorists generate a literature around these and additional characteristics to define a mathematics pedagogy that supports equity. For example, Banks (2003) contends that equitable pedagogy is involved when teachers employ teaching methods that accommodate the differences of diverse students to stimulate academic achievement. This is mainly concerned with interactions between teachers and students and requires a mutual respect in every aspect of instruction. In the mathematics classroom, when teacher-student relationships are fluid and equitable, students learn to collaborate, share tasks, accept criticism, alternate opinions, respect others, construct their knowledge, and be responsible for each other (Dornoo, 2010).

Researchers argue that using a variety of pedagogical strategies such as problem posing, integrating language arts into the teaching of mathematics, small-group work, application of mathematics to everyday real-world contexts that utilizes explicit talk about mathematical meaning, reasoning and mathematical practice, project-based learning, current event analysis and application to mathematics will arouse students’ interest (e.g., Boaler, 2002; Delpit, 1988; Erchick, 2002; Ladson-Billings, 1995, 1997; Learning Mathematics for Teaching, in press). Another important aspect in providing equity pedagogy is to have and maintain high expectations for all students. Moses and Cobb (2001) posit that there is a very high correlation between teacher expectations and student achievement. Further, an equity classroom should be an active classroom in which students are given the opportunity to share their ideas with other students as well as with the teacher. It should be a classroom with a curriculum that utilizes real world examples in specific ways; and teaching that efficiently uses instructional time, emphasizes student effort, sends students the message that everyone can do the work, and that arranges for students to work autonomously (Boaler, 2002; 2009; Delpit, 1988; Dornoo, 2010; Erchick, 2002; Ladson-Billings, 1995, 1997; Learning Mathematics for Teaching, in press).

According to the NCTM (2000), teachers need to select activities that grow out of real-world problems relevant to students. Teachers with strong mathematics content and pedagogical knowledge understand the value of problem-solving activities on any mathematics topic, since it “offers opportunity for rich insight into students’ thinking processes and levels of understanding” (Frost & Dornoo, 2006, p. 222). Pedagogy strategies enacted in the mathematics classroom should adopt the pedagogical theories and practices that use mathematics not only as an analytical tool but also as an opportunity for commitment and/or capacity to develop a deep

---

conceptual understanding of mathematics (Dornoo, 2010). Finally, Jo Boaler “argues that investigations into equitable teaching must pay attention to the particular practices of teaching and learning that are enacted in classrooms (italics in original)” (2002, p.239). Thus, the tool we propose and utilize in this study can help identify and draw attention to the particular practices of equity pedagogy, and the nuances of how these practices are apparent in one’s pedagogy and the particular practices form the set of analysis codes we use in our study.

Methodology

Participants and Context of the Study

Participants in this study are certified or licensed teachers credentialed to teach in grades kindergarten through middle school in Ohio. The teachers work in schools enrolled in the Mathematics Coaching Program (MCP) (Brosnan & Erchick, 2007), a program primarily focused on supporting the lowest achievement schools in the state. These schools are almost exclusively urban and rural schools, and share common demographics of traditionally underrepresented groups in mathematics. Thus the equity perspective of this research is an appropriate one to inform the work of the MCP and to contribute to the work on equity and diversity initiatives.

Data Collection

In this study, twenty teachers provided responses to 10 selections of student work, giving explanations of student thinking about mathematics and suggestions for teacher instructional decisions for each selection. Participating teachers responded at the beginning and at the end of the academic year, responding to the same items both pre and post. The number of teacher participants, responses to student items, and the pre- and post-study data collection schedule resulted in 400 qualitative responses for analysis. Teachers submitted written responses in hard copy, and researchers and their support team entered the data into an electronic document.

Data Analysis

We analyzed teachers’ extended responses by assigning one or more equity pedagogy codes as listed in the abbreviated codebook of Table 1 to each of the content and pedagogy responses. Note that each equity code was designated as an (E)xample or (N)onexample, thus generating 20 codes available for our analysis. Multiple researcher reviews of sample sets of data, collaboration on coding assignments, and comparisons to coding by an outside reviewer helped reach inter-rater reliability of goals in the analysis. Equity codes are supported in the literature and the extended code book provided the research team with narrative description, literature justification, and examples for each code. In addition to interpretation of the qualitative coding, we also conducted a numerical analysis of the resulting codes.

As an example of the research support generated for each equity code, consider the ETR code in Table 1 used to code narrative that represents the ways in which a teacher “Explicitly talks about, or addresses ways of reasoning”. Ladson-Billings (1997) describes a desired pedagogy that is in contrast to a pedagogy of poverty. The teacher in Ladson-Billings’ example questioned students, made suggestions, and used questioning to push students’ thinking. She made reasoning and the students’ communication of it a responsibility of everyone in the classroom. Likewise, Delpit (2006) offers precepts to transform urban students’ experiences. One of her precepts is to demand the critical thinking important for student learning. Through critical thinking students come to experience multiple solutions and understand that mathematics is not a
fixed field of knowledge. Both scholars’ work supports the notion of expectations of reasoning, and that teachers explicitly pursue these expectations with their pedagogy.

The ETR equity pedagogy code also provides us examples of equity pedagogy coding. For a data point to be assigned an ETR code, it reveals teacher actions toward and/or expectations of student reasoning, elements of argument and proof, and/or thinking. For example, on one item used to generate participant responses, participants analyzed student responses to the problem: “Bobby was given the problem 17 − 9 = ____ and solved it as follows: 17 − 9 = 17 − 10 − 1.” In their analysis, participant responses revealed a reasoning emphasis in their analysis of the student’s work. Responses of “Bobby might know that 9 rounds to ten and it is easier to subtract 10 than 9. He also might think that since 10 is one more than 9, you need to subtract 1 from 10 to get 9” and “Bobby knew that 10-1 is the same as 9, so he thought that by making a nine on each side he would get the same answer” show how teacher participants considered the student’s potential reasoning in their analysis.

Another example comes from a participant response to the following item: How can we arrange 12 tables, with no spaces in between, to allow the most chairs to be placed around the arrangement? The item included a student response that “Melva said that the most would be 24 chairs” and participants commented on the student’s mathematical thinking. Participants’ responses explaining that Melva “realized that if each table was flanked by a table on each side that there would only be two sides left to sit at but she forgot about the extreme ends,” “understand that all tables must have at least 2 open sides, that tables surrounded by other tables cannot have chairs,” “is confused about area and perimeter” reveal participant lenses to be focused on the student’s reasoning.

Results

We present our findings first in terms of the overall results, then with more details in two teacher profiles, and finally with a comment on emergent results. Andy’s and Chris’ (pseudonyms) profiles provide particular examples from the data for consideration of implications for equity pedagogy and the emergent results provide additional insights.

Overall Results

Pretest data from the group of 20 participants collectively generated 393 equity code examples and 155 nonexamples. Posttest data generated 408 equity code examples and 134 nonexamples.
nonexamples. This small shift in each of examples and nonexamples was positive but not overwhelmingly so. In addition to considering the total pre and post counts, other organizations of the results are of interest. For example, of the 20 possible codes, 6 were represented more than 30 times in the data set (See Table 2). Of those 6, that 5 were examples and 1 was a nonexample, paired with the improvement from pre to post, speaks well of the teacher participants and their growth. Similarly, of the 20 codes, 8 were represented fewer than 10 times in the data set, and more than half of those were nonexamples, again speaking well of the teacher participants.

**Alex’s Equity Pedagogy Profile**

Alex’s profile is an example of a consistently equitable perspective (see Table 3). Where a participant may have as few as 9 equity examples, and as many as 15 equity nonexamples, Alex’s profile includes a high number of equity examples and very few nonexamples. In the multiple data collections, Alex’s responses generated 32 equity examples in one set of responses, and no nonexamples, with half of the equity examples being ETR (Explicitly Talks of Reasoning).

Alex wrote of Mike’s alternative algorithm in the following problem:

Students are asked to solve the word problem: *Candy has 105 jelly beans, she eats 18 of them, and how many does she have left?* (The teacher walks around and sees a variety of answers, including Mike’s to the right.)

Alex’s analysis included that “Mike can see that 105-15=90. That is 3 less than the 18 he is subtracting. So 90-3=87. Mike doesn't need to do the traditional method with this kind of knowledge.” We code this as an ETRE because of teacher’s recognition of and appreciation of the student’s reasoning. Thus we see the teacher as reading the student work through a reasoning lens. Alex also wrote of the student Melva’s response to the following problem:

The teacher asked the class to respond to the following problem: *How can we arrange 12 tables, with no spaces in between, to allow the most chairs to be placed around the arrangement?* Melva said that the most would be 24 chairs. Alex responded that “Melva may have pictured two people at 12 tables and simply multiplied to equal 24. If Melva drew a picture and put chairs all around, [s]he would see the maximum would be 26 chairs” indicating again a reasoning lens in interpreting the student response.

That Alex’s equity pedagogy examples fell so predominantly in the ETR category indicates a kind of modus operandi, a characteristic of this particular teacher that seems to have become a
habit of being in practice. Additionally, even though there was some very slight change from the pretest to the posttest, Alex’s perspective remained consistent throughout, with most instances being the same equity perspectives from pre to post, and about the same numbers in each.

**Chris’ Equity Profile**

Chris’ profile is an example of a teacher with a less consistent lens than Alex’s consistent ETR lens, and revealing a broader range and more equal distribution of equity lenses across the data set (see Table 3). In Chris’ profile, it is in the change from pretest to posttest that we take notice. First, the kinds of equity codes generated, from both example and nonexamples, changed from codes in 9 categories in the pretest to codes in 12 categories in the posttest. Pretest codes showed fewer kinds of codes but larger number of occurrences (4-7); posttest codes showed a greater number of kinds of codes, but fewer occurrences of each (1-3). Finally, the change from pretest to posttest showed an increase in the number of nonexamples, a situation that suggests a step back of some sort. However, that there were more categories also suggests a broadening perspective. With the growth to more perspectives, it is reasonable that some, less practiced, may start as nonexamples for Chris, and over time develop to equity pedagogy examples.

One category where Chris added 2 equity pedagogy examples in the posttest was a category that had no occurrences in the pretest, the Quality of Instruction Time (IT) category. Many data points were assigned multiple codes, and these 2 samples from Chris’ responses are a case in point. Consider this problem in the study: Miss Jones put the following picture on the overhead and asked her students to identify all of the rectangles. Jose picked A, B, and D.

Chris’s response was “Proving a concept is invaluable for students. It can help students understand any misconceptions they may have” followed a suggestion to have students make their case for what figures were indeed rectangle, and why. The response was coded as ITE because of the perspective of using instructional time for a thoughtful and rich experience, thus making it an equity pedagogy example. But the data point was also coded with an ETLE, again an equity pedagogy example, but this one for Explicit talk about the meaning and use of mathematical language. With arguments made by students centering on the definition, the language would be a critical element in the proofs and misconceptions noted by the participant.

Chris’ equity pedagogy examples were distributed across many different equity pedagogy codes indicating a number of things. It may indicate either a range of perspectives or a lack of
focus. The increased number of nonexamples in the posttest could, as alluded to earlier, indicate the initial stages of a broadening perspective, where development will improve and strengthen the categories; or it could mean a regression to less equitable perspectives.

Additional Emergent Themes

Qualitative analysis of narratives also revealed an emergent theme suggesting new questions in this work. Consider two examples: Example one concerned teacher analysis of student work on a graphical representation problem. The graph had no labels or numbers, and the student was asked to write a story to match the graph. The student explanation suggested a representation of distance against time, but every teacher in the sample of 20 viewed the graph as representing only speed against time; hence no teacher interpreted the student’s choice as correct. Example two concerns teacher responses on a probability problem. Participants who responded with thorough explanations usually revealed an understanding of the mathematics; but most responded with responses that were clearly incorrect or with what we might call “non-answers” circumventing the topic and suggesting little to no knowledge of the content. In any case, most did not know the mathematics well enough to question students through suggested probability experiments or help students come to a mathematically valid understanding.

Whether the graphing case represents a lack of content knowledge or represents a limited view of what graphs can represent is not clear; that few participants understood the probability content is better established in the data. In any case, a teacher with a lack of knowledge or a limited view of the content cannot hear, analyze, utilize or even allow students’ explanations; misses equity pedagogy opportunities when the student is providing a diverse perspective to the lesson; and does a disservice to the student who is misdirected as being incorrect. These conditions lead to mis-taught mathematics, an equity issue by any standard.

Closing Discussion

We find the most significant part of this work to be how results of coding can assist mathematics teacher educators and mathematics education researchers in both identifying the nuances of the particulars of a practice of equity pedagogy, and provide guidance to support teacher change. Consider that we see Chris has 3 AUE and 1 AUN. For that AUN, one could suggest a slight adjustment to the instruction that will change the AUN to an AUE. So, for the AUN, a teacher is directing the student on how to do the work, thus taking away the student’s opportunity for autonomous learning, a simple adjustment to pursue explanation from the student and expect further attempts, would change the nonexample to an example.

Addressing adjustments to increase particulars of equity pedagogy also could mean small but significant change in equity pedagogy. And for those teachers who believe that substantive change requires curriculum or resource changes over which they might have no control, or additional activity to add to their work, these results and this tool may help them see pedagogy as a place where sometimes seemingly small and subtle actions can make a difference for students.

Endnotes

1. Equity pedagogy codes adapted from Learning Mathematics for Teaching (in press).
2. The project’s full codebook includes theoretical and empirical warrants to support each of the analysis codes.

In this study we examine the relationship between student mathematics learning and manipulative use for a national sample of elementary-aged Hispanic students. Data for this study were drawn from the ECLS 1998/2004 database (NCES, 2006). Further, students’ home-language and socio-economic status were considered as possible moderators of this relationship. Results indicate that there is a positive relationship between manipulative use and elementary students’ mathematics learning; however, home-language and SES were not found to explain significant variation in this relationship.

Introduction

The National Council of Teachers of Mathematics (NCTM, 2000) states that “all students, regardless of their personal characteristics, backgrounds, or physical challenges, must have opportunities to study—and support to learn—mathematics” (NCTM, 2000, p. 12). Therefore, English Language Learner (ELL) students should not be impaired because of language (Khisty, 1995). Many ELL students encounter learning situations in their classrooms in which their limited language proficiency impedes their ability to succeed in mathematics. However, teachers’ use of multiple instructional strategies in the classroom may help these students reduce cognitive demand due to their limited language proficiency (Herrell, 2000). Several educators have proposed the use of mathematical manipulatives as a strategy to help ELL students’ mathematics learning process (Lee & Jung, 2004; Lee, Silverman & Montoya, 2002), which may help to reduce cognitive demand (Herrell, 2000). As Lee and Jung (2004) suggest, “the focus is on the increased use of manipulatives… to facilitate communication between the teacher and student, helping the student to access key conceptual ideas without being dependent on the language” (p. 271).

However, few studies have analyzed the impact of manipulative use on ELL students’ mathematics performance. Posadas (2004) studied the effects of manipulative use and visual cues on ELLs’ mathematics learning. Sixty-four Hispanic students who had failed at least four mathematics objectives of the Texas Assessment of Academic skills (TAAS) participated in this study. Students were separated into three groups: two treatment groups (manipulatives or visual cues) and one control group. The objectives assessed in the study were multiplication, division and estimation strategies to solve problems. One day per week, for 5 weeks, students worked on a specific objective, and during instruction either manipulatives or visual cues were used for either one of the treatment groups. Participants’ performance was measured one time before treatment and once every week of treatment. Posadas found no significant differences between the treatment groups and the control group performances. One possible reason for these results, as stated by Posadas, was the short period of time that students used the tools. According to Sowell (1989), students need to use manipulatives for a period of time of at least a year in order for their performance to improve. No studies analyzing the use of manipulatives for ELL students for that period of time were found.
In the current study, we used a national sample of elementary-aged Hispanic students to analyze the relationship between mathematics learning and manipulative use. In particular, the aim of this study is to answer the following questions:

1. Is there a relationship between elementary-aged Hispanic students’ manipulative use and mathematics learning?
2. Does student home language and SES moderate the relationship between elementary-aged Hispanic students’ manipulative use and mathematics learning?

**Methods**

**Data**

This study used the Early Childhood Longitudinal Study 1998/2004 (ECLS Kindergarten class of 1998-1999) database from the National Center for Education Statistics (NCES, 2006). The ECLS was designed to collect data from students in Kindergarten during the academic year 1998-99 and follow these students through eighth grade. The data set contains seven waves of data for the participants: two times during the Kindergarten year, two times during first grade, and one time during each of the third, fifth and eighth grade years. For this study, data from four waves was used to examine the longitudinal growth rates in mathematics achievement of students during their elementary school years. The four waves represent (a) baseline measure, Kindergarten Spring semester 1999; (b) First follow-up, first grade Spring semester 2000; (c) Second follow-up, third grade Spring semester 2002; and (d) Third follow-up, fifth grade Spring semester 2004.

This data included a total of 10,673 students. Of these students, about 18.1% of them were Hispanic. This sample represented a total of 1,927 students. We chose to analyze the data of Hispanic students because if the home language for these students is different from English, it is likely to be the same across the group, i.e., Spanish. In addition, NCES provides Kindergarten and First grade students with the opportunity to use a Spanish version of the assessment instruments in the case of limited English proficiency. Therefore, for this group, students’ mathematics scores were less likely to be affected by the language of the assessment instrument and more likely to reflect students’ true mathematical understanding.

**Measures**

**Mathematics achievement.** The dependent variable was mathematics achievement scores. The mathematics assessment included items related to topics such as number sense, properties and operations, measurement, geometry, spatial sense, data analysis, statistics and probability, patterns, algebra and functions; and the items involved conceptual and procedural knowledge and problem solving (NCES, 2006).

Students’ English proficiency was tested at Kindergarten and First grade by using the Oral Language Development Scale. Students who did not have adequate English proficiency and whose home language was Spanish were assessed using a Spanish version of the instrument (NCES, 2006). No translated version of the instruments were used for Third or Fifth grade data collection as it was felt that most students show English proficiency after First grade (NCES, 2006).

Using item response theory (IRT) techniques, the ECLS staff adjusted test scores to make them comparable across the different waves (i.e., grades K, 1, 3, 5). In this study, the IRT scores were used to measure growth in mathematics knowledge, that is, mathematics learning. We
created a linear growth trajectory for each student using four achievement scores from each student. Each student’s linear trajectory was created by regressing student’s achievement on time. The slopes of these lines represent the rate of change over time or learning.

**Independent Variables.** The primary independent variable was manipulative use. In each fall semester data was collected on the frequency that students used manipulatives in their mathematics classroom. At the Kindergarten and First grade level, two questions measuring this frequency were used. One item asked about student’s use of geometric manipulatives, and the other asked about student’s use of counting manipulatives. The exact teacher prompts were: *How often do children in this classroom do each of the following math activities: (a) work with geometric manipulatives, and (b) work with counting manipulatives.* These items were rated on a 6-point Likert scale (1 = *Never*, 2 = *Once a month or less*, 3 = *two or three times a month*, 4 = *once or twice a week*, 5 = *three or four times a week*, 6 = *daily*). The maximum value of these two items was taken as a students’ measure of frequency of manipulative use. For example, if a teacher indicated that a student used geometric manipulatives *once or twice a week* and indicated that the student *never* used the counting manipulatives, in total the student was using manipulatives in mathematics instruction at least once or twice a week.

For the third and fifth grade level, frequency using manipulatives was measured using a 4-point Likert scale (1 = *Almost every day*, 2 = *Once or twice a week*, 3 = *Once or twice a month*, 4 = *Never or hardly ever*). The teacher prompts were: *How often do children in your class engage in the following: work with manipulatives e.g., geometric shapes.* Because the teachers were asked about their students’ manipulative use in a different way at different grades, values for each grade were recoded to create comparable measures across all four grades. The new manipulative use variables were coded as low, medium and high frequency use. The initial values and new values are presented in Table 1.

*Note. The new description is based on a combination of the original K-1 and 3-5 descriptions.*

Student background variables came from the student questionnaire, including students’ socio-economic status (SES), and home language (English or non-English). During Kindergarten Fall semester, student’s home language was identified by asking parents if languages other than English were spoken at home. For this study, home language was coded as *non-English* = 0 and *English* = 1.

In this study, we wanted to examine growth in students’ mathematics learning through their elementary school years. Therefore, because we considered the first wave as the starting point for that growth, we coded the grade levels as 0 = *Kindergarten*, 1 = *First Grade*, 3 = *Third Grade*, 5 = *Fifth Grade*. Because no data were collected in second and fourth grade, it was necessary to code grades to reflect the appropriate time between data points.

---

Analysis

The analysis focused on the relationship between manipulative use and the mathematical learning of Hispanic students throughout their elementary school preparation; and how this relationship was potentially moderated by student’s home language and SES. A two-level hierarchical linear individual growth-curve model (HLM) (Raudenbush & Bryk, 2002) was employed to examine the relationship between manipulative use and growth in mathematics achievement at the elementary school level. Level 1 of our model was a set of separate linear regressions, one per student. These equations regressed students’ four mathematics achievement test scores on time measured according to the grade (Kindergarten = 0, First grade = 1, Third grade = 3, and Fifth grade = 5), frequency of manipulative use (LOW, MEDIUM, and HIGH), and interactions between time and frequency of manipulative use.

In this study, three dummy variables for manipulative use were used. In order to maintain non-collinearity in the regression equation it was necessary to include only two of these variables in the model. In this case, LOW was not included in the model and thus the effects of MEDIUM and HIGH are in comparison to LOW.

**Level 1 (growth model).** The first level involved the within-student growth in mathematics achievement scores, which was specified by the variables of time (grade), two frequency variables (MEDIUM and HIGH) and the interaction between frequency and grade; LOW was used as the comparison group and thus not included in the model. With this model specification, we examine the effects of manipulative use and its interaction with grade. The linear level-1 or within subjects equation was specified as:

\[
Y_{ij} = \pi_{0i} + \pi_{1i} \text{grade}_{ij} + \pi_{2i} \text{MEDIUM}_{ij} + \pi_{3i} \text{HIGH}_{ij} + \pi_{4i} (\text{MEDIUM}_{ij})(\text{grade}_{ij}) + \pi_{5i} (\text{HIGH}_{ij})(\text{grade}_{ij}) + e_{ij}
\]

Where \(Y_{ij}\) is the mathematics achievement score for student \(i\) at time \(j\); grade indicates the grade at which the measure was collected (grade values are 0, 1, 3, and 5); and MEDIUM\(_{ij}\) and HIGH\(_{ij}\) indicates whether the frequency of manipulative use for student \(i\) at time \(j\) was MEDIUM, HIGH or neither of them with values of 0 or 1. The parameter \(\pi_{0i}\) indicates the initial mathematics achievement for student \(i\) when time is zero (i.e., Kindergarten) and the use of manipulative was LOW.

The parameter \(\pi_{1i}\) is the coefficient for the time variable and represents the rate of growth (i.e., mathematics learning) for student \(i\) throughout the elementary school grades. As suggested by Ma and Wilkins (2007), it specifically represents the “natural growth” reflecting cognitive maturity of students during elementary school. The parameters \(\pi_{2i}\) and \(\pi_{3i}\) are the coefficients for the medium and high manipulative use frequency variables and represent the overall main effect of those variables on mathematics achievement (these terms are not pertinent to the present study but are included in the model to account for possible variance due to the main effects). The parameters \(\pi_{4i}\) and \(\pi_{5i}\) are coefficients of the interaction between time and medium and high manipulative use. Different from natural growth, they represent the added growth due to medium and high manipulative use, respectively, compared to low manipulative use. To better understand these parameters, assume that student \(i\) at time \(j\) has used manipulatives almost daily, that is, HIGH=1 and MEDIUM=0. In this case, the model at level 1 simplifies to:

\[
Y_{ij} = (\pi_{0i} + \pi_{3i}) + (\pi_{1i} + \pi_{5i}) \text{grade}_{ij} + e_{ij}
\]
In this way, and similar to the models presented by Ma and Wilkins (2007), we can identify the parameters related to growth in mathematics achievement, \( \pi_{1i} \) and \( \pi_{5i} \). This model, in addition to allowing us to study the growth in mathematics achievement throughout the elementary school years, permits us to investigate the effects of manipulative use on that growth. In this case, \( \pi_{1i} \) is the parameter indicating the natural growth or growth due to maturity and \( \pi_{5i} \) indicates the growth due to using manipulatives more often. If \( \pi_{5i} \) is statistically significant, it means that using manipulatives more often (compared to students using manipulatives less) adds significantly more to growth in mathematics achievement in addition to the natural growth during the elementary school years. Similarly, the parameter \( \pi_{4i} \) is related to the growth added by medium manipulative use compared to low manipulative use. The term \( e_{ij} \) is the error term. In HLM models such as the one in this study, the \( e_{ij} \)'s are assumed to be independent and normally distributed with mean zero and variance \( \sigma^2 \) (Hedeker, 2004).

**Level 2 (between-student model).** At the second level we intend to model the between-student variability in the growth terms. We include home language (HOMELANGUAGE) as a potential moderator of mathematics growth. In addition, SES is included as a statistical control. The second-level model, or between-student equation, was specified as:

\[
\begin{align*}
\pi_{1i} &= \beta_{10} + \beta_{11} \text{SES}_i + \beta_{12} \text{HOMELANGUAGE}_i + r_{1i} \\
\pi_{4i} &= \beta_{40} + \beta_{41} \text{SES}_i + \beta_{42} \text{HOMELANGUAGE}_i + r_{4i} \\
\pi_{5i} &= \beta_{50} + \beta_{51} \text{SES}_i + \beta_{52} \text{HOMELANGUAGE}_i + r_{5i}
\end{align*}
\]

Where \( \beta_{10} \), \( \beta_{40} \), and \( \beta_{50} \) are slope parameters for growth, and interaction between grade and the two manipulative use variables (MEDIUM and HIGH), respectively. The parameters \( \beta_{11} \), \( \beta_{41} \), and \( \beta_{51} \) represent the effect of the variable SES on the coefficients \( \pi_{1i} \), \( \pi_{4i} \), and \( \pi_{5i} \), i.e., the overall growth and the two interactions between manipulative use and growth, respectively; the parameters \( \beta_{12} \), \( \beta_{42} \), and \( \beta_{52} \) represent the effect of the variable HOMELANGUAGE on the coefficients \( \pi_{1i} \), \( \pi_{4i} \), and \( \pi_{5i} \) respectively; and the values \( r_{1i} \), \( r_{4i} \), and \( r_{5i} \) are random individual-specific errors (Hedeker, 2004). Statistically significant values for the HOMELANGUAGE variable indicate that home language is a moderator of growth, that is, change in student achievement over time is different due to student home language (English and non-English).

The statistical analysis, in this study, has several steps. First, a base model was estimated in which no variables were included at the second level. The goal of this first step was to model the relationship between manipulative use and mathematics learning. Second, the variables SES, and HOMELANGUAGE were included in the second level model. With this model, we wanted to explain the variability in Hispanic students’ mathematics achievement growth and the interaction between manipulative use and growth.

**Results**

The longitudinal model used in this study allowed us to identify the added growth in mathematics achievement due to manipulative use (see Ma and Wilkins, 2007). Results from estimating the base model (see Table 2) indicate that growth was statistically significant for students, adding 14.19 points to mathematics achievement annually \( (p<0.001) \). Added growth due to MEDIUM and HIGH manipulative use compared to mathematics learning growth due to LOW is also shown in Table 1. Added growth due to MEDIUM and HIGH manipulative use was statistically significant and greater than the added growth due to LOW manipulative use. On average, MEDIUM manipulative use added 1.12 points \( (p<0.001) \) to mathematics achievement,
and HIGH manipulative use added 4.14 points \((p<0.001)\) to mathematics achievement, annually. Comparing growth added by MEDIUM manipulative use to growth added by HIGH manipulative use, we found that HIGH manipulative use added significantly more growth than MEDIUM manipulative use \((p<0.05)\). To compare the added growth due to MEDIUM and HIGH manipulative use, we calculated the 95% confidence intervals for the two parameter estimates using the largest standard error \((SE = 0.49)\). The confidence interval for added growth due to MEDIUM manipulative use was from 0.14 to 2.1; and for added growth due to HIGH manipulative use the interval was from 3.16 to 5.12. The lack of overlap between these two intervals indicates a difference between the effects.

Next we used student level variables to model the variability in mathematics learning \((\pi_{1i})\), added growth due to MEDIUM manipulative use \((\pi_{4i})\) and added growth due to HIGH manipulative use \((\pi_{5i})\). The mathematics learning variable was allowed to vary randomly in the model, and the parameters related to growth due to manipulative use were fixed. After controlling for SES and home language, mathematics learning growth due to MEDIUM manipulative use remained statistically significant \((\beta=14.59, p<0.001)\) and increased compared to the base model (see Full model on Table 2). SES was found to explain a significant amount of variability in mathematics learning. That is, there is a 0.88 increment in mathematics growth per standard unit increment in SES. Therefore, students with high SES tend to have a higher growth rate in mathematics achievement. However, home language was not found to explain variability in students’ mathematics learning, indicating that students with different home languages have similar achievement growth.

*Note.*** \(p<0.001\), ** \(p<0.01\). Base Model in this table can be read as indicating the average growth in mathematics achievement due to maturity (grade) and manipulative use (MEDIUM and HIGH). Final Model in this table can be read as indicating the growth due to maturity or Medium or High manipulative use after controlling for SES and home language.*

---

Considering growth due to manipulative use, after controlling for SES, and home language, mathematics learning growth due to MEDIUM manipulative use remained statistically significant ($\beta=1.05, p<0.01$). Mathematics growth due to HIGH manipulative use also remained statistically significant ($\beta=4.34, p<0.01$) and increased from the base model (see Full model on Table 2 above). SES and home language were not found to explain a significant amount of variability in added growth due to MEDIUM or HIGH manipulative use. Therefore, students using manipulatives between two and eight times per month (MEDIUM) have similar growth due to manipulative use, regardless of SES or home language. Similar results were found for students using manipulatives almost every day (HIGH).

**Discussion**

The purpose of this study was to examine the relationship between elementary school students’ mathematics learning and manipulative use. Further, we wanted to examine home language as a potential moderator of this relationship. Using the ECLS data, we examined this relationship using a hierarchical linear growth curve model with a national sample of Hispanic students. By using multiple measures of achievement collected over time we were, in effect, able to model student learning as change over time. In this way, we were able to truly examine the relationship between manipulative use and mathematics learning as opposed to the relationship between manipulative use and achievement measured at a single point in time.

From the longitudinal analysis, in general, we found that there is a positive relationship between manipulative use and student mathematics learning for elementary school students. SES and home language were not found to moderate the relationship between manipulative use and mathematics learning. Based on this result, we conclude that manipulative use can potentially help all students independent of their home language. Students whose home language is not English were found to have similar gains in achievement when compared to their English home language peers. Language proficiency can be a limitation for mathematics learning for ELLs (Khisty, 1995), however, manipulative use has been proposed to help ELLs with their learning in mathematics classrooms (see Cummins, 1998; Herrell, 2000; Lee, Silverman & Montoya, 2002, Lee & Jung, 2004). The findings from this study seem to support this proposal as no differences in mathematics learning growth due to home language were found.

From the previous discussion of the results, we can draw two main conclusions from this study. First, there is a relationship between manipulative use and students’ mathematics learning. Student mathematics learning tends to be higher for students who use manipulatives more often during their elementary school years. This result is inconsistent with the results reported in Posadas (2004). However, different from Posadas, the present study investigated manipulative use over a long period of time, which is necessary in order to observe mathematics learning (Sowell, 1989). Second, home language of Hispanic students was not found to moderate this relationship indicating that the relationship between manipulative use and mathematics learning does not vary because of language spoken at home. This finding potentially indicates that manipulative use helps all students learning regardless of their home language; and further, that language issues in mathematics classrooms may be reduced when manipulatives are used.

ON THE USE OF LOCALE IN UNDERSTANDING THE MATHEMATICS ACHIEVEMENT GAP

Robert Klein
Ohio University
kleinr@ohio.edu

Jerry Johnson
Ohio University
johnsoj9@ohio.edu

This paper reports on a multilevel regression analysis using the complete 2000 Kentucky CTBS-5 dataset (nearly 50,000 ninth grade math scores) on individual- and school-level variables representing sex, ethnicity, socioeconomic status (SES), and school size. Significant mathematics achievement gaps emerge for most areas and interactions. The same variables are then compared across “rural” and “non-rural” categories. Findings include that rural schools erase the gender gap and diminish the race gap and poverty gap in math achievement for all students combined, and erase the influence of low SES on mathematics achievement for females and minorities.

Introduction

“Achievement gaps” in school subjects, but most significantly, in mathematics, are the focus of much political and professional discourse (White House, 2010; NCTM, 2005). These gaps are observable differences in assessment scores between two disjoint subsets of the population. Most often, gaps are identified according to socially-ascribed characteristics of the student, such as sex and race or ethnicity; or according to the contextual characteristics of the school and/or community including: aggregated gender, ethnicity, and socio-economic status (SES). School-size is used less frequently as a contextual characteristic despite its importance to structuring social aspects of schooling. Locale-type (loosely: rural, urban, suburban) is used rarely as well, though when it is, it is often coded by urban vs. non-urban.

The exclusion of locale in investigating achievement gaps is a fatal omission given that locale reflects one of the principal ways that society and culture is demarcated—by choice of place of residence. People tend to self-sort into locations in service of and in preference to differing social structures (sense of belonging, access to recreation and fitness opportunities, etc.) (Bishop, 2008). When locale is used as a frame for examining achievement gaps, such studies often focus on “urban” locations in ways that unnecessarily conflate location with race and SES (“urban,” “Black,” and “poor” become nearly synonymous) (Johnson & Kritsonis, 2006). More careful study of the individual variables as they relate to locale could lead to more productive theories of action to address gaps. Large-scale quantitative measures of achievement gaps according to rural locations were not extant in the authors’ review of research.

The current study contributes to the understanding of the influence of “the usual suspects” for detecting mathematics achievement gaps by examining the complete dataset from the mathematics portion of the 2000-2001 Kentucky Comprehensive Test of Basic Skills (CTBS-5). The present study is unique in that we include an “unusual suspect”—school size—and then frame the investigation of the same variables outlined above, but comparatively between rural and non-rural locales. Multi-level regression analysis on the complete dataset detected school-level and individual-level significance in mathematics achievement by several variables including interaction variables. The secondary analysis (rural vs. non-rural schools) reduced to non-significance several factors that showed significance in non-rural and complete data. Hence, the study provides evidence of the importance of understanding the possible affordances and

constraints of rural vs. non-rural schooling and, more broadly of the socio-spatial and cultural features inherent to locale as they relate to achievement and the processes of schooling.

**Background and Relevant Literature**

Educational leaders contend with achievement gaps as an equity issue revealed by state and federal accountability systems. Reform efforts of recent decades would suggest that the manipulation of process variables (e.g., teacher qualifications, professional development, curriculum alignment) has proven difficult to implement and has been limited in its effectiveness (Steinberg, 1996). Structural variables, particularly organizational size or scale, offer opportunities that have been largely unexplored by policymakers, practitioners, and researchers.

Achievement gaps are commonly used to describe inequitable distributions of achievement (whether “distributions” is used in the descriptive sense or in the sense of a purposeful, agentive allocation). Reproduction theorists see achievement gaps as evidence of schools’ role in maintaining broader social and economic inequities (Bowles & Gintis, 1976; Bourdieu & Passeron, 1990). According to this theory, it is unreasonable to expect that any educational unit—school, district, state, region—will ever reflect an equitable distribution of academic achievement because inequities are necessary for the reproduction of a stratified society. Alternately, liberal progressivists view school reform as existing primarily to close achievement gaps and equalize educational outcomes (Haycock, 2001).

The inclusion in this study of smaller organizational size as a key structural variable follows research showing how it can be used to mediate the relationship between SES and academic achievement (Friedkin & Necochea, 1988; Howley & Howley, 2004; Johnson, 2007; Lee & Smith, 2001). In general, these scholars find that smaller organizational size is associated with diminished explanatory power of variables operationalizing poverty. This study extends such size-by-SES lines of inquiry to further investigate the possible interaction of (1) size and student gender, and (2) size and student ethnicity. As such, the study also contributes to a considerably smaller literature—and one that is characterized by less consistent findings than those reported in size-by-SES studies (Arnold & Kaufman, 1992; La Sage & Renmin, 2000). While less consistent in their findings, these studies suggest the potential for inquiry into the influence of school size on achievement gaps related to race/ethnicity, and gender.

Methodologically, the current investigation contributes to a limited subset of the school size literature using student level data (e.g., Howley & Howley, 2004; Lee & Smith, 2001). The present study similarly uses individual student data as the foundation for a nested design. It differs from earlier studies, however, in that the current model uses the universe of student-level data for the 2000-2001 grade 9 cohort in Kentucky. Using the entire population rather than a sample eliminates issues related to sampling and weighting, and therefore offers the possibility that findings will more accurately characterize the relationships of interest.

**Methodology**

The following research questions guided the quantitative investigation in this study:

1. In what ways (strength and direction) is mathematics achievement among students influenced by socially-ascribed characteristics of the student (gender and ethnicity), by the contextual characteristics of the school community (aggregated gender, ethnicity, SES, and school size), and by the interaction of individual and contextual characteristics?
2. To what extent do influences on mathematics achievement vary according to school locale (rural or non-rural) in which the student is enrolled?

Multi-level regression techniques appropriately model the hierarchical structure of educational data and offer several advantages over other statistical approaches such as Ordinary Least Squares regression (Hox, 1995; Iversen, 1991). Moreover, by using independent variables at student- and school-levels, the model can detect possible importance of cross-level interactions. For example, the effects of student ethnicity may vary depending upon the poverty level of the school.

Data set
The dataset was prepared using information obtained from the Kentucky Department of Education (KDE) and the National Center for Education Statistics (NCES). The resulting merged data set comprised 49,979 cases representing all members of the 2000-2001 Kentucky grade 9 cohort with CTBS-5 scores reported. For the purposes of investigating differences related to school locale, we also created subsets of the data comprising (1) students in rural Kentucky schools (n=17,315) and (2) students in non-rural Kentucky schools (n=32,491). Rural and non-rural school designations relied on NCES locale codes (locales 7 and 8 = rural; locales 1-6 = non-rural).

Variables
The dependent variable represents measured student achievement in mathematics, operationalized as scores on the math component of the CTBS. The distribution of values for the dependent variable was reviewed using descriptive statistics (i.e., skewness and kurtosis), histograms, and Q-Q plots, with findings suggesting a relatively normal distribution of values.

The independent variables represent student-level socially ascribed characteristics, school-level contextual characteristics, and cross-level and same-level interaction terms. Student-level independent variables included sex (SEX1) and ethnicity (ETH1). Additional independent variables represent the school-level aggregation of these same variables: SEX2 (the calculated school-level percentage of female students) and ETH2 (the calculated school-level percentage of minority students). The distribution of values for the two school-level variables was reviewed using histograms and Q-Q plots. Values for the ethnicity variable were highly skewed toward lower values (i.e., there were many more schools with small or non-existent populations of nonwhite students). To allow for a useful degree of variability, values for ETH2 were transformed using the natural logarithm. Review of a histogram and Q-Q plots confirmed that the distribution of values for the transformed variable was close to normal.

Two additional school-level variables operationalized school size and school socioeconomic status. The school size variable (SIZ2) represents the Fall 2000 student membership, and the school SES variable (SES2) represents the school-level free and reduced meal rate for the 2000-2001 academic year. Histograms and Q-Q plots suggested relatively normal distributions for these variables.

Following Cronbach (1987), all student- and school-level variables were centered to reduce the collinearity of related independent variables. All student-level variables were centered on the mean of individual schools (Bickel, 2007). All school-level variables were centered by subtracting the state mean from each case value. To account for cross-level influences in the
multilevel model, several interaction terms were computed from the centered independent variables:

The eight cross-level interaction terms were implied by model choices—that is, by choices related to fixed and random effects, and to hypotheses about variability in the random intercept and random slopes. The additional interaction term (SES2SIZ2) was suggested by findings from Bickel & Howley (2000).

\[
\begin{align*}
(1)(\text{SEX1SEX2}) & \text{ student sex X school percent female;} \\
(2)(\text{SEX1ETH2}) & \text{ student sex X school percent minority;} \\
(3)(\text{SEX1SES2}) & \text{ student sex X school poverty;} \\
(4)(\text{SEX1SIZ2}) & \text{ student sex X school size;} \\
(5)(\text{ETH1ETH2}) & \text{ student ethnicity X school percent female;} \\
(6)(\text{ETH1SEX2}) & \text{ student ethnicity X school percent female;} \\
(7)(\text{ETH1SES2}) & \text{ student ethnicity X school poverty;} \\
(8)(\text{ETH1SIZ2}) & \text{ student ethnicity X school size;} \\
(9)(\text{SES2SIZ2}) & \text{ school poverty X school size}. \\
\end{align*}
\]

**Data Analysis**

The research model theorized that 15 independent variables (at both levels and including cross-level interaction terms) exert influence over the dependent variable representing mathematics achievement. Specifically, the model hypothesized that student-level sex (SEX1), and ethnicity (ETH1), school-level proportion of female students (SEX2), ethnicity (ETH2), socioeconomic status (SES2), and school size (SIZ2) constitute a robust set of predictors for mathematics achievement. The model further hypothesized that the influences of the student-level variables are moderated by school-level ethnicity, proportion of female students, size, and SES. The model also hypothesized that the influence of school socioeconomic status is moderated by school size.

In sharp contrast to most empirical research, the dataset includes the entire population: all ninth graders in Kentucky who took the CTBS math test in 2000-2001. Thus, there was no need to make inferences from a sample to the larger population. Relationships that differed from zero were, by definition, “real”. Inferential statistical procedures are therefore both gratuitous and potentially misleading. While statistical significance was then—strictly speaking—immaterial to the study, significance levels are nevertheless reported and can be treated as indicators that an observed relationship might be of practical significance (Bickel, 2007).

**Results**

Table 1 reports descriptive statistics for the dependent variable (operationalized math achievement score) and the school-level independent variables. Table 2 reports frequency statistics for student level independent variables, ethnicity (ETH1), and sex (SEX1).

The first numerical column of Table 3 below reports the results from the regression model predicting mathematics achievement for the combined dataset from the 15 independent variables described above. Two research questions guided the quantitative investigation grounding this study. The first considered the distribution of individual student achievement among students with differing individual characteristics and across differing school environments. Results reported here indicate that socially-ascribed characteristics of students influenced achievement in ways commensurate with results in the extant literature. Specifically, all else equal: (a) male students, on average, would be expected to score about 6% of one standard deviation higher than...
female students, and (b) minority students, on average, would be expected to score about one-third of one standard deviation lower than white students.

Notes:  N1 = N at level one (students); N2 = N at level two (schools); *p ≤ 0.05; **p ≤ 0.01; ***p ≤ 0.001.

Results suggest that contextual characteristics of schools exert influence over achievement levels among students—here too consistent with descriptions from the literature. The influence was substantially weaker than the influences of student-level characteristics, however. In

particular, the results suggest that, all else equal: (a) increases in percent poverty would be expected to decrease math scores for all students regardless of individual SES, and (b) increases in percent minority enrollment would be expected to decrease math scores for both minority and white students. The influence of school size was nonsignificant for math achievement.

With regard to interaction effects, results indicated that the composite influence of student and school characteristics exerted influence over achievement that was stronger, on average, than the influence of school characteristics alone. These results suggest that contextual characteristics influence students differently according to student sex and ethnicity. School ethnicity exerted nearly one-third more influence over outcomes for female students than it did for all students combined. In contrast to its negative influence over all students combined, school SES exerted a slight positive influence over achievement for girls (i.e., all else equal, girls, on average, would tend to score higher in higher poverty schools). The interaction of school SES and student ethnicity was also positive and relatively weak, suggesting a similar pattern. The interaction of school-level and student-level ethnicity was negative and quite strong, indicating that the negative influence of school ethnicity was more than six times stronger for minority students than for all students combined. The significant interaction of school size and school SES indicated that the negative effects of school SES were mediated by school size (i.e., smaller school size diminishes the negative influence of poverty over student achievement).

The second research question considered whether these influences vary according to school locale (specifically, rural versus non-rural). To allow for comparing results for students in rural schools with other Kentucky students, Table 3 includes coefficients obtained from the same regression using (1) the data set comprising all valid Kentucky cases, (2) a subset comprising all valid rural cases, and (3) all valid non-rural cases.

When results for rural and non-rural student populations were compared, the following results emerged:

1. The influence of student sex on math achievement was reduced to nonsignificance in rural schools (i.e., the achievement gap between male and female students in rural schools is so small that it should not be considered real).
2. Student ethnicity exerted a weaker influence over math achievement in rural schools than in non-rural schools (i.e., white students, on average, outperformed minority students by a smaller margin; the achievement gap was narrower).
3. Among all students combined, the influence of school SES on math achievement was weaker in rural schools than in non-rural schools.
4. Among female students, the influence of school SES on math achievement was reduced to nonsignificance in rural schools.
5. Among minority students, the influence of school SES on math achievement was reduced to non-significance in rural schools.

**Discussion**

Perhaps most striking of results 1-5 above is that rural locale, in a sense, “erases” the gender gap and “diminishes” both the race gap and the poverty gap in mathematics. Given the attention given to gender and race equity in the past century of educational discourse, this result suggests that a better understanding of the influence of the places and structural elements of rural schools and communities may offer insight into mechanisms to reduce the gender and race gaps in mathematics elsewhere. Minimally, further study could illuminate obstacles for achieving equity.
in non-rural locales. It should be noted, that this result hardly demonstrates the absence of gender or race discrimination in rural areas. Indeed the importance of this finding remains to be seen in further investigations of schooling in rural areas. Still, it suggests that the relative lack of research on rural education (Arnold, Gaddy, & Dean, 2004) should be addressed, both by researchers and by funding agencies committed to improving mathematics education. Much of the rural education research points to the centrality of community, family, and attachments to the land in rural life (most notably, Theobald, 1997). Further research could determine the extent to which these key characteristics may structure social supports that promote equitable outcomes in mathematics achievement in rural schools, as suggested by findings 1-3 of the present study.

For female and minority students, schools in rural locales again erased the influence of poverty on mathematics achievement that was detected in analysis of the complete dataset. Rural areas in Kentucky, and the United States more broadly, face high rates of poverty (Johnson & Strange, 2009). It is reasonable to surmise that the effects of poverty are, in a sense, more equitably distributed, and its effects therefore, are relatively less pronounced than for other locales where, as previously mentioned, one’s ethnicity or gender is a stronger physical marker of poverty than would be the case in a rural locale. Result 5 in particular seems less generalizable to a national picture of rural vs. non-rural mathematics achievement by social or contextual characteristic. The rural central Appalachian region of which Kentucky is a part has a notably different ethnic profile than, say, the rural Southwest, suggesting that this result merits further scrutiny for states or regions where rural demographics differ significantly from that of Kentucky. In most other ways, results from this study of Kentucky could be considered a fairly representative picture of rural America (Johnson & Strange, 2009).

Overall, this study suggests that the current focus of efforts on process reforms such as instructional strategies, same sex grouping, and injections of professional development as part of efforts to “close achievement gaps” ignore potential benefits of focusing on structural variables such as school (district) size, administration, and the like. Understanding these results clearly involves further investigation, but one that is open to the possibility that the values, commitments, and arrangements underlying community and locale may explain mathematics achievement gaps better than process variables such as the qualifications of a teacher. These results may even suggest, as in the work of Paolo Freire, that an underlying community-centered ethic can raise achievement broadly; indeed, that a person’s success in a given area may depend on the success of his neighbor. As Cesar Chavez remarked, “We cannot seek achievement for ourselves and forget about progress and prosperity for our community... Our ambitions must be broad enough to include the aspirations and needs of others, for their sakes and for our own.”

PUTTING THE CITY BACK IN “URBAN”: HIGH SCHOOL MATHEMATICS TEACHING IN LOW-INCOME COMMUNITIES OF COLOR

Laurie H. Rubel
CUNY- Brooklyn College
lrubel@brooklyn.cuny.edu

Haiwen Chu
CUNY- Graduate Center
Haiwen.chu@gmail.com

This study reports interim findings from an ongoing research and professional development project at urban high schools located in two low-income, communities of color. The project collaborates with teachers on improving their instructional practices, using a framework of culturally relevant mathematics pedagogy, which is described in this paper. We measure instructional practices by a qualitative and quantitative analysis of data from 49 classroom observations of seven teachers. In particular, we use culturally relevant mathematics pedagogy to describe effective practices of the highest-rated teachers.

Introduction

The preparation and training of mathematics teachers to teach in “urban” contexts is a pressing issue. Although “urban” has taken on a wide spectrum of connotations, its meaning here literally indicates “of or relating to a city.” Urban schools, by virtue of being located in densely populated areas, are contained in large school districts, which are typically associated with bureaucratic leadership structures, emphases on standardized testing, high teacher turnover rates, as well as a mixture of certification, induction and mentoring programs (Weiner, 2000). In addition, larger numbers of people are concentrated in geographically smaller spaces in cities, creating a pattern of islands of homogeneity. Therefore, while a city as a whole may be diverse, the neighborhoods are often homogenous in terms of race and socio-economic class. One consequence is that African American or Latino students from the lowest income families tend to be segregated, de facto, in particular urban schools (Lipman, 2004).

The research described in this paper is conducted in two such low-income neighborhoods in New York City. Each neighborhood contains about 130,000 residents: Bushwick’s residents are primarily Latino (Puerto Ricans, Dominicans, Mexicans, and Ecuadoreans) and Brownsville’s residents are primarily African American. More than half of the families in Bushwick, and more than 2/3 of the families in Brownsville, are in the bottom two quintiles of New York City income (Furman Center, 2008); these neighborhoods are among the ten poorest neighborhoods citywide. We conduct our research at two case high schools; each school enrollment about 400 students largely from their surrounding neighborhoods.

At these two high schools, many, if not most, students enter high school with below proficient elementary and middle school mathematics state test scores, indicating that they likely have weak backgrounds in school mathematics, in crucial areas such as number and operations or ratio and proportion. At the same time, they skillfully navigate a complicated urban environment, and demonstrate that they are sophisticated problem solvers outside of the standardized testing context. As a field, we know little about effective mathematics teaching in situations like this, situations that are typical in schools that serve students of color in low income, inner-city neighborhoods. In this paper, our goal is to share details of an approach to analyzing teaching around a framework of culturally relevant mathematics pedagogy, specifically in a context of these two urban high schools.

Teacher Learning of Culturally Relevant Mathematics Pedagogy

A promising approach to effective mathematics teaching is culturally relevant pedagogy (Ladson Billings, 1995). As Tate (2005, p. 35) explains, “one barrier to an equitable mathematics education for African American students is the failure to ‘center’ them in the process of knowledge acquisition and to build on their cultural and community experiences.” Centering the Teaching of Mathematics on Urban Youth aims to improve teachers’ practice by creating and sustaining a teacher learning community around culturally relevant mathematics pedagogy. We have currently completed seven months of the two-year professional development and research. At this early stage, we can offer a detailed picture of our thinking about culturally relevant mathematics teaching and mathematics learning opportunities for students.

To enable all students to have equitable access to success in mathematics, culturally relevant teaching (Ladson Billings, 1995) is proposed, as instruction that meets three criteria: 1) emphasizes students’ academic success, 2) encourages the development of cultural competence, and 3) facilitates the students’ development of critical consciousness. We extended the ideas of Ladson Billings (1995) and Gutstein, Lipman, Hernandez, and de los Reyes (1997) to formulate culturally relevant mathematics pedagogy, which consists of three, tiered pedagogical components. The primary tier is teaching mathematics for understanding, which implicates both its definition as connections between mathematical concepts, procedures, and facts (Hiebert & Carpenter, 1992) as well as the sociocultural definition of understanding as the valued activity of engaging in sense making of problematic situations (Wenger, 1998). Teaching for understanding emphasizes the importance of classroom tasks that enable students to make connections across ideas and procedures, as well as classroom norms that support varied structures for student participation.

One potential mechanism of mathematical understanding is thought to be the use of relevant or meaningful real-world contexts as a regular aspect of mathematics instruction (Moses & Cobb, 2001). Accordingly, the second tier of culturally relevant mathematics pedagogy is that teachers should include local, relevant or familiar contexts in their teaching, and, as Tate (2005) suggests, “center,” at least in part, the instruction on the students’ experiences. One interpretation of “centering” is that mathematics be used to describe or analyze contexts that are “real” to students’ worlds. An additional interpretation is that teachers can create classroom norms or structures for participation that are accessible to students so that they can be central participants in the building of mathematical understanding (Hand, 2003).

The third tier of culturally relevant mathematics pedagogy invites teachers to address local or societal issues of power and fairness (Diversity in Mathematics Education Center for Learning & Teaching, 2008), to develop students’ critical consciousness and mathematical literacy. One way to conceptualize analyzing issues of power is in terms of unequal distribution of power and resources among people across society. For instance, mathematics could be used with students to analyze local demographic patterns, over time, in connection to the growth of low-income public housing “projects”, or to use mathematics to analyze the compound interest rates built into subprime mortgages that have led to high rates of home foreclosure in these neighborhoods. These types of mathematical investigations correspond to the examples presented in the teaching mathematics for social justice literature (c.f., Gutstein, 2003). Developing students’ critical consciousness in mathematics class also includes addressing issues of power between people and mathematics (Skovsmose, 1994). In other words, opportunities can be given to students to be critical thinkers about the mathematics that they study: who creates it, for what purposes, and with what impacts? When mathematics is viewed as a social practice generated by human agency
for communication, representation, or efficiency, this shift in perspective inverts the typical power dynamic where mathematics is a gate, guarded by the teacher, to be passed through.

Culturally relevant mathematics pedagogy is a comprehensive approach to mathematics teaching that lends itself to longer-term professional development. The Centering the Teaching of Mathematics on Urban Youth is a two-year project that focuses on improving high school teachers’ instructional practices, using the framework of culturally relevant mathematics pedagogy. Participants do mathematics together, collaborate to learn about their students and the socio-historical context of the communities in which they teach, reflect about their instructional practices using the framework of culturally relevant mathematics pedagogy, and analyze the relationship between their instructional practices and their students’ participation and learning. The project is comprised of three activity types: two five-day summer institutes over consecutive summers, bi-monthly school-based department meetings, and work with individual teachers through observations, debriefings, interviews and planning sessions. The approach to professional development and details about its content are described elsewhere (Rubel, under review).

In this paper, we focus on our findings after the project’s opening semester, after the first summer institute, six group meetings at each high school, and seven classroom observations of seven focal teachers. Our analysis demonstrates culturally relevant mathematics pedagogy as a framework with which to analyze teaching. At the same time, our analysis also offers a nuanced description of mathematics teaching and student opportunities for learning at these two urban high schools.

**Methods**

Four of five mathematics teachers at Harwood HS and three of four mathematics teachers at Carver HS (both school names are pseudonyms) are full project participants (along with three preservice teachers and seven teachers from four other urban high schools). Three of these seven focal teachers identify as White, two as Afro-Caribbean, one as African, one as African American. Three of the teachers are male, and four are female. The most experienced teacher has eight years of experience, the least experienced teacher is a first year teacher, and the median number of years of experience is six. None of the teachers are local to these particular communities; only two of the teachers were themselves raised in New York City.

In the first semester of the 2009-2010 school year, we visited each teacher for seven observations in three rounds (three consecutive classes in October, two consecutive classes in December, and two consecutive classes in February), for a total of 49 observed lessons. Each teacher’s observations were conducted in the same class period, with the same group of students. We took detailed fieldnotes during those observations to complete a Classroom Observation Inventory (COI), in an attempt to measure and categorize how the teaching in that lesson corresponds with the three components of culturally relevant mathematics pedagogy.

The COI notes a variety of dimensions of teaching and learning. First, the COI contains adapted instruments from Kitchen, DePree, Celedón-Pattichis, & Brinkerhoff (2007) and Weiss, Pasley, Smith, Banilower, & Heck (2003) for ratings of: lesson design, implementation, mathematical discourse and communication, intellectual support, and engagement, each on a 1 to 5 point scale. Second, we adapted instruments from Stein (2004) to classify the lesson’s main mathematical task in terms of its cognitive demand, using the ranked categories of doing mathematics, procedures with connections, procedures without connections, and memorization (Henningsen & Stein, 1997). Third, we adapted the categories of student participation in Weiss
et al. (2003) to create a set of modes of student participation: listening; investigating or problem solving; discussing; reading, writing, or reflecting; using technology; and practicing skills. Each of these categories is further subdivided into more specific categories. We tabulated the duration of student participation for each participation category in each lesson. Finally, we also described if and how teachers used local or other relevant contexts in each lesson observed, as well as if and how teachers drew on students’ language or other cultural resources in the lesson.

Results

We begin with results of the COI ratings across the categories of lesson design, lesson implementation, mathematical discourse & communication, intellectual support, and engagement, as a way to demonstrate the range of ratings across the seven teachers. Table 1 indicates each teacher’s mean rating for each of the five categories across the seven observed lessons, as well as their overall mean rating.

Lessons that had higher ratings in design and implementation also had higher ratings in mathematical discourse and communication, intellectual support, and student engagement (Pearson correlation coefficients of at least 0.703, at 1% significance level). Teachers F and G had ratings that are higher (with statistical significance) than the other teachers, and teachers A and B had ratings that are lower (with statistical significance) than the other teachers. In the remainder of the results section, we focus on these two subsets of teachers. We present our results in terms of three aspects of culturally relevant mathematics pedagogy: a) promoting understanding by using tasks that enable students to make connections between and among mathematical ideas and procedures, b) creating multiple modalities for students to participate in learning mathematics in the classroom, and c) connecting with students’ everyday experiences.

Lesson Mathematical Tasks

The main, enacted mathematical task in each observed lesson was identified, described, and then rated according to its requisite level of cognitive demand, using the categories of Henningsen & Stein (1997): memorization, procedures without connections, procedures with connections, or doing mathematics. None of the tasks were rated at the highest level, as “doing mathematics.” The majority of the lessons, 34 of 49 lessons, contained tasks that were rated as low-level cognitive demand, either memorization (9) or, more often, procedures without connections (25). The two teachers with the lowest mean ratings presented their students with tasks only at these low levels. Thirteen of the lessons had high level tasks, procedures with connections, but these tasks were limited to the lessons of just three teachers. Twelve of these

thirteen tasks were in the lessons of the same two teachers who also had the highest rated lessons in terms of design, implementation, mathematical discourse and communication, intellectual support, and engagement. This correspondence demonstrates a relationship between the task’s level of cognitive demand and other aspects of the lesson.

Modes of Student Participation
Throughout each observed lesson, we classified and quantified student participation, according to the following mutually exclusive categories, adapted from Weiss et al. (2003): a) listening; b) discussing, c) investigating or problem solving; d) reading, writing, or reflecting, e) using technology, or f) practicing skills. Across all 49 observed lessons, the most frequent mode of participation offered to students was listening, which accounted for 33% of all instructional time (30% of the total instructional time was spent listening to a teacher presentation). The second most frequent mode of student participation was practicing skills, which accounted for 23% of total instructional time. Less frequent for students were investigating and problem solving (19%), discussing 10%, all in whole group format); reading, writing, or reflecting (4%) and using technology (2%). The remaining 9% was spent on teacher “housekeeping” activities that are not instructional in nature.

</table>

There is variability across the seven teachers, as shown in Table 2 above. For teachers A and B, who had the lowest mean lesson ratings, the combined categories of listening (to the teacher), practicing skills, and teacher “housekeeping” formed nearly the entire range of modes of participation in their two classes (95% for A and 98% for B). The lessons of teachers F and G, the teachers whose lessons had the highest mean ratings, also devoted substantial amounts of time on listening, practicing, and teacher “housekeeping” (39% for F and 49% for G). However, their lessons also included substantial amounts of time devoted to other types of participation like investigating and discussing (a total of 51% for F and 46% for G). Ms. Kendall (a pseudonym), one of the teachers with the highest mean lesson ratings, stands out in terms of participation structures in that in her class, students about as much time problem solving or investigating (34%) than they do listening (29%) and practicing skills (6%) combined. Ms. Kendall’s classes are characterized by her students’ enthusiasm to participate and discussions in

which students’ ideas are explored even when they may not yet correspond with normative mathematics in terms of representation or correctness.

**Connections to students’ experiences**

The two teachers with the lowest lesson ratings selected low-level tasks focused on memorization of facts or procedures and contexts were typically abstract, like a geometric figure or an algebraic equation. In some instances, these teachers’ lessons included contexts that could potentially connect to students’ experiences but did not facilitate student engagement or increase depth of student knowledge. For example, in one lesson, a teacher listed a set of jersey numbers for members of a basketball team, and a second set of jersey numbers for members of the team who could not play in that game. The prompt was then to find the members of the team who *could* play in the game, all as a way to model the notion of a set and its complement. The set notation does not illuminate aspects of the game of basketball, and conversely, the context of basketball does not illuminate this particular mathematical notation or idea.

Another of the seven teachers, Ms. Tristan (a pseudonym), one of the two teachers with the highest mean lesson ratings, demonstrated a range of ways of connecting to students’ experiences as a way to promote student participation and build understanding of mathematical ideas. Ms. Tristan capitalized on geometric features of the urban environment in her mathematics instruction and used neighborhood maps in several ways. These activities extended her experience in our professional development, in which we explored the use of local maps as a mathematical context in a variety of ways, which are described in detail elsewhere (Rubel, Chu, & Shookhoff, under review).

Ms. Tristan used maps in several different ways in her lessons. For one lesson that involved learning the distance formula as a way to compute the distance between two points, Ms. Tristan used a gridded neighborhood map and had the students consider the “as the crow flies” distance from the school to the nearest subway station. In a different lesson, that dealt with perimeter of polygons and unit analysis, Ms. Tristan’s students were asked to calculate a precise estimate of the time it would take to walk the perimeter of the neighborhood. Students coordinatized a gridded map and used the Pythagorean Theorem to find the perimeter of the polygon-shaped neighborhood. In a third lesson, dealing with triangle points of concurrency, Ms. Tristan had each student plot his or her own address and that of two friends on the neighborhood map and then calculate a fair meeting location, which was defined as each person traveling the same distance. This lesson hinted at critical thinking about using mathematics to define and negotiate aspects of fairness.

Using neighborhood maps is a literal interpretation of “centering” mathematics on students’ worlds. Ms. Tristan demonstrated other interpretations of how to connect instruction to students’ everyday experiences. For instance, Ms. Tristan showcased one student’s break-dancing abilities to demonstrate the notion of balance point, as a way to introduce the geometric idea of centroid. In another lesson on finding shaded areas within geometric figures, Ms. Tristan presented a series of “optical illusion” images that involved positive and negative space. Students eagerly deconstructed each total shape into positive and negative space, an approach that extends well to shaded area mathematics problems. In this last example, Ms. Tristan did not draw on students’ out-of-school experiences, but created within the classroom an accessible, shared experience for students to use as a problem-solving anchor and structured the lesson so that students could be central participants.
Discussion

These results begin to challenge the notion that reform teaching practices that emphasize student communication and problem solving might not be effective with students from low-income communities (Boaler, 2002). Our results demonstrate relationships among ratings of lesson quality as well as between those ratings and categories of task cognitive demand and types of student participation structures. The cognitive demand of a mathematical task sets a range of modalities for student participation. Low-level tasks, requiring only memorization of facts or executing steps of a procedure, lend themselves only to listening and practicing. By contrast, tasks with higher-level cognitive demands, in which students must detect patterns or make connections across mathematical representations, afford opportunities for more varied participation modalities. Ms. Kendall’s lessons, with tasks of higher level cognitive demand, also had higher ratings of mathematical discourse and communication and student engagement and had the most varied participation opportunities for students.

These preliminary findings also add nuances to the description of culturally relevant mathematics pedagogy, in terms of instructional practices and in terms of student participation and engagement. Other studies have demonstrated that the use of contexts can be a distraction, (Boaler, 2002), especially for students from low-income communities, most notably when the students have different experiences with the context than the teacher realizes. In our project, we have begun to see examples of teachers using contexts that are, instead, local to the students. Since this is the focus of the professional development activities, we hypothesize that we will see development of such practices among other participating teachers as the professional development continues. We hypothesize that Ms. Tristan’s use of local and relevant contexts are related to the high levels of student engagement we have observed in her classes. These contexts authentically connect students’ experiences with the mathematics in question.

In this article, we have profiled the instructional practices of two teachers as a way to more fully describe the framework of culturally relevant mathematics pedagogy and how we are measuring it in classrooms in urban schools. These initial findings also function as formative assessment for the ongoing professional development activities. Taking a longer-term perspective, we are hopeful that over the course of this project, teachers will continue to grow, in ways that we have and have not yet anticipated. We anticipate that continued collaboration will lead to sustained growth in challenging mathematical tasks, flexibility and variety in participation, and connections to students’ experiences.

FACILITATING MULTIPLE STRATEGIES USE IN A HIGH POVERTY CLASSROOM THROUGH PROBLEM-BASED LESSONS

Jonathan Bostic  
University of Florida  
dbostic@ufl.edu

Tim Jacobbe  
University of Florida  
jacobbe@coe.ufl.edu

All learners need opportunities to experience mathematics in a rigorous fashion that promotes success and draws upon their prior knowledge. A series of problem-based lessons that encouraged the use of multiple strategies were implemented in a fifth grade classroom. Students completed a pretest, posttest, and follow-up test six months after the intervention. They showed significant gains in their use of multiple strategies after the intervention and a marked increase in their ability to solve word problems. Students reported transferring their use of multiple strategies to their typical classroom and feeling more self-confident.

Introduction

Problem solving is a process standard that has been hotly debated by the mathematics education community and parents (National Council of Teachers of Mathematics [NCTM], 2000; Saunders, 2009; Schoenfeld, 2004). Problem-solving instruction varied across decades. From a focus on content-specific heuristics to transferring experts’ use of explicit strategies to novices, and embedding problem-solving notions within lessons centered on a specific mathematical topic (Schoenfeld, 2004). Besides explicit problem-solving instruction, some advocates suggest that problem-based instruction [PBI] engages learners in rich learning experiences they might utilize in the future (Herried, 2003; Pecore, 2009). While debates over modes of mathematics instruction continue, the achievement gap remains too wide (United States Department of Education [USDOE], 2008; 1990-2007). Recent scores from the National Assessment of Educational Progress [NAEP] indicate there are gaps in students’ mathematics knowledge related to race and income status (USDOE, 2007). On average, Caucasian fourth grade students outperformed African-American peers by 20 points and similarly, Caucasian fourth grade students scored 21 points higher than Hispanic peers. All children can achieve at high standards and should be given opportunities to learn in a caring environment filled with challenging learning opportunities (Ayers, 2008). Literature from the last decade provides evidence for using student-centered mathematics instruction to facilitate learning for conceptual understanding (Ball, 1993; Lampert, 2001).

Literature Review

Student-centered mathematics instruction

Student-centered mathematics instruction uses learners’ “backgrounds and cultural values, as well as abilities” as the starting point for effective instruction (National Research Council [NRC], 2005, p. 14). The National Mathematics Advisory Panel created their own unique definition of student-centered learning that prevented previously mentioned studies from being used as evidence for student-centered learning (Boaler, 2008), however the authors will not make that same mistake. Student-centered learning acknowledges that learning for all individuals may occur in different ways for each child (NRC, 2005). Discourse and activities promoting reasoning are two common features of student-centered mathematics instruction (Cobb, Yackel, & Wood, 1992; Lampert & Cobb, 2003). There are varying degrees of student-centered
mathematics instruction, from learner-selected inquiries to fairly teacher-guided discussions about a mathematical topic. Problem-based learning [PBL] uses complex problems as the means for teaching content and problem-solving strategies (Pecore, 2009; Ronis, 2008). Problem-based tasks often employ students’ experiences as starting points for investigations (Pecore, 2009). PBL advocates suggest that it (1) facilitates learners reasoning and metacognitive actions while problem solving, (2) develops students’ social skills as part of a problem-solving team, and (3) motivates students intrinsically (Hmelo-Silver, 2004). Instructors perceiving mathematics as the study of logical analysis that gives learners tools to “describe, abstract, and deal with the world in a coherent and intelligent fashion” (Schoenfeld, 1982, p. 30), may utilize PBI to provide opportunities to learn content and engage in mathematics as problem solvers.

Problem solving

Problem solving has an extensive history in educational psychology literature and has been a mainstay of mathematics education research (Mayer & Wittrock, 2006; Polya, 2004). De Corte and Verschaffel’s (1981) problem-solving framework uses three phases to characterize the cyclical problem-solving process, (1) thinking, (2) execution, (3) verification. The thinking phase involves all behaviors and actions necessary to begin carrying out problem solving. This includes reading the problem, creating internal representations of the task, and considering possible strategies. After considering the task, problem solvers execute one strategy and carry out necessary computations. Verification requires using strategies to verify whether the solution is correct and appropriate for the context. These strategies may not necessarily include overt behaviors.

Verschaffel and De Corte (1997) noticed that many elementary-aged children solve word problems and fail to consider whether the solution jives with their authentic experiences. They employed a teaching experiment to examine whether 10-12 year old boys might benefit from PBI. They provided students with authentic, complex word problems and investigated whether students were able to provide more realistic solutions than their peers receiving traditional instruction. After five lessons, students in the experimental group had significant growth from pretest to posttest in the number of realistic responses to word problems, p<.0001. They also showed a significant increase in correctly solving problems requiring transfer, p<.05. One month following the instructional sequence, these students continued to provide significantly more realistic solutions to word problems than their peers, p<.05. Verschaffel and De Corte indicated that more realistic responses to word problems may lead to solving more word problems correctly and should be investigated. One limitation of this study was that both control and experimental groups were entirely male. Much of the foundational problem-solving literature’s evidence stems from work with gifted or older students, learners working in sterile labs, and examining students’ work on highly contrived problems (Lesh & Akerstrom, 1982). Lesh and Akerstrom (1982), as well as Lester (1982) suggest that problem-solving research needs to investigate problem solving with younger or non-white students. The present study aims to answer Verschaffel and De Corte’s (1981) wondering about solving more word problems correctly. It also aims to answer Lesh and Akerstrom’s call for examining what strategies young learners employ when solving word problems and their flexibility with employing multiple strategies.
Representations and strategies

Representations are valuable for their ability to communicate ideas and as a means for learners to discuss knowledge (Greeno & Hall, 1997). Facility with multiple representations influences learners’ strategy-use somewhat (Bostic & Pape, in press; Brenner et al., 1997). Students with more knowledge about representations and adequately developed schemas for problem solving have shown enhanced mathematical knowledge on achievement tests (Brenner et al., 1997). Recent studies using graphing calculators (i.e., Bostic & Pape, in press; Herman, 2007) showed that technology-use influences what solution strategies students choose. During one month of instruction on quadratics equations in an Algebra II classroom, students’ achievement was higher for those using a graphing calculator that provides better on-screen linking of representations than older graphing calculator models (Bostic & Pape). Students using the newer technology reported that instruction, coupled with the graphing calculator, assisted them in thinking about which strategy was most effective to solve a word problem. Furthermore, students valued learning more strategies to become better problem solvers. One likely step in advancing research on students’ facility with strategies is to examine what strategies students select while engaged in PBI.

Summary

This study examined elementary students’ problem-solving achievement and facility with multiple solution strategies. PBI lessons that related to students’ experiences were developed and implemented. The intent behind the lessons was to enhance students’ use of multiple strategies during PBI. Students were interviewed six months following the initial study and their responses were investigated to determine whether the intervention impacted their current problem-solving behaviors and self-confidence. The research questions for this study were (1) in what ways did PBI influence students’ ability to solve word problems and problem-solving behaviors and (2) how did students’ self-confidence as problem solvers change after the intervention? Both quantitative and qualitative methods of analysis and results will be discussed.

Method

Participants

The state of Florida grades its schools using an A through F scale each year using several factors, summative state-wide tests are key factors determining that score. Louisville elementary school is located in a mid-size city in Florida; its school population during the time of this study was 95% African-American and 96% of the student body received free-and-reduced-lunch. Its highest score in the last seven years was a C; the last three years it scored F. Louisville’s faculty and staff are deeply committed to supporting students and making them successful inside and outside of school. The principal invited mathematics education faculty and graduate students to work with students. Fifteen fifth grade students attended a voluntary summer school program and all students were invited to participate in the study. Parents and guardians were given the option of having their child participate in a traditional mathematics program taught by one of the classroom teachers during the intervention. No parent or guardian asked to have their child removed, however nine parents/guardians and students returned completed informed consent and assent forms. One participant was not available to complete the pretest on the first day. In the following academic year, the instructor returned to Louisville to interview participants and administer a follow-up test. Four students from the summer program left Louisville elementary school during the school year.

school and were not able to participate in the follow-up study. All participants in the intervention identified themselves as African-American. All names of places and people are pseudonyms.

**Instructional program**

The instructional program consisted of PBI over four days. During the week, the classroom teacher observed the instructor and students. Problems were adapted from word problems found in National Science Foundation-funded curricula. Problems correlated with Florida’s Sunshine State Standards (Florida Department of Education, 2007), incorporated authentic experiences germane to students, and could be solved using multiple representations. One mathematics education professor and one elementary teacher examined the problems for evidence of validity, appropriateness for the grade level, and whether the problems’ scenarios were relevant to students’ experiences. The validity team suggested that the problems were appropriate, met grade-level expectations, and incorporated students’ relevant experiences. A detailed description of the PBI used in this study is presented by Bostic and Jacobbe (2010).

**Data collection**

Students completed a pretest on the first day, a posttest on the last instructional day, and a follow-up test six months following the intervention. Questions were created using the same resources as those used for the intervention. All assessments consisted of three problems; the items were similar across the instruments except for changing some numerical values and some language (e.g., a dog has four legs was changed to a cricket has six legs). According to the validity team, changes did not affect problem difficulty, grade level appropriateness, or prevent solution strategies from being explored. Fraction operations, combinations, and number fluency were selected as the three topics for the problem-solving achievement tests. Participants took approximately 10 minutes to complete the pretest and 25 minutes on the posttest and follow-up tests.

Six months later, students were interviewed individually in an empty classroom for about 20 minutes each. The interviewer asked participants to reflect on their experiences from the summer, discuss whether they perceived any changes related to their problem-solving capabilities or mathematics achievement, and how their experiences from the summer compare to their current classroom experiences.

The authors used thematic analysis to identify key themes related to effects on students’ problem solving behaviors after the intervention (Hatch, 2002). First, the authors read the transcripts and located potential statements for analysis. Statements were lifted from the transcript and copied into a word processing document. This new document contained approximately forty statements. After several iterative readings of the statements, the authors organized the statements under potential thematic headings. Themes were scrutinized and those with a paucity of evidence were not included in the final set of themes. Two themes had substantial evidence and will be discussed here.

**Results**

**Correctness and solution strategies**

Participants’ responses to each problem were coded as either correct or incorrect. Next, the authors examined students’ solution strategies. A solution strategy was considered unique if it was different from a previous strategy for the given problem. For instance, a student might use three distinct symbolic solution strategies to solve a problem. Paired t-tests allowed comparisons...
of participants’ growth during the intervention; one-way interpretations were employed due to prior studies indicating that it is likely students would experience growth in their ability to solve complex word problems after engaging in PBI (De Corte & Verschaffel, 1981; Charles & Lester, 1984; Verschaffel & De Corte, 1997).

Participants demonstrated statistically significant growth from pretest to posttest in solving more problems correctly, t(7) = -2.69, p = .011. Most students could not solve any problems correctly on the pretest. There was not significant growth from pretest to follow-up test however this is likely due to participants leaving the school and the low power necessary for achieving statistical significance. The five students who participated in the follow-up testing did show statistically significant gains from posttest to follow-up test, t(4) = -2.138, p = .049. This result may be confounded with students’ mathematical knowledge growth and classroom experiences during the academic year after the summer program.

Besides solving more problems correctly, students also used more strategies to solve each problem after the intervention, t(7) = 2.525, p = .020. Even with low power, students continued to employ more strategies on the follow-up test than the pretest, t(3) = 4.70, p = .002. Classroom teachers’ instruction was somewhat traditional in nature however they also incorporated student-centered aspects such as cooperative grouping and encouraging content-related discussions.

Students’ choice of various strategies changed somewhat after the intervention and while not statistically significant, the results point towards a trend to significance. Participants tended to use more pictorial representations on the follow-up test than pretest, t(3) = 2.324, p = .051. Participants also tended to use more verbal strategies on the posttest than pretest, t(7) = 1.825, p = .055.

**Problem-solvers’ current behaviors**

Participants suggested that they engage in the problem-solving process in their current classroom as described by De Corte and Verschaffel (1981). Bobbie characterized the three stages in her own words.

First, I read over the problem. Then go back and if it has numbers, I look at those again. Then I try some strategies like add, subtract, multiple, and divide. If they have that ‘how many’ or ‘altogether’ or I forgot the word. But if they [problem] say ‘multiply’ or ‘divide’, I do that. And then I work them all our and see if they have an answer and I work it all out and see if I have the answer. Then I have the answer.

When asked about whether she checks her work, Bobbie indicated that she does it explicitly “sometimes” but typically she examines the problem’s solution and determines whether it seems reasonable. Bobbie’s description of how she solves word problems provides evidence that adds to De Corte and Verschaffel’s finding (1981). Like her U.S. peers, Bobbie perceived word problems as problems that are usually solved in one step and have language within the problem that cued her into employing a specific operation. Many students tried to use one of the four arithmetic operations as a means for solving problems on the pretest. These students have developed a word problem schema due in part to the instructional opportunities they had in the classroom prior to the study. Students’ use of strategies broadened somewhat after the intervention. Participants indicated they use pictorial strategies in their current classroom more frequently, “I get scrap paper and I’ll draw pictures so that way I’ll get it better” (Storm). Storm’s strategy choice was typical and similarly described by the other participants.

---

Participants also commented that they valued their peers’ use of multiple strategies during problem-solving activities in their current classroom. They commented that listening to their peers’ different strategies assisted them while problem solving. “I love seeing how others solve a problem” (Logan). The teachers in the participants’ current classrooms created a classroom environment that stimulated students’ minds for thinking about multiple strategies at times. Logan described how his classroom teacher provided him an opportunity to examine other’s strategies in a whole-class learning environment.

Well, they [peers] don’t have to explain it to me but they can go up there. Mrs. Patricia, she bring [sic] up people. One time she bring up [sic] a girl. We had these dry erase boards and she do [sic] it on the chalkboard, you know, the person who do [sic] it real good. She tell [sic] them to go up and put it on the board and put it there. And I be [sic] like, ‘oh that’s cool’ and I like that and I try to learn it.

Logan went on to elaborate that he did not necessarily hold this view until after working with his classmates during the summer PBI. Their current classroom environment may have contributed to students’ statistically significant test scores between posttest and follow-up test. Students were cued into thinking about multiple strategies to solve word problems during the school year. They commented that they continued to employ various strategies during the school year, especially symbolic and pictorial strategies.

**Self-confidence**

Some participants described feeling more self-confident after the summer PBI. The support in the classroom from the instructor and other students may have influenced students’ perceptions. When they perceived the classroom as a community of problem solvers, they might have experienced feelings of confidence and desire to maintain engagement in problem solving. Storm suggested that she

had more struggles in summer school and because I had a lot of people helping me out and we had more strategies we could use, which is great and now when I’m in there [current classroom], I bring them all in there and I know how to do it and my grades came up.

Storm and her peers talked about grades in class as a factor in their engagement in mathematics instruction and self-confidence. During the intervention, students were challenged with difficult word problems, encouraged to delve deeply into the question, and think critically about viable solutions. Logan’s feelings about hard problems and problem solving changed “from there to here. I had a difficult question in the summer and I get [sic] aggravated. But now I kind of get aggravated but I get more into it and work hard” (Logan). Furthermore, they used each other as a resource for support during problem solving. Bobbie felt support from her peers and instructors also influenced her understanding of mathematics topics.

I had more struggles in summer school and because I had a lot of people helping me out and we had more strategies we could use, which is great. And now when I’m in there [current classroom], I bring them all in there. And I know how to do it and my grades came up…and it got me to a higher level that I can move on from.

The influence of a demanding, student-centered problem-solving classroom may have influenced students’ self-confidence and problem-solving behaviors for the long term.

**Discussion**

Students engaged in PBI experienced positive benefits in their problem-solving capabilities, facility with multiple solution strategies, and self-confidence. As problem solvers, these students not only perceived themselves as more capable but also demonstrated that they were more likely to solve word problems correctly. Participants described feelings of empowerment and self-confidence related to problem solving.

In their current classroom, participants continue to experience instruction that somewhat facilitates learners using multiple solution strategies and examining problems from multiple perspectives. While students’ use of specific solution strategies, such as using pictures or verbal representations were not statistically significant, the trend towards significance provides direction for future investigators to consider interventions that support students’ use of pictorial and verbal solution strategies. Some older students perceive non-symbolic representations as less mathematically rigorous thus it is imperative that mathematics instruction continues to stress the value of all representations as being useful (Bostic & Pape, in press; Brenner et al., 1997; Herman, 2007). Starting instruction that encourages multiple strategies in elementary grade levels and carrying it through to middle and high school may enable students more options while engaging in problem solving. Without instruction that scaffolds mathematical learners to consider various strategies during the thinking phase, students may continue to use overly simplistic or inappropriate means to solve problems. PBI provides these opportunities for learners to engage in problem solving and build robust knowledge of strategies. By aligning content-focused pedagogy with student-centeredness, problem solving, and facility with multiple strategies, it may be possible to narrow the achievement gap.

STRUGGLING FORWARD: REFINING A FRAMEWORK FOR TEACHING MATHEMATICS WITH AND FOR SOCIAL JUSTICE

Joel Amidon
University of Wisconsin-Madison
jcamidon@wisc.edu

In this paper I describe the creation, use, and refinement of a framework for understanding the practice of teaching mathematics with and for social justice. This framework emerged out of a self-study of my own teaching practice where I attempted to document the struggles of a mathematics educator learning to teach mathematics for social justice. The refined framework calls for the defining of the student to match the definition of content to be learned, with implications for lesson design and further research.

Introduction
Teaching mathematics for social justice has been presented as a way to address some of the inequities present in mathematics education and the world at large (Gutstein, 2006). Inclusive education has been presented as a means for providing all students, regardless of challenges and abilities, access to engaging content in the classroom (Villa & Thousand, 2005). Combined, these approaches to education can be summarized as teaching with and for social justice (Wager, 2008). Though these approaches have been presented as promising, the changing of practice to enact these approaches in the classroom has been described as a problem for in-service mathematics teachers, specifically teaching mathematics for social justice (Brantlinger, 2007; Gau, 2005; Gutstein, 2007). Schoenfeld (1985) defines a problem as a task that is complex with an unknown method for completion. As a member of the research community, I am interested in describing the problem of attempting to change one’s practice towards what is proposed in teaching mathematics with and for social justice. The purpose of this study was to document the struggles of a mathematics educator moving towards this pedagogy of inclusively teaching mathematics for social justice, from an insider’s perspective, in order to provide insights to teacher educators and practitioners wanting to promote or engage in this work, which is in direct response to a call for work to be done to “see what teachers struggle with as they learn to teach mathematics for social justice” (Diversity in Mathematics Education, 2007, p. 420) What emerges from this effort is a framework for understanding the practice of teaching mathematics with and for social justice, with implications toward designing instruction.

Theoretical framework
In Lampert’s (2001) study of her own teaching, she developed a framework for understanding the practice of teaching as a network of relationships. The teacher has a relationship with the content, the student, and the student-content relationship (See Figure 1). Ultimately, the goal for a teacher is to get the student to “study” mathematics, where studying is described as “any practice engaged in by students in school to learn.”(p. 32). Thus, forging a relationship between the students and the intended mathematical content, but how does the problem space change when the task shifts to teaching mathematics with and for social justice? Lampert’s framework provides a base with which to overlay the other two perspectives: Gutstein’s (2006, 2007, 2009) representation of teaching mathematics for social justice and
Udvari-Solner, Villa, & Thousand’s (2005) conception of inclusive lesson design, the Universal Design Process.

![Diagram](Image)

**Figure 1. Lampert’s (2001) visual representation of the “problem space of teaching practice”**

Teaching mathematics for social justice (Gutstein, 2003, 2006) is an approach to mathematics education that attempts to realize the goals of culturally relevant pedagogy (Diversity in Mathematics Education, 2007) to “produce students who can achieve academically, produce students who can demonstrate cultural competence and develop students who can both understand and critique the existing social order” (Ladson-Billings, 1995, p. 474). Gutstein (2006, 2007, 2009) articulates the teaching of mathematics for social justice as simultaneously promoting the use and development of three types of knowledge: classical, critical and community (See Figure 2). Classical knowledge is the mathematical knowledge needed to gain access to advanced mathematics and to excel at high-stakes tests (Gutstein, 2006). Critical knowledge is the knowledge (both mathematical and otherwise) necessary to understand one’s sociopolitical reality (Gutstein, 2006). Community knowledge is the knowledge (both mathematical and otherwise) that exists within individuals from the school community context, which may not be understood by those who do not participate in the community (Gutstein, 2006). This component of teaching mathematics for social justice acknowledges the “funds of knowledge” (Gonzales, Moll, & Amanti, 2005) that exist in the community and can provide context and motivation for facilitating the use and development of critical and classical knowledge. Taken together these three domains describe the aims of teaching mathematics for social justice and the challenge of providing instruction that respects the validity and power within each of them.

Expanding on Lampert’s notion of content are the components of teaching mathematics for social justice as articulated by Gutstein (2006, 2007, 2009). A teacher engaged in teaching mathematics for social justice is concerned with the student learning the identified mathematical objectives of the unit (classical knowledge), learning how the identified standards can be seen in the everyday reality of the student (community knowledge), and how the mathematical objectives could be used to better understand that everyday reality or impact it for the better (critical knowledge). By expanding the notion of content in the problem space of teaching, all other relationships are now affected. For example, if the mathematical content for the lesson is to be rooted in radically local contexts, then the teacher is concerned with the student “studying” not only the mathematics, but also the community and critical knowledge that situates the
mathematics. Thus the entire problem space of teaching is impacted, even though teaching mathematics for social justice is put under the umbrella of content.

![Image](image_url)

**Figure 2. Teaching mathematics for social justice as intersection of knowledge (Gutstein, 2009)**

Some of the issues associated with in-service teachers attempting to teach mathematics for social justice has been described as a curriculum or lesson development issue. Gutstein (2007) specifically names the time, resources, and skills necessary to develop a social justice curriculum are not necessarily available to in-service teachers. In her study of teachers attempting to teach mathematics for social justice, Gau (2005) noticed that teachers were unable to balance between teaching mathematics and teaching for social justice and doing one exclusive of the other, rather than in concert.

To address some of these documented struggles, I applied the Universal Design Process (Udvari-Solner, et al., 2005), which is a means for developing lessons that addresses the needs, abilities, and interests of all students who are to engage with the lesson. The Universal Design Process is commonly associated with supporting teachers of inclusive classrooms, where all students, regardless of label and/or ability, are taught together, and the underlying assumption is that “living and learning together benefits everyone” (Falvey & Givner, 2005, p. 5). The intent of the Universal Design Process is important to highlight, because to decide to teach mathematics for social justice, suggests the enactor of such an approach realizes that there are inequities in the mathematics classroom and/or the world at large that can be addressed with such an approach. Having made such a choice to teach mathematics for social justice would also suggest that the teacher would want to provide “a socially just community in which students participate equally” (Wager, 2008, p. 99) or to teach mathematics *with* social justice. It is my belief that the Universal Design Process can help with both of those intentions and assist in addressing some of the problems identified above.

Specifically, the Universal Design Process (Udvari-Solner, et al., 2005) has four components: a) learning about the students in the classroom, b) naming the content that is to be learned, c) deciding how students will engage with the content, and d) how students will demonstrate their learning of the content. Learning about the students calls for “developing positive profiles of students’ social and academic abilities, strengths, and learning concerns…” (p. 138). This component goes beyond learning the students’ names and interests but actively seeking out the optimum means for delivering instruction, or learning how the students learn best. Udvari-Solner, et al. (2005) recommend using a multiple intelligence perspective (Gardner, 1993) in order to understand the students as learners in the classroom, for the purpose of making appropriate design decisions throughout the process.
By declaring one’s intention to teach mathematics for social justice, the dimensions of content have already been defined by Gutstein (2006, 2007, 2009). But in addition, the Universal Design Process calls for the teacher to decide “what level of knowledge or proficiency students are to demonstrate; and what context, materials, and differentiation are necessary to allow all students, including those with disabilities, a point of entry to learning” (Udvari-Solner, et al., p. 141). Another way to consider this design point is to define how the student will relate with the content, or defining the nature of the relationship.

Deciding how students will engage in the relationship with the content, or the “process” component, involves deciding on the “instructional strategies that afford students multiple means of engaging with the curriculum”(p. 143). The students engage with the content through the tasks and environment that the teacher has designed and enacted. This component represents how the students will learn the content of the lesson, given their specific learning profiles. Referring back to Lampert’s (2001) framework, this component of the Universal Design Process would equate with the student-content relationship (see Figure 3).

The last piece of the Universal Design Process, or the “product” component, asks teachers to decide “how students will demonstrate and convey their learning”(pp. 145-146), which is the assessment portion of the design and provides an opportunity for students to reflect their learning within a tangible artifact. This is the evidence that the students are “studying” the content. Further, the product can be used as evidence that the process component was effective in facilitating students learning what the lesson was designed to teach (see Figure 3). This evidence of learning, or lack thereof, can also be equated with evidence of success/struggle in attempting to teach mathematics for social justice, which foreshadows the methodology of this study.

![Figure 3. Problem space for teaching mathematics with and for social justice](image)

The resulting framework provides a visual representation of the practice of teaching with and for social justice, with implications towards instructional design and evaluation.

**Methods**

I chose an insider’s perspective (Ball, 2000) in order to articulate the nature of the struggles a teacher may have in attempting to teach mathematics for social justice. I assumed the role of teacher in a public high school mathematics classroom in a rural school district in the Midwest and attempted to teach a mathematics lesson with and for social justice (Wager, 2008). The lesson, that was taught over 6 class periods, was designed with information gathered during a three-month pre-lesson enculturation period, using the framework described previously. Ball...
Ball’s (2000) first question asks: “Does the researcher have a conjecture or image of a kind of teaching, an approach to curriculum, or a type of classroom that is not out there to be studied?” (p. 391). My interest lies in describing the struggles experienced by a teacher of mathematics who decides to shift his or her pedagogical practices towards what is envisioned in teaching mathematics for social justice. Finding a teacher with a genuine desire to change his or her pedagogical practices to those described by Gutstein (2006, 2007, 2009), and willing to be studied in the midst of that change would be difficult to find. My other desire was to capture this event in a context that is different from what the literature already contains. Brantlinger (2007) suggests that this approach to mathematics should be used in non-urban environments, such as the rural community where I situated this study. Combined, finding a teacher wanting to change his or her practice to what is described, in the desired context, would be difficult. Thus, necessitating the creation of such a situation.

Next Ball (2000) asks if the researcher has the tools necessary “to be a designer, developer, and enactor of the practice or would an experienced practitioner be a more reliable partner in this construction?” (p. 391). I would describe myself as an experienced teacher of reform mathematics and an inexperienced teacher of mathematics for social justice with a desire try this approach to mathematics education, thus making me “well equipped” to fill the role of teacher in this study. Regarding my position as a researcher, I may not have been the best equipped to develop and enact this study, but given the resources and expertise of those surrounding me in the university that I am associated with positioned me as sufficiently equipped to engage in this work.

Ball’s (2000) third question asks: “…is what the researcher wants to know uniquely accessible from the inside or would an outsider be able to access this issue as well, or perhaps better?” (p. 391). From the work of Lampert (2001) and Heaton (2000) it can be seen that there is something to be gained by having a teacher critically examine her or his own practice. And in my time as an in-service teacher I was constantly examining and modifying my practice to better meet the needs of my students and my responsibilities as their teacher. That experience was primarily concerned with identifying areas of struggle and reacting accordingly, and what I added to do this study is the act of documenting the experience. Admittedly, a better situation for this study could be to have a paired examination of the teaching practice with myself examining from the inside and someone else examining from the outside. But given the scarcity of resources and the scale of this study this ideal situation was not possible to realize.

Lastly, Ball (2000) poses: “…is the question at hand one in which other scholars have an interest, or should have an interest, and if so, will probing the inside of a particular design offer perspectives crucial to a larger discourse?” (p. 391). In addition to what I have stated previously, the Diversity in Mathematics Education Center for Learning and Teaching suggests that, “More work is needed in this area to see what teachers struggle with as they learn to teach mathematics for social justice…” (2007, p. 420). If this approach to mathematics is at all fruitful in its attempts to address inequities within the classroom and in the broader world, then understanding the struggles of teachers attempting this approach is a worthwhile and necessary endeavor. In sum, I would argue that capturing the struggle of a teacher trying to engage in a new pedagogy, specifically this approach to mathematics education is a valid candidate for an insider’s perspective.
Chapter 6: Equity and Diversity

The data sources included student products, transcribed audio teacher journal (Cochran-Smith & Lytle, 1993), and classroom video recordings. Analysis of the transcribed data called on the tradition of grounded theory (Corbin & Strauss, 2008; Emerson, Fretz, & Shaw, 1995). Open coding was used to identify units within the transcript that were associated with perceived struggle within the class period. A second pass allowed for refining and categorizing the specific areas of struggle, with a third pass allowing for themes to emerge from the coded data. I compared the themes from the transcript data with the student product data looking for areas of agreement.

Results and Discussion

…if we are looking at the three C’s of classical, critical, and community, I don’t think I did that.

Audio journal excerpt from 6.2.2009

The above quote was recorded immediately after my last day of teaching and refers to whether or not what happened in the classroom could be defined as teaching mathematics for social justice and suggests the frustration I had over what had occurred during the six-day lesson. The analysis of the data revealed poorly defined tasks that assumed students would “study” (Lampert, 2001) rather than explicitly designing tasks where students would need to study. The most troubling problem I encountered, was the scarcity of mathematics being used within the student products, thus lack of evidence demonstrating students learning of the mathematical objectives.

Given the problems experienced in this lesson, what improvements can be made for the next attempt? Or what could practitioners or teacher educators take away from this experience if they were to either promote or attempt this approach to mathematics education? I propose adapting the framework to better fit the demands of teaching mathematics with and for social justice and better define the learners of mathematics for social justice.

In the students’ final products there was a low level of fidelity between the intended content to be learned and the level of demonstration in the products. Previously in this paper, I proposed that the notion of content within the problem space of teaching be expanded to contain the classical, critical and community components proposed by teaching mathematics for social justice, which is also what is being assessed within the product component. I now propose that the three components extend into other design elements of the framework. Instead of merely developing a learning profile of a student, a teacher should gauge the students’ aptitude for the various components of knowledge suggested by teaching mathematics for social justice. What is the collective knowledge about the community context? What perspectives have students considered in thinking about the topic? What positions do students hold? How could mathematics be used to learn more about the topic? These are all questions that when answered would create a classroom profile that would better inform the lesson design, which leads me to discussing process. Instead of defining students as learners from a multiple intelligence perspective (Gardner, 1993) as suggested by Udvari-Solner, et al. (2005), I propose defining students as learners of mathematics for social justice (see Figure 4). This redefining of the student may also serve to address some of the concerns practitioners or teacher educators may have with Gardner’s Multiple Intelligence theory, which has been criticized within the literature (Waterhouse, 2006).
Connected to the redefining of the learner is the problem of connecting tasks to a purpose. What I propose to answer that challenge is to be explicit in the process component of the lesson design as to how specific tasks will allow students to “study” the named content, and to be explicit with students over intent of the topic. This is similar to what Harel (2008) proposes, in his “necessity principle”, where a well designed problem will create a need to use certain mathematics, only I wish to extend it to include the two other components of knowledge proposed in teaching mathematics for social justice.

![Diagram of process components]

Figure 4. Defining students as learners of mathematics for social justice

Conclusion

This study was designed around an aspiration I had to teach mathematics with and for social justice. Given the problems that existed previously in the literature concerning in-service teachers attempting to teach mathematics for social justice I made an effort to address those problems using the Universal Design Process. Taking an insider’s perspective, I documented my experience in an attempt to define some of the problems associated with taking such an approach towards mathematics education. What resulted was a different way of defining students as learners of mathematics for social justice and a retooled framework that utilizes this different interpretation of students and aims to be explicit in how students are to engage with and learn all of the components of content that teaching mathematics for social justice entails. This framework should aid me in future explorations of the challenges of teaching mathematics with and for social justice within contexts not traditionally represented in the literature. It is also my desire that the struggles that I experienced may provide some insight for practitioners and teacher educators wanting to improve classroom practice toward something more just.

TEACHERS DEVELOPING MATHEMATICS DISCOURSE COMMUNITIES WITH LATINAS/OS

Craig Willey
University of Illinois at Chicago
cwille3@uic.edu

In the U.S., more and more teachers find Latinas/os in their classrooms. Yet, few are adequately prepared, both academically and socially, to address the unique strengths and needs of this growing population. This paper depicts the journey of a middle grades teacher as she navigates the complex reality of the mathematics teaching and learning process with linguistically diverse students. The concept of Mathematics Discourse Communities is introduced and elaborated to highlight the critical role of language development in the mathematics classroom, particularly how it conveys beliefs, values, and meanings surrounding students’ ability to do and be successful with mathematics.

Introduction

For roughly the past 25 years, there has been much discussion around and research conducted on the role of language in mathematics education (Schleppegrell, 2007). The interest in mathematical talk was accelerated with the inclusion of “Communication” as a standard by the National Council of Teachers of Mathematics (NCTM, 1989). Communication, however, has often been narrowly conceived as “talk about mathematics” (O’Connor, 1998). Recent texts addressing the mathematics teaching and learning of English Language Learners (ELLs) present the role of language in mathematics learning in relatively simple ways that do not reflect the complex social dynamics that impact language use and development (e.g., Bresser, Melanese, & Sphar, 2009). It has become clear that new perspectives are needed on the way that language and literacy intersect with mathematics teaching and learning. Language, or mathematics discourse, can no longer be thought of merely as a mechanism to express mathematical thinking.

At the same time, discussions of Latinas/os in education inherently involve issues of language given their affiliation with Spanish. While many Latinas/os are native English speakers, the majority is not (U.S. Census Bureau, 2005). Therefore, millions of Latinas/os enter schools with linguistic skills that are largely not valued or seen as resources by schools. In classrooms across the country, their “English learning” status is seen as an obstacle, a flaw that requires intense, compensatory attention to “fix” (Ruiz, 1984). Often times, the consequence of this position is to design learning environments that emphasize remedial skills, positioning English learners to fall further behind (Lipman, 2004). A preoccupation with learning English becomes the priority above all else (Gutiérrez, Asato, Pacheco, Moll, Olson, Horng, Ruiz, García, & McCarty, 2002).

The serious issue of underachievement in mathematics among Latina/o students calls for a re-evaluation of our orientations towards Latina/o learners, our conceptions of the intersection of mathematics and language, and the alignment of our mathematical teaching methods with these realities. A focus on how mathematics teachers create and develop Mathematics Discourse Communities (MDCs) has the potential to address all three of these elements.

The primary question I aim to address is: How do monolingual middle school teachers develop and utilize MDCs with Latina/o students? More specifically, what issues and challenges (e.g. sociopolitical, institutional, pedagogical, curricular) surround the teachers’ development and
utilization of MDCs? In this paper, I will elaborate upon the concept of MDCs, describe the context of the study, and provide a vignette of a teacher. The vignette will reveal how the teacher perceives and addresses the unique strengths and needs of bilingual learners in mathematics class. An analysis of the data follows the vignette. Finally, I will outline the implications of these findings and offer recommendations for practitioners and researchers.

**Theoretical Framework**

Studying the development of MDCs among Latinas/os is important not only to “see” how they are socialized to and within the discipline of mathematics, but also to see how other realms of schooling intersect with the mathematics teaching and learning process. Despite common belief, mathematics is not an isolated field of study that produces an objective skill base with which students should walk away; rather, it is embedded in a complex, multi-dimensional social web of values, ideologies, and modes of operating. The teacher is the primary – though not exclusive – vehicle through which these (dominant) values, ideologies, and modes of operating are brought into classroom and transmitted to the students. However, students are agentive (not passive in the learning process) and unique (when compared to one another), and they, too, will bring unique perspectives forth in the mathematics learning process. Examining MDCs with Latinas/os will illuminate the points of contention and difference amongst students and between the students and teacher and how these contentious spaces lead to (mathematics) learning (Gutiérrez, Baquedano-López, & Tejeda, 1999) or alienation (Gee, 2004).

Understanding that language is unique to a particular social setting, Gee (1996) introduced the notion of Discourses (with a capital D). Discourses are:

ways of behaving, interacting, valuing, thinking, believing, speaking, and often reading and writing that are accepted as instantiations of particular roles (or ‘types of people’) by specific groups of people, whether families of a certain sort, bikers of a certain sort, business people of a certain sort, church members of a certain sort, African-Americans of a certain sort, women or men of a certain sort, and so on through a very long list. Discourses are ways of being ‘people like us’. They are ‘ways of being in the world’; they are ‘forms of life’. They are, thus, always and everywhere social and products of social histories (p. viii).

Discourses, Gee argues, include much more than language and should be appreciated in its social context. Consequently, when investigating the role of language in any context, we cannot focus on language alone.

From this perspective, mathematics classrooms inherently maintain a unique Discourse community, a MDC. When combined with the work done on cultural social practices (e.g. Gee, 2004; Rogoff, 2008), the power of Discourse communities to socialize youth becomes apparent. Given that Latinas/os largely are not finding success in mathematics, examining the MDCs in which they learn becomes all the more necessary and urgent. Schieffelin and Ochs (1986) put forth that, in terms of language, there are two, concurrent socialization processes; “socialization through the use of language and socialization to use language” (p. 163). In other words, we not only learn language through social interactions, but are also socialized into particular communities of practice (Wenger, 1998) through particular language practices, or Discourses. Furthermore, membership in these particular Discourse communities is intimately connected to one’s identity (Wortham, 2006). Martin (2000) writes: “...it is my firm belief that detailed
analyses of mathematics socialization and identity – and the multiple contexts that affect them – offer the best hope for understanding long-standing achievement and persistence problems” (p. 186).

The focus of this investigation is on the teacher’s role in developing MDCs. MDCs involve ways of being, thinking, and speaking that are unique to a mathematics environment. While MDCs refer to the participants, the setting, and the interactions within the setting and between the participants, the process of being apprenticed into the specialized community can be thought of as socialization. The teacher, being the person of authority, is instrumental in the mathematics socialization process. Each teacher, as a result of their particular beliefs, values, and experiences, initiates the mathematics teaching and learning process in a unique way, and students interact with this socialization process incurring mixed results (in terms of affiliation with mathematics, for example) (Martin, 2000).

Gee (1996) also argues that classroom discourse is not a discrete feature of the classroom experience, but rather is inextricably and intimately connected to the particular ways one ought to act, think, believe, and value, with respect to a particular community. In mathematics, Franke, Kazemi & Battey (2007) contend that “students ways of being and interacting in classrooms impact not only their mathematical thinking but also their own sense of their ability to do and persist with mathematics, the way they are viewed as competent in mathematics, and their ability to perform successfully in school” (p. 226). From this perspective, language is more central to mathematics learning outcomes than previously thought. Accordingly, attention should be focused on how language interacts with other dynamics in MDCs. The need to study mathematics discourse, as it is developed in particular communities of practice (Wenger, 1998), becomes even more critical.

**Potential Indicators of Mathematics Discourse Communities**

While Mathematics Discourse Communities can be indexed by an infinite array of words, gestures, and actions, it is useful to articulate some of the more discrete indicators that play a major role in establishing distinct MDCs. These indicators are meant only to provide the reader a clearer picture of the way the two participants’ view and convey the mathematics teaching and learning process, specifically with Latina/o learners. Table 1 below outlines some of the themes that emerged repeatedly throughout the year and contributed to the respective Mathematics Discourse Communities established by each teacher.

**Context of Investigation**

The data presented here is part of a larger study examining the practices of two teachers, Ms. Hendrix and Mrs. Lenihan, who teach at the same school, Southwest Elementary School. Southwest is located on the southwest side of a very large, Midwestern city. Of the 1300 students, approximately 70% of the students are Hispanic, 15% White, and 15% African American. Of the “White” demographic group, the majority is of Middle Eastern descent. 85% of students qualify for free or reduced-cost lunch, and 30% of students are enrolled in the bilingual or ESL program (though probably 75% of students are native speakers of a language other than English). I have
known the two teachers professionally for two years, because I have been working with them in their classrooms and have had them as students in Masters courses at the university.

The data consists of fieldnotes, audio recordings of planning sessions and interviews, and video recordings of lessons. Collaborative planning sessions (the two teachers and I) took place once-per-week. This planning session eventually evolved into sessions where we watched footage from past lessons and discussed what transpired and what might be done to improve upon lessons. The teachers identified two classes on which they wanted to focus. For each teacher, one of those classes was the English Language Learner (ELL) class. Per administrative decision, the students scoring lowest on language proficiency assessments were grouped into one class. In 8th grade, the “ELLS” were prohibited from enrolling in the Algebra class, which is the other 8th grade section on which we focused our attention. The four classes were videotaped about twice-per-week.

For data analysis, I used two approaches to arrive at appropriate and accurate claims about the phenomenon of my investigation: grounded theory and critical discourse analysis. Grounded theory (Corbin & Strauss, 2008) was utilized to isolate the most important themes that surfaced in the data. These themes resulted from an ongoing analysis of the empirical data and are developed in concert with the theoretical lens through which the data was evaluated.

Because of the intimate relationship between language and ideology, created through sociohistorical interactions, discourse needs to be analyzed in a particular way. Critical discourse analysis aims to answer that call. Traditionally, most discourse analyses have only considered the literal value of words; that is, what can be seen or heard in this moment. Gutiérrez and Stone (2000), however, argue for a critical discourse analysis that accounts for the vertical text, or the diachronic history of a text, which considers the sociohistorical context that informs and supplements what is being said.

**Vignettes**

Mrs. Lenihan teaches mathematics to all of the 7th grade students. Each year, she is also responsible for teaching either Language Arts (essentially, vocabulary development) or writing to her homeroom class. Mrs. Lenihan is in her third year at Southwest, and her fourth year overall. She is a young, White, energetic, monolingual teacher who completed her teacher preparation at a well-known, local private university. She often speaks of trying to create a classroom that is “student-centered.” As a result, students’ desks are arranged in clusters, and on most days, the students are given an activity in which they are to work with their groups. Though she has access to traditional mathematics textbooks, she chooses not to use them with her classes. Instead, she strives to develop meaningful mathematics lessons that are project-based and grounded, as much as possible, in the lived experiences of her students.

Mrs. Lenihan often remarks about the importance of being able to communicate mathematically. For the past two years, she has attempted to develop her students’ ability to write proficiently about mathematics problem-solving activities. Her motivation for this goal is largely rooted in the state’s assessment program, which requires students to respond to multiple “extended response” items. Mrs. Lenihan has developed an extended response protocol and regularly draws on past test questions in order to help her students improve their mathematics writing skills.

Also, Mrs. Lenihan tries to cover the 7th grade mathematics topics through projects. For example, she has designed a lengthy project called the Dream Home Project to connect many concepts, such as measurement, area and perimeter of polygons, surface area, proportional

---

reasoning, and cost formulas. Not only does this project activate students’ creativity and engage students who might otherwise not fully engage in mathematical tasks, it is successful in tapping into family resources, or funds of knowledge, as students frequently rely on parents and other family members to help them through the complex process of envisioning, designing, constructing, and decorating their Dream Homes. Typically, the project is completed in pairs or groups of three, though working alone is an acceptable option.

The students reported that the Dream Home Project helped them master particular skills. For example, the students overwhelming claimed that this project allowed them to learn well how to measure with a ruler. Surprised that they had not learned this skill in the primary grades, I asked them to share their experiences with measurement in the elementary grades and explain how this measuring in the Dream Home Project was different. One student responded:

*When we were in elementary school, we really didn’t measure things like we measure in 7th grade, like how do you use a quarter inch, or how do you use... We measured small things. The only time that we would measure things was on a test, or we’d just skim past it and that would be it.*

Mrs. Lenihan offered this evaluation of her students’ comments:

*I think what you’re getting at is when we measure something now, it has to make sense; it has to all go together. Maybe in previous years or when I gave a quiz, I would just put lines on it [to measure]. You could say, “Oh, that’s 1 ¼, or 2 inches, or 3 inches,” but [now] it has to make sense. If it didn’t [in the Dream Home Project], you knew your measurements weren’t right.*

This exchange uncovers an important distinction: teaching to cover topics and teaching for meaning. As it turns out, the students did have experiences measuring with a ruler. However, their experiences were likely limited to two dimensional shapes and test-like problems, activities that did not carry meaning when evaluated in light of their lived experiences. Mrs. Lenihan’s Dream Home Project intended to provide a significantly different context, an authentic problem-solving situation. The measurement tasks were embedded in a larger framework and enabled the students to make meaning of measurement as it related to their lived experiences or future lives. As one student put it: “I learned how to construct walls and use creativity and imagine things as though I were a real architect.”

Mrs. Lenihan developed another small project in which students identified their daily or weekly activities (in a bound unit of time) in order to examine the various representations of rational numbers (i.e., fractions, decimals, percents). The culminating activity of this project is to construct circle graphs representing the students’ various daily or weekly activities. While this idea is not necessarily unique to Mrs. Lenihan’s class, her theoretical approach to learning mathematics contrasts sharply from a teacher implementing reform-oriented curriculum through a traditional approach (see, for example, Brown, Pitvorec, Ditto, & Kelso, 2009).

Even though Mrs. Lenihan’s lessons often operate within a larger project, some are delivered more traditionally. Below is a depiction of a lesson delivered during the rational numbers project mentioned above:
As usual, the day begins with a warm-up. Mrs. Lenihan has worked hard to establish a routine in which students enter the room and immediately begin work on the warm-up. In order to institute this mathematics class norm, she walks around the room passing out tickets, which is part of a school-wide positive reinforcement program. At times, Mrs. Lenihan will also use tickets to reward students who have completed their homework. The tickets can later be redeemed for out-of-uniform passes, entry to holiday dances, or entered in a drawing for various prizes.

Concurrently, the following warm-up appears on the board:

Put the #’s in order from least to greatest: 8/3, 63/7, 0.25, 12½%

The students struggled with the meaning of 12½%. Many students argued that it equaled 1,250, apparently moving the decimal point two positions to the right. Mrs. Lenihan suggested that this equality did not logically make sense, and she asked the students to consider 12.5% “as a portion of a pizza.” The moment Mrs. Lenihan was about to say “pizza,” one student finished her thought with the word “whole,” but his appropriate use of mathematics language went left unacknowledged. Mrs. Lenihan quickly instructed the students to “discuss in their groups why 12.5% is less than 1.” After the two minutes and after she felt she had sufficiently convinced the students that 12.5% was a fractional part less than 1, Mrs. Lenihan offered the following summary:

L: So, 1,250 doesn’t make sense; neither does 12.5 pizzas. The decimal has to be less than 1.

Expressing frustration with this hurried process of ordering abstract numbers, one student commented:

St: It’s easier to do it on the board than talk about it.

Next, Mrs. Lenihan quickly moved on to the lesson of the day: converting fractional parts of a circle into percentage equivalents (e.g. 6/24 = ¼; ¼(360°) = 90°). She delivers this lesson in 4 or 5 minutes with the work-up from the previous class. Mrs. Lenihan talks very fast in an effort to complete this lesson and the rest of her objectives in the short 40-minute class period. She does not conduct any checks for understanding, as there is no time.

Analysis

While this is certainly only a snapshot of life in Mrs. Lenihan’s mathematics class, there are a number of themes that can be gleaned from these interactions. First, from dialoguing with Mrs. Lenihan and observing her class over the years, it is clear that she has wonderful intentions to maximize student engagement, provide plentiful opportunities for students to communicate (both in whole-class discussions and small group collaborations), and generally help students make meaning of mathematics concepts. However, there are institutional pressures that weigh on her (i.e. short class periods, frequent modifications of daily class schedules, obligatory external assessments, pressure to directly prepare students for what is typically on high-stakes assessments in an effort to raise test scores, etc.).

Mrs. Lenihan’s good intentions and corresponding instructional practices are compromised by these pressures. For example, the implications of short class periods are observable daily. Classes at Southwest are 40 minutes, with zero minutes to pass between classes, essentially leaving 37 minutes for instruction. In the instance above, when Mrs. Lenihan was about to say “pizza” and the student finished her thought with the word “whole,” Mrs. Lenihan may have missed an opportunity to capitalize on a brilliant contribution made by a student, but given the context, it is more likely that she felt hurried to move along. Moreover, Mrs. Lenihan frequently

has to end whole-class discussions abruptly, take over discussions for the purpose of making her point quickly, or carry over lessons to the following day. This results in a more disjointed flow of the curriculum (and pedagogy) and places the class behind their ideal pacing schedule.

Second, it has been my experience that ticket distribution for positive reinforcement campaigns and “character development” programs are wide-spread in urban schools. It is hard to criticize teachers’ efforts to make clear behavior expectations and class norms, and acknowledge those who successfully accomplish them. However, there seems to be an underlying objective to use the program to curb non-conforming behaviors and nudge less productive students to do more. Thus far, there is no evidence that shows that not giving these students tickets motivates them to change their ways. The implementation of this program raises questions about how we perceive particular students and what ought to be done to change students’ academic and behavioral patterns.

Third, the warm-up “problem” chosen by Mrs. Lenihan is decontextualized and illustrates how she has caved to pressures to familiarize students with test questions. By decontextualized, I mean that the “problem” only carries meaning to those with a firm understanding of rational numbers. Furthermore, only those students fluent in the discourse of rational numbers will be able to participate in sharing-out. With her students’ “achievement” in mind, she selected the item because she is aware that there is always a problem like this on the state’s standardized assessment. This type of “question”, however, does not work well if Mrs. Lenihan’s objective is for her students to cognitively understand the relationship between the different representations of rational numbers. The task makes it difficult to facilitate the learning of the concept, and as a result, the students struggled to make sense of the activity.

Finally, the student’s aside about the difficulty of talking about complex mathematical idea speaks both to the inadequacy of the warm-up problem as well as the lack of opportunities to engage in mathematical communication. While Mrs. Lenihan regularly incorporates opportunities to problem-solve collaboratively and negotiate meaning, communicating mathematically is a difficult norm to establish in a matter of months – especially if students have experienced years of mathematics instruction centered around teacher explanations. To her credit, Mrs. Lenihan continually aims to foster productive group dynamics and mathematical responses from her students that reflect the specialized language of mathematics.

Conclusions and Implications

There is consensus that the traditional methods of teaching mathematics are not sufficient to advance achievement among learners, especially the Latinas/os (e.g., Khisty & Willey, 2008). Given the persistent mis-education of Latinas/os and the corresponding social realities they experience (Gándara & Contreras, 2009), there is an urgent need to evaluate classroom learning from new perspectives. No longer can we examine and view the mathematics teaching and learning process with Latinas/os solely through a cognitive lens, as if learning can be defined by what the teacher says and how well the student’s brain absorbs the information. There is an emerging need to foreground particular components of the mathematics teaching and learning process, such as the role of language and the development of specialized discourse communities, the tools used to make sense of mathematics, and students’ participatory patterns, among others.

Paying attention to MDCs requires us to focus simultaneously on the overall mathematics classroom environment, embedded in a school context and nested in a sociopolitical reality, as well as the micro interactions that make up daily activities. Examining MDCs allows us to see the implicit and explicit messages conveyed to students about the discipline of mathematics and
the mathematics teaching and learning process. It allows us to identify what norms and mathematical obligations the teachers intend to establish in their classrooms. It will begin to answer Cobb, Gresalfi, & Hodge’s (2009) call to “understand not merely whether but why students have come to identify with their classroom obligations, are merely cooperative with the teacher, or are developing oppositional identities (p. 48).”

For teachers, reflecting on the community of practice(s) we establish makes evident to us what we believe about mathematics, how that manifests in classroom instruction and activities, and how easily our underlying beliefs and assumptions are portrayed in what we say and do. It will help us clarify what it is that we want our students to be able to do, important among them being able to seamlessly participate in sophisticated mathematics discourse communities. Utilizing the framework of MDCs will enable us to implement the strategies that promote productive micro interactions, ultimately achieving more of the results we desire. At the same time, it will help us weed out counter-productive assumptions – assumptions that contribute to the macro educational reality Latinas/os endure today.

sarah_berenson@uncg.edu

Girls on Track is a longitudinal study in its eleventh year, following over three hundred fast math track middle-school girls. Each cohort started with a summer math camp data collection via observations, surveys, content tests, school records, and interviews. Every several years we interviewed study participants about their current relationships with STEM disciplines, family dynamics, and career plans. This paper focuses on the significance of mathematics in the development of plans and dreams of four women from the first cohorts. These case studies are viewed against the backdrop of all study data. Over the years, our models became more centered on girls and their immediate communities and networks, rather than the institutional track. Roles of mathematics in the persistence of deeper meanings of women's lives are significantly more complex than sequential milestones in the linear school-to-career "pipeline" model.

Introduction

This paper centers on four case studies of women who were on the fast math track in middle school ten years ago. One of them is now a math major, two are in applied STEM fields, and one is a journalism major. We compare and contrast the view of STEM as a direct job goal, and education as a series of steps toward that goal through a narrowing, increasingly more challenging pipeline (Barker & Aspray, 2006; Blickenstaff, 2005; Stage & Maple, 1996), to the view of mathematics as a personal strength, an asset in a variety of shifting career roles, and a tool for constructing meaning (Belenky, McVicker Clinchy, Goldberger, & Tarule, 1986; Csikszentmihalyi, 2008; Jungwirth, 1993; Wenger, 1999). This paper is a step toward an integrated model connecting academic track point of view and personal and community significance of mathematics. Such a model can provide a greater diversity of perspectives in STEM education, and ultimately support better solutions of human problems through pedagogical developments.

Theoretical Background

The under-representation of women in science, technology, and engineering careers continues to be a big national concern (Barker & Aspray, 2006; National Research Council, 2001). In the nineties, the differences in elementary and middle school mathematical achievements between girls and boys, pronounced in earlier studies, ceased to be significant, as, for example, data from the Third International Science and Mathematics Study show (Beaton et al., 1996). However, girls do not persist at the same rate as boys in continuing their study of mathematics beyond middle school, taking less rigorous courses and leaving the pipeline leading into science, engineering, and technology field careers, with mathematics serving as a filter or a gatekeeper (Blickenstaff, 2005).

These and other reports cite the importance of rigorous high school mathematics as vital to improving the quality of the workforce for the twenty-first century, and call for increased intervention efforts that encourage girls and young women to select rigorous advanced mathematics courses beginning as early as middle school algebra and continuing through
calculus in high school. However, fewer studies are done about the meaning and significance of mathematics in the lives of girls and women (Jungwirth, 1993), and social structures outside of classes, such as "geek circles" (Varma, 2007) that may support STEM careers. This paper is an exploration of the significance of mathematics in the persistence of meaning threads in the first ten years since the middle school.

Four Cases And Their Threads of Meaning

From the pipeline point of view, Cara is the very model of a modern female STEM career woman, studying for a PhD in mathematics. Lorna is an example of someone who switched from a math path to an applied and traditionally female-oriented biomedics path, still staying close to STEM. Hellen selected hydrology, another STEM application, and Kelly dropped out of the fast math track and STEM career path, initially wanting to be a veterinary doctor, but by high school going into journalism. In this part of the paper, we explore the roles of STEM in some examples of personal meaning threads that emerged from these four cases. In the next part, we situate the threads within a model that comes from the larger study.

Cara: The Conceptual Architect

Cara is a poster woman for the math pipeline model. She is currently studying for her PhD in mathematics. In her undergraduate years, she took all available math courses at her institution, and obtained a math major and two STEM minors. In high school, Cara was taking all math courses earlier than the average, and at a more advanced level, which defined her as a fast math track student. She partially attributes the rather surprising fact that she never met a math teacher she did not like to always being in earlier, faster classes that tend to be assigned to better teachers. However, Cara experienced a switch in future job plans in high school, in a scenario not rare for girls that age (Blickenstaff, 2005): she did not like the math requirements of her chosen career. She wanted to be and prepared to be an architect, taking and enjoying AutoCAD classes. However, conversations with people from the field convinced her that architecture required "the wrong kind of math": a lot of tedious number crunching and memorization for field exams. She examined her strengths and decided to be a mathematics major, because she deemed she was stronger at conceptual understanding. Her current major is a very applied area of mathematical modeling, with prospective jobs in the private high-tech companies or a combination of private and academe research. This is the superficial story, however. The threads of meaning that emerged as interview data categories are the following.

Controlled information and communication. Cara is a family-centric, strongly religious person for whom obeying authority and controlling information and communication sphere is a matter of explicit attention and utmost importance. She would not take a programming class at school because of the immaturity of other students in it, for example. Likewise, she rejects much of social networking: "Everybody uses Facebook, so I would not." For Cara, mathematics is associated with a pure, controlled, conceptually advanced system she can embrace and follow in the company of a selective group of people. This thread is the reason Cara does not want to take an academe path, because she can't control who she will be teaching, and her past experiences clearly demonstrated teaching occasionally becomes rather unpleasant because of the randomness of students.

Close groups of geeky, serious friends became an integral part of this thread. Cara talked at length about following older friends' advice in choosing classes, the academic advisor, and leisure activities. She is an avid gamer, for example, and a path into web site programming, then

architecture, then mathematical modeling has been supported for her by gaming since she can remember herself. Gaming with friends, as a part of an exclusive, geek culture REF reinforces STEM orientation for Cara.

"I am very practical." Cara spends a lot of time carefully researching, planning and discussing with her network of family and trusted friends all matters of learning and future career. She selected her graduate advisor based on the fact he hooked every graduate student with a multitude of internships, providing job connections and opportunities from early on. Cara graduated with multiple minors by applying AP courses to her college work. She carefully selects professors for her classes, which, again, leads to "never met a math or science professor I did not like." This thread pulled Cara toward an advisor with a strong business network, and a career in the private sector.

Modeling. Far beyond being a mere future job, or even a career, modeling is a thread of meaning for Cara. In middle school, she and her friends made art, and she was the person creating web sites to host their art projects. She explained how building architectural constructions, using software, grew out of these early pursuits, and then modeling real life phenomena with mathematics was a continuation of the same thread. While architecture and web sites seem hands-on and visual, Cara approached web design from the coding rather than WYSIWYG perspective, and architecture from programming - so her "design" thread has been growing into the increasingly conceptual and mathematical direction of modeling.

Lorna: The Academic Caring

Lorna was going to be a mathematician or a math teacher, but higher-level math courses proved too abstract for her. She describes one class where she struggled and succeeded somewhat, but the next one "started with that proof that square root of three is irrational, and I had no idea how to even start, so I dropped the course and switched my major." She decided to switch to biomedics.

Parenting as teaching. In her interviews, Lorna talked about her mother in detail, tenderly remembering the many advanced, very pleasant academic interactions from her early childhood on. She describes her mother as very smart, despite having to support the family from the age of fifteen as a first-generation immigrant from India, and not getting a college education. When Lorna progressed into math courses beyond those her mother had before, their roles reversed, with Lorna teaching math to her mother as a way to understand it better. This may explain Lorna's success at landing a job at the Sylvan Learning center as a calculus tutor, with "everybody there at least twenty years older than I was." Lorna also sounded indignant (with apologies, catching herself at it) about parents of struggling school or college students not helping them better throughout their academic lives. She sees parenting as teaching, and teaching as so much related to caring as to be, metaphorically, parenting. She tutored relatively advanced math throughout high school, and chose the math major as a continuation of this "caring" thread.

As college mathematics became more abstract, Lorna could not assume this caring role anymore. She described her dismay at being able to understand material with some help from another student, but not having enough mastery over it to help others. While capable of being a math student, she was no longer in the position of "math parent" and therefore decided to change things around. Biomedics supports her image of "parenting" or "caring" through the participation in an advanced and sophisticated field.

There's nothing I can't do. Another defining thread in Lorna's life is her incredible assertiveness. For example, she described several instances of persevering through multiple
rejections while landing jobs as a young teen, and most recently finding a biomedics internship that took waiting by doors and multiple calls to five different professors repeatedly saying, "No." Lorna says, "There's nothing I can't do if I put my mind to it!" Her early childhood and teen years experiences with mathematics, especially tutoring, supported that image of assertiveness and power.

But what about dropping off the math track in college? Paradoxically, Lorna claims she wanted to do it to keep her feeling of power, including math power. The major switch had her take quite a few advanced science classes in her last college semesters, and she wanted to feel capable and confident, especially about mathematics involved. It was a challenge, but in ways appropriate for her personally. It is Lorna's self-confidence that kept her from continuing with the math major, which, given her previous track, she was likely quite capable of getting, just not in that parenting, helping, assertive manner that was so important for her.

**Hellen: The Art Of The Science**

Hellen fondly recalls doing math with her big brother when she was young, but back then, she wanted to be an entertainer. "Saturday Night Life people seemed so happy!" Starting from high school, though, she turned toward sciences, and is currently applying to enter a graduate school in hydrology. Hellen's threads of meaning reveal a surprising path toward science for her.

*Ownership through creativity.* Hellen is an outgoing, friendly person who smiles a lot. She mentioned how she can make others laugh, and how entertaining others was so important that she considered it as a career. But what really hit a chord with Hellen was designing her own science experiments. She specifically recalls a biology camp where she did this over several summers, and a school project about water quality that got her interested in that endeavor. Later, she liked classes where she could be creative about her assignments, making beautiful and meaningful outlines and working hard on presentations. For her, science is about design, it is a creative, almost humanistic endeavor. Theater is still her big hobby. Hellen was thrilled that at her graduate school interview, her writing skills were highly prized as something that will give her an edge as an applicant. She is looking forward to graduate school experiences being more open for that sort of creativity than undergraduate courses. Designing experiments is the thread that pulls Hellen toward STEM.

*Muti-generation networks.* Family and friends play a big role in Hellen's professional orientation. Her dad went to the science camp that somewhat determined her choice of subject. She mentioned keeping in touch with camp counselors, who were undergraduate students at a time, and following in their steps. Hellen kept connections with many of them, now advising her on the choice of a graduate school. Since her creativity, including scientific creativity, is also audience-oriented, the network thread plays a key role in pulling Hellen into the direction of a STEM career.

**Kelly: Stories With A Face**

Kelly studies to be a journalist, works as a journalist for several student organizations, and volunteers in various journalist capacities for friend and community projects. In the middle and high school, she wanted to be a veterinarian, but an experience with an internship made her realize it's not a job for her. However, anything and everything about journalism is tremendously satisfying. She wants to present important and interesting stories either through being a news anchor, or through investigative reporting. Are there any threads in Kelly's life related to mathematics? Here are two examples.

---

"People relate to my stories with a face" - Kelly talks about the importance of information being personal and human, delivered by someone listeners know, recognize, and trust. She thinks it is her particular cognitive strength to give stories a twist people appreciate and understand, and to present information in interesting ways. She works for days and weeks improving her videos, "But when you are done and there is three minutes of it, you can see a strong story." Visual and information literacy at this level, while not directly mathematical, is related to situated STEM skills.

"It takes a village." Kelly is a highly networked woman, she has many friends and is a member and a leader of many student organizations. Mathematics was always challenging for her, took more time, and required more efforts than other subjects. School mathematics was also separate from life mathematics such as finances, and not something ever, ever used. Kelly's family, however, rallied around her, helped her when they could and hired tutors when they could not. Kelly noted the very positive feeling that she was constantly supported in challenging and extrinsic hardships, and able to pass these gatekeepers through collective efforts of her family and her own hard work. In a sense, mathematics was something to rally against.

Situated complexity. As a possibility not yet set in stone, Kelly considers going into investigative reporting, and she discusses at length the joys of seeing unexpected twists in stories, playing devil's advocate and otherwise deeply interacting with her daily subject matter. Undoubtedly, this requires logical abilities and very likely at least some statistics and data analysis, but Kelly does not see this as mathematics (Lave & Wenger, 1991). She does acknowledge that her work as a club treasurer involves math, but again, she sees that as very different from "school math" (Hoyles, Noss, & Pozzi, 2001). The use of technology and software she describes in her award-winning short video work is sophisticated too, but mathematics in it is very much applied. Kelly's thread of complexity in everything she does suggest high logic abilities, without an attempt to explicate them or to apply them to any STEM direction.

From The Leaky Pipeline To Persistent Threads of Meaning

Leaky Pipeline

Many studies considering women in STEM careers adopt the "leaky pipeline" perspective, starting somewhere around the first Algebra classes and ending in PhD degrees, with many women not making it all the way through (Barker & Aspray, 2006; Blickenstaff, 2005; Stage & Maple, 1996). We summarized the characteristics of several pipeline models from the literature:

- The pipeline is linear, with no turns, pauses or detours.
- People who drop out of the pipeline are gone forever.
- Milestones within the pipeline, such as classes or internships, are motivated by being prerequisites to further milestones.

Threads of meaning

Yet this picture does not seem to match women's own views on meaning and significance of STEM in their lives, or our analysis of the same when we adopt a perspective centered on women rather than classes and institutions. From case studies, as well as quantitative analysis of larger samples of our longitudinal data, emerge individual threads and thread categories of personal meaning that form each woman's path, and in which STEM has varied significance.

Cara's controlled information and communication and "I am very practical," Lorna's parenting as teaching, Hellen's multi-generation network, and Kelly's "it takes a village" threads belong to the category of PLNs, personal learning networks (Siemens, 2005) that start with
families, and develop to include friends and eventually colleagues. These threads also belong to the **Parent Power** category. We found that threads from these intersecting categories had a strong impact on STEM tracks of all study participants.

Cara's *modeling*, Lorna's *ownership through creativity*, and Kelly's *situated complexity* are examples from the thread category of **content-specific ways of knowing** (Belenky et al., 1986; Lave & Wenger, 1991) These content threads may not tie with particular academic or curricular subjects, but are overarching themes or topics important in each person's life and developing from naive to sophisticated forms as the person matures. The pedagogical practice of cross-disciplinary unit studies (McColskey, Parke, Furtak, & Butler, 2003) is connected to this category.

Cara's *"I am very practical,*" Lorna's *"There is nothing I can't do,*" Hellen's *ownership through creativity* and Kelly's *"People relate to my stories with a face"* are examples of women's awareness and focus of their **personalities** in career paths. STEM skills have particular, complex relationships with personality traits, a topic women discuss at length in their interviews.

Lorna's *parenting as teaching* and *"There's nothing I can't do,"* and Kelly's *"People relate to my stories with a face"* are examples from the **caring and helping** thread category. While studies show that women in the academe are not any more likely than men to find job satisfaction in caring or helping roles rather than research roles within the field (Stage & Maple, 1996), girls in our study integrated caring into career selection and explained how they view their work as helping people and the world.

Cara's *modeling* and Kelly's *situated complexity* belong to the category defined by the **abstract-applied** gradient. The need for grand causes and abstract concepts, or the need to immediately see results of pursuit are expressed in, and supported by, different approaches to STEM.

### Conclusions

We would like to finish with a quote about life dreams from Janush Korczak, a Polish pedagogue and a champion of children's rights (Korczak, 1990):

> When we don't have enough material to reason, there appears a poetic meaning of what little we have. Into a dream we transform the feelings that don't get realized in reality. The dream becomes our life's program. If we only knew how to decipher it, we would see that dreams do come true.

> If a poor boy dreams of being a doctor and becomes a nurse, he fulfilled his life's program. If he dreams about being rich, but dies on the bare mattress, his dream did not come true only superficially: after all, he did not dream about hard work toward a goal, but about squandering money away; he dreamed about champagne, but drank moonshine; dreamed about salons, but had bar brawls; wanted to throw gold to the wind, but wasted coppers. The other wanted to be a priest, but became a teacher or simply a groundskeeper, but, being a teacher, he's a priest, being a groundskeeper, he's a priest.

> She wanted to be a terrible queen, and is she not a tyrant to her husband and children, having married a low-level clerk? Another wanted to be a beloved queen, and is she not ruling a folk school? The third one wanted to become a great queen, and is her name not covered in glory, the name of a wonderful, extraordinary seamstress or matron? (p.112)
While the dreams and plans change and transform, the personal meaning threads, and the corresponding significance of STEM in threads and thread categories are continuous and persist through time. Examining these meanings and significances at the level of individuals and their networks can prove fruitful in understanding how to support women in STEM careers.

UNDERSTANDING THE CONSTRUCTIONS OF MATHEMATICS AND RACIAL IDENTITIES OF BLACK BOYS WHO ARE SUCCESSFUL WITH SCHOOL MATHEMATICS

Robert Q. Berry, III  Kateri Thunder  Oren L. McClain
University of Virginia  University of Virginia  University of Virginia
robertberry@virginia.edu  thunder@virginia.edu  oren@virginia.edu

This study investigated the mathematics and racial identities of Black 5th through 7th grade boys who attend school in a southern rural school division. The data pool consisted of focus group interviews, mathematics autobiographies, review of academic records, and observations. Four factors positively contributed to mathematics identity: (a) the development of computational fluency by third grade, (b) extrinsic recognitions, (c) relational connections, and (d) engagement with the unique qualities of mathematics. For these boys, racial identity in school is connected to perceptions of others’ school engagement; this sense of “otherness” led to a redefinition of their own mathematics and racial identities.

Introduction

The success of Black boys in mathematics receives little attention, although there is a vast amount of literature that describes the academic achievement and schooling experiences of Black boys in terms of failure (Thompson & Lewis, 2005). Despite the highly documented underachievement and low-level course enrollment patterns of Black boys, not all of them achieve at low levels. In fact, there are Black boys who stand in opposition to the literature that documents their failure and underachievement. Black boys’ mathematics identities are shaped by culture, community, and experiences with mathematics (Berry, 2003 & 2008). The development of a positive mathematics identity is essential towards helping boys sustain an interest in mathematics and develop persistence with mathematics. Examining the perceptions of successful Black boys is critical to identifying the strengths, skills, and factors that promote their success.

This study investigated the constructions of mathematics and racial identities among thirty-two Black 5th through 7th grade boys who are considered successful in school mathematics as measured by high pass rates on the state standardized mathematics assessments and above average grades in mathematics. The purpose of this phenomenological study is to investigate mathematics identity development of Black boys and explore how racial identity interacts with mathematics identity.

Theoretical Perspective

Martin (2009) contends that mathematics learning and participation should be conceptualized as “racialized forms of experience” that are structured by the relations of race that exist in the larger society (Martin, 2009; p. 299). This paper considers two constructs of Martin’s framework: conceptualization of race and conceptualization of learners. The conceptualization of race focuses on race as a sociopolitical construction that is historically contingent. Conceptualization of learners considers the negotiated nature of identity with respect to mathematics by asking, “What does it mean to be Black in the context of mathematics learning?” We sought to understand how Black boys conceptualized race in the context of learning mathematics and how they negotiated their identities as learners of mathematics. This study defined mathematics identity as one’s belief about (a) their ability to do mathematics, (b) the
significance of mathematical knowledge, (c) the opportunities and barriers to enter mathematics fields, and (d) the motivation and persistence needed to obtain mathematics knowledge (Martin, 2007).

Nasir, McLaughlin, and Jones’ (2009) reviewed the research on the relations between racial identities of Black students and school-related outcomes to find that the literature indicated three conflicting findings. First, findings indicated that when students hold strong identities as Blacks, their academic achievement suffers and/or academic identification decreases (Fordham, 1996; Noguera, 2003; Osborne, 1997). Second, other findings indicated the opposite of the first finding, suggesting that racial identity is a protective factor for education for Blacks and serves as a buffer for racial discrimination (Chavous et al., 2003; Oyserman, Harrison, & Bybee, 2001; Sellers, Copeland-Linder, Martin, & Lewis, 2006; Wong, Eccles, Sameroff, 2003). The third finding suggested that there is no linear relationship between racial identity and academic outcomes for Black students and that it varies depending on the nature of Black identity (Carter 2005; Chavous et al., 2003, Harper & Tuckerman, 2006; Sellers, Chavous, & Cooke, 1998). Nasir, McLaughlin and Jones (2009) offered two explanations for these mixed findings: (1) researchers have used various definitions of racial identities; consequently, this lack of consensus may contribute to differential findings; (2) difference in racial identity is constructed in local contexts; thus being Black in a southern rural town may be different than being Black in a large urban city. This study defines racial identity as the meanings the boys assign to themselves and the Black racial group.

Research on the mathematics and racial identities of Black boys who are successful with school mathematics suggest intrinsic and extrinsic factors contribute towards the development of Black boys identities. In a study focusing on racial and mathematics identities of middle school Black boys who are successful with school mathematics, Berry and McClain (2009) found three overlapping components that contributed to the development of a positive mathematics identity: (a) motivation to succeed in mathematics; (b) strong beliefs in their mathematical ability; and (c) caring mathematics teachers. Additionally, Berry and McClain (2009) found that parents of Black boys engaged in racial socialization practices designed to help their sons’ manage in a world where racial prejudice and discrimination are likely to be aimed at them. The boys received explicit messages about racism and messages of expectations concerning high levels of mathematics and academic achievement.

Research Questions

1. How do Black 5th through 7th grade boys who are considered successful in school mathematics construct their mathematics identity?
2. How do Black 5th through 7th grade boys who are considered successful in school mathematics construct their racial identity within the context of learning mathematics in a rural school division?
3. What is the relationship between construction of mathematics identity and racial identity amongst Black 5th through 7th grade boys who are considered successful in school mathematics?

Methodology

Participants

The participant pool consisted of 32 rising fifth through seventh grade Black boys who participated in a two-week summer program focusing on algebraic reasoning and problem
solving. Thirteen rising seventh graders, 12 rising sixth graders, and 7 rising fifth graders attended the summer program in which they were the only attendees. The boys were selected for the program based on their potential for placement or their current placement in advanced mathematics courses. All of the boys earned or were close to an “advance pass” designation on the state standardized test. All of the boys attend schools in the same school division in a southern state in which Black students made up approximately 12% of the student population.

Data Collection

For this study, we employed focus group interviews, boys’ mathematics autobiographies, review of documents (grades, test scores, and teachers comments), and observations. The purpose of the focus group interviews was to gain insights into the boys’ experiences and perceptions. For example, one of the focus group questions was: “When you think of someone who is good at mathematics, what characteristics do they have?” Fourteen boys participated in one of three focus group interviews (four to five boys per focus group) that lasted about 45 minutes. A focus group protocol was used to maintain consistency across all groups. All focus group interviews were video-recorded and transcribed. The purpose of the mathematics autobiography was to engage the boys in thinking about their experiences with school mathematics, document important mathematical milestones, and gain a sense of how the boys perceive themselves as learners of mathematics. The boys’ student records (courses, grades, standardized test scores, teacher comments, and exceptionality status) were reviewed for placement in the summer program, to get a sense of the boys’ mathematical history, and to verify previously collected data. Informal daily observations during the two-week summer program provided insights into the boys’ interactions with their peers and with their teacher.

Data Analysis

Analysis occurred after the two-week summer program because the authors were also the instructors of the summer program. The video-recording was transcribed and copies of the mathematics autobiographies were made so that memoing could occur within the transcription and the mathematics autobiographies. Memoing allowed the authors to do initial coding. The codes used during the memoing came from the literature. One of the initial codes used was “beliefs about the significance of mathematical knowledge” drawn from Martin’s (2007) research on mathematics identity development. For each code, definitions were created so the codes could be consistently used throughout the analysis of data. Once initial coding was completed, the data was reread and re-coded to verify the initial coding and to ensure consistency. After this, the database was sorted by codes then reread and re-coded. At this point, we looked for themes within each section (code) to see if there were dimensions that required the data to be further discriminated. Through this process, themes emerged from the data. From this categorization and classification of the data, we described the findings.

Findings

Three themes arose from the data and presented according to the three research questions: (a) construction of their mathematics identity, (b) construction of their racial identity, and (c) the relationship between these two processes to redefine their own racial and mathematics identity. Four factors positively contributed to mathematics identity: (a) the development of computational fluency by third grade, (b) extrinsic recognition in the form of grades, standardized test scores, tracking, and gifted identification, (c) relational connections between
teachers, families, and out-of school activities, and (d) engagement with the unique qualities of mathematics. For the boys in this study, racial identity in school is connected to perceptions of other students’ school engagement. The interaction between the boys’ racial and mathematics identity led to a sense of “otherness” and resulted in a redefinition of their own racial and mathematics identity.

**Four Factors Positively Contributed to Mathematics Identity**

*The development of computational fluency by third grade.* The boys articulated computational fluency as a characteristic of people who are good at math. During focus groups, several boys described this attribute similarly. For example Tinashe stated, “I think I’m good at math because there are some things that I can get down quickly.” Fluency with mental mathematical strategies and computing large numbers was defined by boys as a significant characteristic for mathematics achievement. As the boys wrote their mathematics autobiographies, they described computational fluency as an attribute that contributed positively to their mathematics identity. Their speed and accuracy with mathematics operations initially drew boys to mathematics. For most boys, they recognized computational fluency as a positive factor contributing to their mathematics identity in third grade. Derrell and Jamal’s voices represent this recognition: “I was first drawn to mathematics in 3rd grade. My whole grade was learning multiplication, decimals, and fraction… I picked up on it very quickly. I finished my work quicker and faster than everyone so I would have to read” (Derrell, Mathematics Autobiography); “I was drawn to math when I was in third grade. What drew me to math was realizing that I was really good at it. I saw that I could solve math problems faster than I could solve problems in any other subjects” (Jamal, Mathematics Autobiography).

*Extrinsic recognition.* The boys utilized extrinsic recognition as a factor in contributing to their mathematical identity. Several outside authorities such as grades, standardized test scores, tracking, and gifted identification provided the boys with proof of their mathematical success. For example, Vince stated, “…because every time I answer a question or something, well not every time but most of the time, I get the question right. And most of the time at school or math tests I usually get A’s and B’s every time.” Similarly, Calvon, stated, “Yeah because…in sixth grade we had a lot of tests, and I got A’s and B’s on them. And I was a really good student, and I had A’s on my report card in math.” School performance was a defining attribute of their mathematics identity. The boys shared the standard of A’s and B’s on tests and report cards to demonstrate success in mathematics. Other boys referenced their scores on the standardized state mathematics test.

The boys’ awareness of tracking in advanced mathematics classes and gifted identification in mathematics also contributed to their mathematics identity. Zuberi and Eddison’s quotes are representative of the boys’ reflections about tracking and gifted identification: “I think I’m successful in mathematics because I’ve been in advanced math classes and I’ve done a lot of hard stuff…I was in it this year and I think last year and maybe third grade” (Zuberi, Focus Group) and “…because most of the time I’m good with numbers. And the past four years I think I’ve been in either advanced or advanced honors” (Eddison, Focus Group). The boys realized that being placed in advanced or gifted mathematics courses meant that others recognized them as successful in mathematics.

*Relational connections between teachers, families, and out-of school activities.* The boys’ relationships with their teachers, families, and out-of school activities contributed to their mathematics identity. In their mathematics autobiographies, many boys described their parents...
as having a significant impact on seeing themselves as successful at mathematics. For example, Geff wrote in his mathematics autobiography, “My mom actually was the first person to tell me I was good at math. I felt good because my mom told me it can lead to a good education.” Marcus described his parents’ support and extension of mathematical learning: “My dad is a math teacher so I learned most of the stuff I know from him. It felt fun because I was learning things I never knew. My dad helped me realize I was good at math. My best math teacher was my mom because I would come home not knowing what to do with my homework and my mom helped me.” These excerpts are representative of the significant role of families in positively impacting boys’ mathematics identity. Families provided positive reinforcement, motivation, and academic support as well as instilling a sense of the significance of mathematical knowledge for the boys’ educations and futures.

Connections with mathematics outside of school often created contexts for boys to construct positive mathematics identities. For example, Derrell described an out-of-school context in which his family enabled him to realize his positive mathematics identity: “I realized I was good at math when my mom, brother, sister, or grandparents were doing bills or taxes and needed to know simple multiplication like 8x8=64 and I knew the answer in one second...Also, everyone asked me, ‘How did you know this and that?’ That made me feel very happy.” The out-of-school activity of doing bills and taxes provided an opportunity for Derrell to demonstrate his computational fluency. His family’s praise initiated Derrell’s development of his positive mathematical identity. Beyond mere positive recognition of the boys’ mathematical abilities, these contexts provided opportunities for the boys to connect school mathematics with their outside-of-school lives and to experience additional success as mathematicians.

Relational connections with teachers contributed to the boys’ mathematics identity as the boys described individual mathematics teachers who helped them connect with mathematics in positive ways. The following excerpt from Rasheed’s mathematics autobiography is typical of boys’ positive descriptions of teachers:

> My mom and teachers helped me realize I was good at math. My best teacher was my fourth grade teacher, Mrs. Hebblethwaite. She was my best math teacher because she pushed me to the limit. She was a good math teacher. It was fun to be in her class because she always made math fun. She was different from my other teachers because she took time to explain and help me when I had hard work. (Mathematics Autobiography)

The boys described influential teachers, like Rasheed’s, who “made math really exciting” (Calvon, Mathematics Autobiography), “challenged” boys (Jamal, Mathematics Autobiography), “could be fun and could get you to do your work” (Reymond, Mathematics Autobiography), and “actually helped” boys understand mathematics (Vince, Mathematics Autobiography).

**Engagement with the unique qualities of mathematics.** The boys differentiated between the unique qualities of mathematics and other disciplines by describing the challenge of mathematics and their pride at persevering to completion. Jamal’s portrayal of mathematics is representative of boys’ comments:

> What I like about math is it’s kind of complicated, and I like, I want my work to be complicated so I can actually do better when I get to higher grades. And it feels like I finished something. It’s like when it’s hard, like when we were doing an engineering
project, I feel like I finished something really good, like I did a really good job with it. (Mathematics Autobiography)

The boys’ descriptions of mathematics included words like complicated, complex, challenging, and requiring concentration. The boys also described the distinctive ways mathematics problems engaged their thinking through problem solving, engaging interactively, utilizing multiple strategies, and making connections to other disciplines.

**Racial Identity In School Connected to Perceptions of Others’ School Engagement.**

The boys’ construction of racial identity in school was influenced by their perceptions of other students’ school engagement. The boys perceived that teachers treated groups of students differently, based on race, gender, or ability. The following focus group conversation is representative of these comments:

- **Damitri:** Some of the teachers. Like sometimes teachers give other kids more attention than other kids. Well it feels that way.
- **Keeshawn:** Yeah.
- **Damitri:** Like different races of kids. Yeah they favor kids. Well in my math class, my math teacher favored a couple of kids over me and a couple of my friends. Well when I’d like raise my hand when she’s working with some student and then she’d say, ‘I’ll come to you in a minute.’ And so she’d be like, ‘I’ll come to you after this student.’ And then she’d look at me and then walk to a different student and then go over and help them and then help me.
- **Keeshawn:** Yeah, it’s happened to me but not with race. It’s not about like your skin color or anything. It’s about like the people who usually get more questions right.
- **Damitri:** The smarter students or the ones they think are smarter.

Black boys were in the minority in these boys’ mathematics classes and schools. As a result, many boys felt isolated. One of the purposes of the summer program was to bring this group of Black boys together because many of them were the only Black boy in their mathematics class. For some boys, the feeling of isolationism created discomfort. Wynn and Kavion’s quotes represent the perceptions shared by boys during focus groups: “At my school really it matters what classes I’m in. I was the only Black who was in there the whole year. It’s better in the gifted classes because personally I think the teachers are nicer,” (Wynn, Focus Group); “I kind of feel uncomfortable in my school cuz…they wear shirts and it has [confederate flags] on it. It just makes me feel very uncomfortable. So when I see a whole group of them in the bathroom, I just don’t go. I just go back to my class,” (Kavion, Focus Group).

**A Sense of “Otherness” and Redefining Their Racial and Mathematics Identity**

As the boys connected racial identity with their perceptions of others’ school engagement, they made distinctions between other Black males in mathematics at their school and themselves. This sense of “otherness” caused many of the boys to reflect on how they perceive other Black boys and how others perceive them. The following focus group conversation is representative of the boys’ descriptions of other Black males in mathematics:

---

Jamal:  I think some African Americans just give up on math because they say they can’t do it and they don’t even try to learn. So I think that’s part of their parents talking to them.

Mateo:  I see that at my school too.

Jamal:  Yeah, some people are just trying to be cool.

*Echoes of yeah, yeah*

Jamal:  And then some people will pretend that they’re cool and not nerds and not answer questions.

Mateo:  I see that at my school.

Eddison:  Mostly they’re failing. They gave up.

Jamal:  Cuz like most of the black people in my grade they don’t have black friends so they would rather be cool cuz they think if you’re cool you might get more friends.

Mateo:  If you be yourself, you’ll get more friends.

Jamal:  I’m sometimes called nerd in my grade.

The boys described other Black boys as preferring to “show off” (Wynn and Kavion, Focus Group) or “be cool” (Jamal, Focus Group).

The boys also clarified that Black males can be successful in mathematics. Some boys described the perception of Black males’ lack of success in mathematics as a “negative stereotype” (Malcolm, Focus Group). For example, Calvon described this when he said, “I think like African Americans are good at math. It’s just that like some people like putting them down and like not making them feel good” (Calvon, Focus Group).

Collectively, the boys described people who are successful in mathematics as those who follow directions, persevere, collaborate, want to learn, meet challenges, and are smart. Boys contrasted these attributes with their perceptions of others’ school engagement. The interaction between boys’ racial and mathematics identity led to a sense of “otherness”. Keeshawn described the impact of his perception of others on his own mathematics identity:

I know that African American males aren’t usually, don’t achieve too well in math and stuff. But I feel that just because like statistics show that African Americans don’t do as well in math, don’t achieve more, I still feel that we can do good. It’s just statistics say most African American males, so that kind of makes me, that kind of gives me a boast. (Focus Group)

The boys used these perceptions to redefine their own racial and mathematics identity. Tinashe and Zaire’s quotes are typical of boys’ connections between attributes of mathematics success and their experiences with racial identity in school: “I think [being Black] hasn’t affected me because it doesn’t really matter what color I am... I’m addicted to math,” (Tinashe, Focus Group) and “[Being successful in mathematics] feels ok because some people think we’re actually, we’re smart,” (Zaire, Focus Group). The boys recognized important attributes in themselves that enabled them to be successful in mathematics.
Discussion and Recommendations

The boys in this study attended schools with a small percentage of Black students and most were the only Black male in their advanced mathematics classes. Understanding this context provides a lens of the developed sense of “otherness.” The perceptions of “otherness” allow these boys to engage in school differently from their own and others’ perceptions of how Black boys engage in schools. The perceptions of “otherness” shifted during the summer program because the boys were surrounded by other Black boys who were identified as smart in mathematics. Many of the boys saw this as an opportunity to engage with other boys by collaborating and challenging one another. The boys often position themselves in postures of confidence and challenge when solving mathematics problems. Teachers must understand the structure of the boys’ experiences to appreciate that such postures are not deficit nor defiant; rather, they are transferences from other settings. A study of transferences across settings may be necessary to broaden understandings of Black boys’ development of mathematics identity. Teachers’ knowledge and appreciation of the unique qualities of mathematics that attracted, motivated, and engaged these Black boys may provide them with a lens to identify mathematics problems that may positively impact the development of the boys’ mathematics identity. Also, the complexity and challenge of mathematics was one significant quality of mathematics that should not be ignored. Mathematics should not be simplified or dumbed-down but rather teachers should hold high expectations for their students to solve challenging and complex mathematics problems. This careful balance between creating a learning environment where challenging mathematics is accessible but without negating the challenge appears to be instrumental in promoting the boys’ positive mathematics identity.

Endnotes

1. We use the term Black because it represents broadly the boys in this study. Four of the boys are bi-racial (all have African American and White parents) and three boys are African.

This study investigated the nature of adult mathematics-related talk during free play with children between 18 and 39 month olds and whether the nature of the adult input depends on the child’s gender. Thirty-six parent-child dyads participated in a 30-minute free play session. The adult speech was transcribed and coded for mathematically-related input. Our findings suggest that parents talked more about numerical quantities (e.g., quantity words) and numerical relations (e.g., cardinality and transformation of numbers) than on mathematical attributes such as shape and color with their young children during their free play interactions in spite of the child’s gender.

Introduction

Difficulties in mathematics are widespread in many industrialized nations such as Canada and the United States. Children who are weak in basic arithmetic may not acquire the conceptual structures required for advanced mathematics, which serves as a gateway to careers in many disciplines. Development of counting is a critical pathway to learning about numbers. Counting weaknesses have been linked to mathematical difficulties later in formal schooling (e.g., Geary, 2003). Additionally, the informal acquisition of number concepts before children enter kindergarten has been found to be related to number knowledge development, which is a strong predictor of arithmetic achievement in first grade (Baker et al., 2002; National Mathematics Advisory Panel, 2008). Moreover, a children’s emergent mathematics competence in kindergarten has been found to be a stronger predictor of subsequent academic achievement than emergent reading competence (Duncan et al., 2007).

Much of the research on the development of numerical knowledge has focused on preschool-aged and kindergarten aged children with the objective of designing and setting the standards for early childhood mathematics curricula (e.g., Clements, Sarama, & DiBiase, 2004; Clements & Sarama, 2008; Starkey, Klein, & Wakeley, 2004). However, research in neuroscience has demonstrated that learning in the first three years of life sets the trajectory for a person’s subsequent capacity for learning (e.g., Greenough, 1997). Hence, it is important to investigate mathematics learning during the first three years of life in order to better understand factors that influence mathematical development. As such, more research is needed on young children’s daily numerical experiences in order to better understand how early home environment influences their acquisition of number knowledge (Sophian, 2009). Unlike language development, very few studies in mathematics development have examined the adult input that children receive at home on number concepts. The few existing studies using interviews and checklists suggest that parental mathematical input is related to four- and five-year-olds’ level of number knowledge, such as knowing differences in quantities and that numbers have magnitudes (e.g., Saxe et al., 1987; Blevins-Knabe & Musun-Miller, 1996; LeFevre, Clarke & Stringer, 2002). The current study investigated the nature of adult mathematics-related input (such as the use of count or quantitative words) in the facilitating the acquisition of number concepts between 18- and 39-month-olds in a naturalistic free play session. Furthermore, we examined whether the quality and/or quantity of adult mathematical input depend on the child’s gender.

Theoretical framework

Language acquisition studies have indicated that children’s general vocabulary growth is related to the amount of language input they receive (e.g., Hart & Risley, 1992; Naigles & Hoff-Ginsberg, 1995). Moreover, children’s understandings of mental states are facilitated by the maternal use of mental verbs such as ‘think’ or ‘know’ (Adrian, Clemente, & Villanueva, 2007; Tardif & Wellman, 2000). A recent study of preschoolers by Klibanoff, Levine, Vasilyeva, & Hedges, (2006) found a relation between the amount of mathematical input of daycare teachers and the growth of children’s mathematical knowledge during the year. Moreover, developmental studies suggest that early mathematics representations such as numerosity (1 unit or 2 units of something) are linked to mathematics language, for example, the knowledge of count words (e.g, one and two) (e.g., Huttenlocker et al., 1994; Jeong & Levine, 2005). Children learn the cardinal word principle and the meanings of all the number words within their counting range after acquiring the meanings of one by 2.5 years old, two by 3.0-3.5 years old, and three by 3.5-4.0 years old (Wynn, 1990, 1992). These studies suggest the importance of the amount of mathematical talk children receive in the daily lives during the early years of life and its impact on their acquisition of mathematical language and concepts. Specifically, parents who provide quantitative input to their children by using sentences such as “You need two more puzzle pieces” while engaging in a play activity may foster the growth of children’s mathematical development. However, we currently do not have a good overview of what kind of mathematical talk young children receive at home.

Furthermore, by analyzing adult input, this study seeks to address the question of whether socialization plays a role in mathematics learning in boys and girls. Gender-stereotyped perceptions about children’s mathematics competence by parents have been reported as early as preschool and kindergarten (Lloyd, Walsh, & Yailagh, 2005; Lee & Schell, under review; Manger & Eikeland, 1998). Boys as young as four years old show an advantage over girls in number sense (Jordan et al., 2006) despite the lack of consistent gender differences observed in young infants performing a numerosity judgment task (e.g., Lipton & Spelke, 2003; 2004) as well as in three-, four-, and five-year-old children performing counting and magnitude comparison tasks (Lee & Schell, 2009). This raises the question whether gender differences in early mathematics are related to socialization and motivation such that boys are encouraged more than girls on number tasks, even at an early age (e.g., Aunola et al., 2004) or whether there are cognitive explanations for gender differences in early mathematics (Geary, 1998). By examining the interactions between caregivers and their children in a free play session with a standard set of toys picture books, differences in the quality of talk in terms of introducing mathematical-related words (e.g., caregivers focusing more on how the doll is driving the car to work with girls vs. caregivers focusing more on how many trucks are on the floor with boys) could be identified. The free play session requires video recording young children and their caregivers in order to capture both the verbal and nonverbal ways in which mathematical words are presented to the children. Without the need for questionnaires or checklists that rely on parental memory, this approach allows us to examine the input that occurred in a more naturalistic manner and to obtain the frequency and nature of incidental mathematically relevant input that children receive at home.
Method

Participants

In the current study, 36 families (19 boys and 17 girls) between 18 and 39 months old and their parents (usually the mother) engaged in a 30-minute naturalistic free play session in their home. Seventeen and nineteen children were in the 18- to 28-month-old group and the 29- to 39-month-old group respectively. Nineteen children were enrolled in part- or full-time daycare or nursery program while the remaining seventeen children were looked after by their stay-at-home parents. These families were predominantly Caucasians with average socio-economic status (SES) using maternal education as a proxy for SES since studies such as Catts, Fey, Zhang, & Tomblin (2001) have found that it is a good proxy measure for SES. All but four mothers have attained a college or higher degree. Children and their families were recruited through birth announcements, online advertisements, recruitment flyers and contacts provided by families that participated in this study. Each family received a $5 gift card for their participation.

Materials

To minimize differences in the immediate environment and in the activities that the children and caregivers engage in, each child-caregiver dyad was provided with a standard set of toys (e.g., five balls, eight car counters, ten animal counters, twelve Lego blocks) which could be used and labeled in a number of ways for free play session as well as two pop-up books on colors, numbers and shapes. Furthermore, the various sets of provided toys could facilitate in eliciting the use of number words during the interactions. Consequently, any observed differences between the verbal labeling and interactive practices can be attributed to inherent differences between individuals, rather than differences in the environment.

Transcription and Coding

Each free play session of the parent-child dyads was videotaped, transcribed and coded using a portable Observer XT system that allows the experimenters to work the two cameras using a remote control in a separate room from the dyad. The parent-child dyad was also asked to wear a wireless microphone each to ensure a high audio quality. Such an arrangement ensured that the free play session was as naturalistic as possible. All the adult speech were transcribed and coded by at least two trained research assistants for the mathematically-related input in the following categories: i. shape and ii. color, iii. quantity words (e.g., how many, less than, more), iv. cardinality (stating or asking for the number of items in a set without counting), v. counting words (e.g., one, two), vi. counting objects in an array or in sets, vii. ordering numbers (e.g., ‘Three, what comes after three?’), and viii. transformation of object arrays involving addition or subtraction (e.g., “If one cow went missing, how many do you have now?”)

Results

The total word tally for the utterances by parents in the 36 play sessions was 38,512 and 34,587 words for boys and girls respectively. Only 2,434 (4.43%) and 2,175 words (4.12%) were mathematically-related words heard by boys and girls respectively. Thus, our young children in this study heard on an average of 4.28% of mathematical talk produced by their caregivers during the 30-minute play session. In terms of mathematical talk, our results indicate that about 69% of the mathematically-related adult utterances involved quantity words, counting words, counting objects, cardinality, ordering, and transformations of object arrays. Specifically, parents used more words that indicate quantity (31%) and cardinality (25%). In contrast, words about shapes and colors made up about 31% of the total mathematically-related speech (see Table 2).

Note: Ordering numbers = 0 for boys and girls

A series of t-tests were conducted to determine whether there were gender differences in parent mathematically-related input. Based on the frequency or incidence of mathematically-related utterances in the eight categories, our t-tests did not reveal any significant gender differences that could be attributed to inherent differences between individuals.

differences. Thus, parents did not differ in terms of their use of mathematically-related language with girls or boys.

Discussion

In sum, our findings suggest that though parents talked more about numerical quantities (e.g., quantity words) and numerical relations (e.g., cardinality) than about mathematical attributes such as shape and color, the total amount of mathematically-related talk heard by young children was about 4%. Moreover, we did not find any gender differences in terms of the mathematical talk parents produced and the different aspects of numerical knowledge such as counting objects or cardinality.

The low amount of adult mathematical talk is disconcerting in light of studies such as Klibanoff et al. (2006) indicating a positive correlation between the amount of mathematical input by early childhood educators and the growth of mathematical knowledge of preschoolers. Furthermore, some researchers have suggested that the mapping of non-verbal number concepts or numerosities to number words that represent quantity, and ultimately the acquisition of counting principles is facilitated by the acquisition of mathematical language (e.g., Gordon, 2004). This low amount of mathematical talk could possibly be a reflection of the parents’ personal comfort level with mathematics or due to the parents’ assumption that mathematical knowledge is something that is taught in school. The latter reason is more consistent with the feedback that we have obtained from our parents during the debriefing session after their free play interactions. Almost all the parents, even those with older children (between 29-39 months old), reported that they have been focusing on naming objects rather than mathematical attributes or numerical quantities and relations.

A limitation of this study is that our free play sessions of the parent-child dyads were overwhelming those of mothers due to the inherent nature of more women are the primary caregivers. For this study, we have specifically requested that the primary caregiver who spent more time with the child to participate to try to obtain as naturalistic interactions as possible.

Nevertheless, this research is poised to make interesting contributions in understanding the acquisition of number words and counting concepts by children younger than 3.5 years old. No studies currently exist that seek to investigate the types and amount of mathematical talk young children receive at home from their parents in a naturalistic setting or examine whether gender of the child is a factor that influences the nature of adult mathematical talk. Additionally, this research, situated in the earlier childhood years (18-39 months), begins to make a novel contribution to the existing research which largely explores later childhood years (3-5 years old). Our findings will help to inform early childhood educators and policy makers of the amount and type of mathematical knowledge children have already acquired when they first enter either a preschool or kindergarten educational program. As an illustration, the small percentage of adult mathematical talk on counting words or counting objects in an array reported in this study would suggest that more time has to be spent to focus on the acquisition of verbal rote counting.

Therefore, knowing how parents talk about everyday mathematics would facilitate the design of better early childhood mathematics curricula and intervention programs for children at risk for mathematical difficulties.

At the same time, parents and caregivers should be encouraged to use more counting words as well as to engage in more counting and patterning activities with their children in daily life. This approach of learning mathematical concepts through daily activities could lay a foundation for subsequent mathematics competence for children to give them a head-start once they enter
formal schooling as well as prevent some children from gradually learning to avoid things involving mathematics or even developing mathematical anxieties or phobias (e.g., Ashcraft, 2002).

Chapter 6: Equity and Diversity

A BALANCING ACT:
MATHEMATICS TEACHER EDUCATION IN PUBLIC INTEREST

Jean M. Mistele
Virginia Tech
jeanm@vt.edu

Laura Jacobsen Spielman
Radford University
lspielman@radford.edu

While internationally there is ample interest among mathematics educators in social justice, the literature base on mathematics teacher education for social justice is very limited (Gates & Jorgensen, 2009). The Mathematics Education in the Public Interest (MEPI) research project provides preservice elementary and middle school teachers (PSTs) with a mathematics content course, Math for Social Analysis, that integrates development of mathematical knowledge needed for teaching with knowledge needed for critical, responsible citizenship. This poster presents various practical challenges that we, as mathematics teacher educators, face in course design and implementation, including: (1) Mathematics content and social critique; (2) Mathematics content and pedagogy; and (3) In-class and out-of-class experiences and learning.

Balancing Mathematics Content and Social Critique: The greatest challenge we face is finding appropriate balance in depth and breadth of emphases on helping PSTs learn mathematics while helping them to critically engage with social issues. Nolan (2009) explained how the “statistics and figures” content approach that takes mathematics as usual and appends social justice concepts will not be enough (p. 207). Math for Social Analysis addresses all five NCTM content strands, yet we found number and operations and statistical concepts naturally align with social issues more easily. We struggle to balance time spent examining mathematical concepts for deep understanding with time spent engaging PSTs with social issues.

Balancing Mathematics Content and Pedagogy: We dualistically aim to balance PSTs personal experiences with learning rich mathematics within the context of social issues, while: (1) critiquing their own understanding of mathematics as a discipline in relation to the democratic purposes of schooling and (2) building new pedagogical content knowledge embedded in MEPI principles.

Balancing In-Class and Out-of-Class Experiences and Learning: Our challenges extend outside of the classroom as we strive to balance the in-class and out-of-class experience through service learning. The partnership requires a greater commitment from the service learning organization to address the scheduling and assessment of our PSTs. Their feedback becomes a component of the PST’s course grade.

ARE YOU SURE THIS IS MATH? USING SOCIAL JUSTICE IN MATHEMATICS EDUCATION

Sharlonne Rollin
University of Georgia
sharlo34@uga.edu

The goal of this research was to further explore the significance and effects of incorporating social justice into mathematics curriculum. My interest in this topic was ignited while reading articles on alternative mathematical instruction discussed in a mathematics publication (Gutstein & Peterson, 2006) and reflecting on past experiences as a math teacher at an inner city middle school based on unmotivated and disinterested mathematics students, students desires to discuss current political and social events, and my struggle to teach curriculum with meaning and teach mandated curriculum simultaneously. Critiquing banking concept of education, I illustrate negative effects of traditional mathematics curriculum on student and teacher practices.

Using Friere’s perspective of banking concept in education and critical theory, I analyze the differences between traditional mathematics and justice oriented mathematics. Friere (1998) describes banking concept of education as the teacher putting money into the bank, the student regarded as empty receptacles into which the teacher deposits the knowledge. Dialogue doesn’t exist in banking education and therefore critical thinking is not utilized. The absence of dialogue and critical thinking leads to missed opportunities of students to exist as change agents in classist societies. Friere draws upon social and political consciousness which arises from dialogue and critical thinking. This theory lends to the importance of engaging students in justice oriented mathematics which allows students to dialogue and become conscious of social ills which occur in society.

Data was collected over a course of six months (from December 2008 to May 2009) and visits were made three times weekly. Data collection included teacher and student post interviews and pre interviews, observational field-notes, and document collection. To further enhance data collection, I maintained a researcher’s journal that included a record of my concerns or feelings that arose during fieldwork.

Much of the research concerning children from poor communities of underrepresented racial groups has aimed to describe their lack of access to socially realistic mathematics. An exploration of the strategies teachers use when engaging in socially just mathematics lessons could help other educators to develop more equitable curricula and teaching practices in the future. This critical study also emphasizes a need for critical examination of mathematics curriculum used in urban communities and represents the beginning of an effort to broaden our understanding of the role that social class plays in educational achievement.

CULTURALLY RELEVANT TEACHING IN MATHEMATICS EDUCATION: DOES IT ADD UP?

Mardi Schmeichel
University of Georgia
mardi@uga.edu

Although the continued call for the need to do culturally relevant teaching in mathematics is an indication that the battle to convince teachers to adopt culturally relevant strategies has not been won, the argument that educators should be doing culturally relevant teaching, and that children are, indeed, culturally different from each other, are truths that are uncontested in equity literature. But what made it possible to conceive of children as culturally different? How did culturally relevant teaching emerge as something that could and should be done?

The purpose of this conceptual paper is to apply Foucault's (1977) genealogical methodology to the concept of culturally relevant teaching. First, I will describe genealogy and the value of using a genealogical research design to consider culturally relevant teaching. Then, I will identify the eruption of forces that intersected to make it possible to conceive of students of color as culturally different. I will provide an overview of Ladson-Billings’ (1994) theory of culturally relevant teaching, analyze its take up in mathematics education discourse, and propose that the synonymy of culturally relevant teaching with equity prevents us from questioning it as a problematic way of thinking about equity work in schools.

This qualitative project was a Foucauldian (1977) genealogical study of the discourse surrounding children of color and culturally relevant teaching in education research and mathematics education discourses. For Foucault, genealogy was a framework for investigating and thinking about present truths in a way that could disrupt the perception that our present reality is an inevitable result of a linear series of events. Genealogy is useful for tracing the emergence of a belief that is so commonsensical that we might see it as without history, in order to consider how it has become the truth.

This genealogy traces references to culturally relevant education and teaching within the education literature -primarily American education research journals, books, and practitioner publications- in order to understand why and how it came to be possible to think of children as culturally different.

Until we can talk openly about the dilemmas within and around this equity strategy, and other attempts to transform mathematics classrooms into more equitable places, the time and space that is opened up in schools for equity work may do very little to improve the school experiences of children of color and may be supplanting more critical and effective ways of “doing equity”.

EXPLORING AFRICAN AMERICAN STUDENTS’ IDENTITY CONSTRUCTION AND THEIR MATHEMATICS ACHIEVEMENT

Francis Nzuki
The Richard Stockton College of New Jersey
francis.nzuki@stockton.edu

A growing numbers of studies focus on the importance of students’ understanding and the mathematical meaning created by the students as they participate in mathematical studies. These studies emphasize the socially and culturally situated nature of mathematical activity with learning viewed as a collective process of enculturation into the norms and discourse practices of the mathematics class that foster students’ ability to see themselves as doers of mathematics (Boaler & Greeno, 2000). From this perspective, the development of identity, or the process of identification, is seen as an integral part of students’ engagement and participation in the mathematical practices of a community constituted by the students and their teacher in a classroom (Boaler & Greeno, 2000). It is through the social interaction and participation structures that students’ identities as learners and as active agents are enacted as they participate in the classroom mathematical practices mediated by cultural artifacts and resources.

This study involved a case study of an intermediate algebra classroom at a low-SES high school. The aim of the study was to investigate African American students’ identity construction and note the sense of agency exhibited in the process. I focused on five key informants who were selected using a purposive sampling method and comprised of two high achievers (male and female) and three low achievers (two females and one male). The stories told by these key informants helped illuminate their sense of identity and agency that they developed and enacted within the figured worlds in which they participated. In investigating the students’ identities and agencies, I draw on Critical Race Theory (CRT), and Holland, Lachicotte, Skinner and Cain’s (1998) framework of figured worlds, positioning and authoring.

The results of this study revealed that all the participants had seemingly positive racial identifications and were aware of the constraints and the social devaluation that face African Americans in the society. However, they differed in their interpretation and negotiation of these constraints and in the sense of agency they exhibited in the process that influenced their opportunities to participate in mathematics and hence their mathematical identities. Additionally, how students positioned themselves and authored their mathematics identities was influenced by how they negotiated the classroom norms and the constraints and affordances in the figured world of the mathematics learning in which they participated.

FROM THE POLITICS OF REMEDIATING MATHEMATICS: FACTORS IMPACTING STUDENTS’ MATHEMATICS LEARNING EXPERIENCES IN UNDERGRADUATE ALGEBRA COURSES

Gregory Larnell
Michigan State University
larnellg@msu.edu

While equitable access to mathematics has been a longstanding (yet still-emergent) interest among mathematics education researchers, the expanding role of mathematics in students’ transitions to public, four-year, research-oriented universities has received little attention. Despite calls for research that “opens the box” and explores students’ experiences in critical transitionary courses at the university, there has been no research that explores the ways in which mathematics is intended (e.g., in curricular materials), enacted by teachers and students, or supported by institutional programming and peer networks in these settings.

The present study focuses on the institution-, course-, and individual-level mathematics socialization factors (Martin, 2000) that impact the mathematics experiences of a group of first-year, African American undergraduates—students who were enrolled in the university’s lowest-level, non-credit-bearing mathematics course. Conducted over several semesters, the study questions and empirically investigates the role of structural and personal factors that impact students’ mathematics learning experiences, particularly mathematics identity, classroom engagement, and institutional policies and practices. Classroom-level participant observation, field notes and classroom interaction charts were used to document students’ engagement with mathematics in the classroom. Semi-structured interviews with students, instructors, and university personnel were conducted in order to study the impact of institutional programming, mathematics instruction, peer networking, curricular goals and expectations, and students’ personal and mathematics identities. Narrative analytic techniques were used to analyze transcripts of these interviews (Juzwik, 2006). The proposed poster will describe each phase of the study’s design and will include findings based on analyses described above. I will outline the factors impacting students’ mathematics socialization in the transition from high school mathematics to the four-year university mathematics pipeline, using race-critical and context-sensitive lenses.

KNOWLEDGE OF HOW CHILDREN LEARN MATHEMATICS: CAN PARENTS USE THIS KIND OF KNOWLEDGE TOO?

David Feikes  
Purdue University-North Central  
dfeikes@pnc.edu

Keith Schwingendorf  
Purdue University-North Central  
kschwing@pnc.edu

Heidi Stevenson  
Purdue University-North Central  
hstevenson@pacific.edu

The purpose of our study is to investigate how knowledge of children’s ways of learning mathematics can also be used by parents in helping their children learn mathematics. As part of an early project we developed resources for preservice elementary school teachers on how children learn mathematics. The Connecting Mathematics for Elementary Teachers, (CMET), an NSF supported project (DUE 0126882 and DUE 0341217). CMET (Feikes, Schwingendorf, & Gregg, 2008) developed a commercially published textbook and supporting material for prospective elementary teachers and their instructors. Realizing that parents might benefit from similar materials for parents, the project team has piloted CMET materials with parents to see how they might interpret these materials and what changes need to be made.

In this study we provided resources adapted for parents and sought their feedback. The intent of these resources is to impact the mathematical understanding of children by providing parents with in-depth knowledge of how children learn and think about mathematics. One of our goals is to investigate the effectiveness of these resources by examining how parents use knowledge of children’s mathematical thinking while working with children.

Data for this study consisted of: a) written reviews of the materials, b) course work in a graduate mathematics education course, c) transcripts from parent focus groups, and d) transcripts from parent interviews. The purpose of collecting this data was to examine how parents might use knowledge of how children learn mathematics in helping children learn mathematics.

Emergent themes that evolved as the result of these beginning research efforts are: 1) Parents want and need more mathematical content knowledge, 2) they are frustrated by their child’s struggle with mathematics, 3) parents began to think differently about helping their child as a result of learning about how children learn mathematics and, 4) even after gaining knowledge of how children learn, parents had a different world view of learning that did not match this new knowledge.

Using knowledge of how children learn mathematics can be helpful to parents but this knowledge may need to be more specifically spelled out or presented in a way that is compatible to their view of how children learn mathematics. Parents may have a different mindset or world view as to how children learn in general; this may hinder their use of resources similar to those developed and used.

UNDERSTANDING OF FUNCTION OF STUDENTS WHO ARE BLIND OR HAVE VISUAL IMPAIRMENTS

Heidi Cowan
Ohio State University
Heidi.cowan@wright.edu

Equity for all students is the first Principle of the *Principles and Standards of School Mathematics* (NCTM, 2000). This presumes that regardless of race, gender, disability, or cultural background, each student should be presented with opportunities to actively be engaged in learning mathematics. This charge can take on a different meaning when the students under consideration have little or no vision. Mathematics is traditionally taught with a heavy reliance on visual context and can therefore be difficult to accommodate for students who are blind or have visual impairments. The research described in this poster presentation is on the current understanding of linear functions of students who are blind or have visual impairments. The following focus questions are addressed.

- What level of knowledge and type of understanding do students who are blind or have visual impairments have of function?
- What factors do high school/college students who are blind or have visual impairments perceive as influencing their development of understanding of linear functions?

Two interviews, the Mathematic Education Experiences and Visual Abilities (MEEVA) survey and the Function Competencies Assessment (FCA), served as the main data collection instruments. The MEEVA follows a standard interview format and is intended to provide demographic information as well as to address the second focus question by providing information on the students’ previous educational experiences in mathematics. The FCA is a task-based interview that consists of problems related to linear functions and their applications. This exam was written using the evaluation taxonomy of Wilson (1971) and analysis of these data utilized the four competencies of function knowledge as described by O’Callaghan (1998). These competencies are: a) modeling, b) translating, c) interpreting, and d) reifying. Analysis also utilized the National Research Council’s (2001) definition of *Mathematical Proficiency*, which speaks to a student’s procedural fluency and conceptual understanding. An emphasis is placed on students’ reification of function as well as their knowledge and use of multiple representations.

“YOU DON’T HAVE ENOUGH DATA TO TALK ABOUT RACE”

Amy Noelle Parks
University of Georgia
amyparks@uga.edu

The title of this piece comes from a recent blind review of a piece I wrote about mathematics teaching in a diverse classroom (Parks, in press). The critique was one I’d heard before about different manuscripts. In each case, the reviewers resounded positively to the piece overall, found my evidence about mathematics learning and teaching convincing, and critiqued my identification of race as a factor that impacted classroom interactions.

The purpose of this poster is to open a conversation about current barriers to discussing race and ethnicity in mathematics education. When Lubienski and Bowen (2000) reviewed the mathematics education literature spanning more than 15 years, they found that only 112 of the more than 3,000 articles examined discussed ethnicity. (In contrast, more than 300 articles discussed gender.) In this poster session, I would like to explore the possibility that our theoretical and methodological conceptions of race limit how we as researchers talk about race—in addition to limiting the ways that we allow others to talk about race. As Lubienski and Bowen (2000) point out, many of the pieces that do discuss race focus on the narrowing of the achievement gap in various contexts. In this type of research, race is conceptualized as an independent variable, and large study sizes allow generalizations about populations to be made. However, when race is conceptualized only as a category for large groups of people, little theoretical space is left for alternative ways of thinking and writing about race. Alternative conceptions of race and ethnicity, which focus not on the characteristics of populations, but on the micro-interactions of small groups of humans might offer more freedom in analysis. For example, Omi and Winant (2004) wrote about “the performative aspect of race” (p. 10), where race is seen as continually acted out in various ways by various people. Thus, race is understood as performed rather than as a population category; and, “the enormous number of effects race thinking (and race acting) have produced” (p. 9) are possible objects of study. Exploring this conception of race within mathematics education might mean that researchers can look at the way performances by individual teachers and students are related to race without suggesting that others who might identify as the same race would perform in similar ways. This sort of complexity might bring a richness to many descriptions of classroom interactions. For example, many socio-cultural analyses of discussions, questioning, and problem solving could be made more complex if researchers attended to the ways that race-thinking and acting (along with gender- and class-thinking and acting) influenced the ways that mathematical ideas were taken up or not in classrooms. After all, one might reasonably argue that socio-cultural analyses of classrooms that don’t explicitly attend to race, gender, and class don’t have enough data to talk about mathematics.

This paper presents a new computer environment for students to explore various topics in geometry. In this design, each student in a small group is assigned responsibility for moving one vertex of a polygon so that the group collectively explores changing properties of that shape. This paper investigates a group of four students completing a series of activities about quadrilaterals. We show how certain features of the computer environment as well as the sequencing of tasks helped students move from initial understanding of shapes as wholes toward focusing on the features to noticing hierarchical relationships between different types of quadrilaterals.

Introduction

In the research literature on geometry, the van Hiele theory (1959/1985) has been widely recognized for providing a coherent framework to explain how students develop their geometric understanding. In elaborating five levels of geometric thinking, van Hiele stressed that it is not maturation or age but rather instruction and experience that facilitate students’ progress within and across these levels. In this paper, we explain how we developed a new computer-based learning environment and organized an accompanying sequence of tasks in order to support students’ geometric reasoning, and use the van Hiele levels as a framework for examining changes in students’ thinking over the course of an instructional sequence. This design is one in a family of learning environments we are developing as part of a longer-term design-based research project focused on supporting novel forms of classroom mathematical exploration and interaction through a local network of graphing calculators or handheld computers (e.g. White, 2006; White & Brady, 2010; White, Lai & Kenehan, 2007).

This paper presents results from a single design experiment conducted as a part of this larger ongoing project. In reporting on this study, the present paper focuses on investigating the extent to which certain features of the computer environment, and the particular sequence of tasks students completed, may address challenges in students’ learning about geometric concepts. In particular, we focus on students’ learning of quadrilaterals, an area in which middle school students have difficulties (Jones, 2000; Yu, Barrett, Presmeg, 2009). Learning quadrilaterals can be difficult for many reasons: 1) students many times have a prototypical image of a shape, 2) shapes have a long list of features, 3) and the categorization of shapes are hierarchical (Fujita & Jones, 2007). We specifically designed three variations of the learning environment and three corresponding tasks to address these challenges. The first set of activities engaged students in dynamic manipulation and open-ended exploration of quadrilaterals in a Cartesian space. The second variation pushed students to focus on the features of the shapes. The third set of activities was intended to help students focus on the relationships among different quadrilaterals. In this paper, we will examine how the design of the computer environment and activities help students progress in their understanding of quadrilaterals.

The Van Hiele Theory

The original van Hiele theory presented five levels, of which the first three pertain to our study. In the first level, Visual, students see shapes as gestalt figures and refer to them using familiar objects. For example, they might say that a rectangle looks like a door. In the second level, Analytic, students begin to recognize components of figures and can see that squares have four equal sides, etc. Progressing to the third level, Abstract, students begin to understand the hierarchical relationships among various shapes. For example, they can begin to see how squares can be rhombuses. Although there is debate as to exact nature of this progression, researchers continue to refer to the van Hiele theory because it provides a clear framework for investigating students’ geometric understanding (Battista, 2007).

Study

Context and Participants

Results reported in this paper come from the first phase of a design experiment (Brown, 1992) we implemented in a charter school located in an urban area. This first phase included a group of four sixth and seventh grade boys who volunteered to participate in the study outside of class time.

Computer Environment

The computer learning environment NetGeo uses the NetLogo modeling environment and the TI-Navigator 3.0™ graphing calculator network (Wilensky & Stroup, 1999). In particular, the geometry environment is based on the Netlogo program PANDA (Perimeter and Area) Bear (Unterman & Wilensky, 2006, 2007). In the activity, each student logs a calculator on to the network and then uses arrow keys to control an individual point displayed on a shared computer screen. These points are linked with those of other students in a small group via the network to form polygons; in the activities for the present study a group of four students thus jointly manipulated a quadrilateral. The screen also displays the lengths of the sides and the angles at the vertices (Figure 1).

![Figure 1. Interface from the NetGeo environment](image)

Activities

Instructional sessions (conducted by the first author) spanned six days and included three variations of computer interface and correspondingly different sets of activities (two days each). Days 1 and 2 focused on familiarizing students with the learning environment and the quadrilateral terms and definitions. For these days, the group was given freedom to explore the space and to construct shapes without constraints, and then asked what their definitions were for the various quadrilaterals they constructed. After terms and definitions were clarified if
necessary, the group continued to work on their construction with the revised definitions. During these two days, students were given a sheet of quadrilateral names (square, rectangle, parallelogram, rhombus, trapezoid, kite, quadrilateral) with blank lines so that they could fill out the definition that the group had collectively agreed on.

During Days 3 and 4, the interface was adjusted so that values (angles and lengths) were now displayed on individual students’ calculators rather than on the computer screen. In addition, students no longer updated these values by simply moving their points, but instead needed to press a “mark” button for a new quadrilateral to be formed, and for the values to be correspondingly updated on the calculators. A sample task for these days was to ask students to first construct a certain shape—for example, a parallelogram. The researcher then “stamped” the quadrilateral on to the screen, and the group was asked to use the least number of steps to make a square. In the case in which a shape is a special case of another shape, no movement would be necessary. For example, if the group had a square and were asked to construct a rectangle, no movement would be necessary and the least number of steps would 0. This task involved more planning, and the goals of this activity were for the students to 1) focus on the values of the shape’s features as displayed on the calculators and 2) begin to notice hierarchical relationships. During these days, the students were also given a sheet with all seven quadrilateral shapes and asked to draw arrows between shapes, in which one shape is “a special case” of another shape.

During Days 5 and 6, the group no longer had information regarding the length and angle values. Instead, there were monitors in the computer environment that indicated certain properties (essential and non-essential) of the quadrilateral: the number of 90 degree angles, number of sets of parallel lines, number of congruent opposite sides and number of congruent adjacent sides. The students were also provided a chart with the names of quadrilaterals displayed by row and the above properties by column, and the students were asked to fill out the chart and leave cells empty if the certain property was not essential to the given shape.

Methods

All sessions were videotaped, and all computer screen states recorded as a video file. Videos of all sessions were transcribed and analyzed with regard to the ways student solution strategies corresponded to different levels in the van Hiele framework. Students were also interviewed before and after the six-day sequence of activities. During the interviews, students were given various cut-out shapes and asked to lay them on a paper, identify them and draw arrows between shapes in which they thought one shape was a special case of another (similar to Jones, 2000). After the sorting quadrilateral task, we asked the students, 1) What is a square? 2) Is a square a special case of a rectangle? 3) What is a rectangle? 4) Is a rectangle a special case of a parallelogram? 5) What is a rhombus? 6) Is a rhombus a special case of a trapezoid?

Results

Pre- and Post-Instruction Interviews

Table 1 summarizes results from the student interviews conducted before and after the instructional sequence. Out of a total of 24 pre-interview responses among the four students, only 10 responses pertained to important features of the shapes and thus would be categorized as van Hiele level 2 or above. In the remaining instances, students typically responded by referring to the shapes in a visual way. For example, for question 2, one student Alan answered, “Yes, because a square can be a rectangle, but a rectangle can not…wait a minute, be a square. It’s too big.” Another student Brad answered question 4 as, “It is part of a parallelogram because of the

shape of it, and how their length and width. And parallelogram is just cut off a little bit on the sides.”

By the post-interviews, only one response would be categorized as van Hiele level 1, whereas 21 responses referred to the attributes or properties of the shapes. For example, the same student Alan from above answered question 2, “Yes, cause square has all the properties of a rectangle but a rectangle does not have all the properties of a square.” During the post-interview, Brad answered question 4 as, “Yes, because a parallelogram has…a rectangle has four right angles, but parallelogram doesn’t have four right angles.”

Below, we present a series of episodes selected from the activity days to illustrate the different type of activities and to examine how instances of student reasoning about these tasks in this environment corresponded to the van Hiele levels.

Episode 1: Attending to the Shape as a Whole (Day 1: Create a Rectangle task)

This episode occurred during the first day of the activities. The students were able to complete the previous task of creating any rectangle by creating a prototypical rectangle with horizontal sides. The group was then given a task to create a rectangle such that none of the sides were horizontal. The following transcript presents the students’ dialogue a few minutes into the task.

1. Alan: You both [referring to Dan and Matt] got to make a 2, 8 length. Hurry up go.
2. [The students move their points around.]
3. Brad: I see what he’s doing…
4. Alan: Move Matt, it’s you.
5. Matt: Left, right, up, down?
7. Matt: There, there. [referring to Figure 2]
8. Interviewer: Is it a rectangle?
9. Alan: 9.8, 9.8, 2.2, 2.2.. why can’t we just make a square?
10. Interviewer: What’s the definition of a rectangle again?
12. Interviewer: So Dan, is this a rectangle?
13. Dan: [shaking his head] Uh uh..

The above episode shows how the group originally relied on their prototypical image of a rectangle and did not attend to the features—a characteristic of van Hiele level 1 thinking. Alan thought that they had accomplished the task (line 7), but he did not attend to the fact that the angles did not display 90 degrees. After the interviewer asked, “Is it a rectangle?” (line 8), Alan noticed the values of the lengths (“9.8, 9.8, 2.2, 2.2”) but still did not properly attend to the values of the angles. The researcher then brought the students back to the definition of a
rectangle, which Brad was able to correctly say required four 90 degree angles (line 11). Dan was then able to recognize that they had not created a rectangle. This episode shows how the group originally saw the shape as a gestalt whole, and after some prompting, began to notice the features. Throughout consequent activities, the students began to rely more on the values displayed on the computer screen to complete the tasks.

Figure 2. Shape created during episode 1

Episode 2: Attending to the Features (Day 3: Changing Parallelogram to a Square)

The following episode occurred during the third session. The students were first asked to create a parallelogram. The researcher then stamped the students’ shape on the computer screen, and in the following task the students were asked to create a square using as few moves as possible.

1. Alan: No no…don’t. Only those two move [pointing to Brad’s and Dan’s points—upper points C and D in Figures 3 and 4]. Him and him move a little bit here. He moves over here.
2. Matt: Guys, move over two.
3. [The students move their points around.]
4. Matt: Yeah, buddy. [referring to Figure 3]
5. Alan: Nah, still not the same.
6. Interviewer: How do you make sure it’s equal length?
7. Alan: [looking at calculator screen] It’s 12, 13.
9. Matt: 90 degrees.
10. Dan: 90 degree angle.
11. Alan: No, no…but the length aren’t the same.
12. Dan: We should’ve all gone to the corner.
13. Alan: Go one more time up. [referring to Dan and Brad], Him and him. [Figure 4]

The design of Day 3 and 4’s computer environment and activities was intended to encourage students to start paying attention to the values of the quadrilateral (angles and lengths) as seen on the individual calculators rather than the computer screen. In this excerpt, after some initial discussion, the students agreed that only two students (Brad and Dan, the ones on the top) should move over to the left. After Brad and Dan had moved to the left and aligned with the bottom points, Matt initially thought that they had completed the task (line 4). Alan disagreed and after the researcher asked, “How do you make sure it’s equal length?” (line 6), Alan attended to the values of the lengths as displayed on his calculator and realized that one side was length 12 and
the other side was length 13 (line 7). The other group members also chimed in and noticed the lengths and also that the angles were 90 degrees (lines 8-10). This episode highlighted how the group members began to attend to the features of the shapes, which is characteristic of van Hiele level 2 thinking. This progression from simply visually inspecting the shapes in the first day of activities to properly noticing the features of the shapes in Day 3 was part of the design of the computer interface and instructional activities to help students to progress along the van Hiele levels.

Figures 3 and 4: Quadrilaterals create during episode 2

Episode 3: Beginning to Notice Hierarchical Relationships (Day 6: Creating a Rhombus)

The following episode occurred on the last day of the activities. In the previous task, the group was asked to create a rhombus, which they successfully accomplished by simply creating a square. The researcher followed up by asking the group to create a rhombus that is not a square.

1. Alan: Yeah yeah, okay Dan…Brad, you move to the other side…Here rhombus [referring to Figure 5], but it’s not exactly a rhombus I know.
2. Matt: [focusing on monitor on “congruent adjacent sides”] No, because a rhombus has a pair of congruent…2 congruent sides.
3. Alan: No no…Yeah, but it has all the same side.
4. Brad: [referring to the upper points] Matt and Dan, go up. There we go.
5. Matt: It’s a rhombus. Check it out. [referring to Figure 6]
6. Alan: It is, it is, because it has the thing…oh no…
7. Matt: It’s a rhombus, it’s a rhombus…
8. Alan: [noticing monitor] It can not be…It doesn’t have two pairs of adjacent sides.
9. [The students continue to talk and move their points around.]
10. Matt: Let’s just make a diamond, remember?
11. Alan: Oh wait a minute, let’s make the diamond you know from the corners.
12. [The students continue to direct each other and eventually end up with Figure 7]
13. Brad: But it has 4 right angles.
14. Alan: No, wait a minute. Wait a minute. We can make it not a square. Dan [referring to top point], you go down, I [referring to his lower point] go up. Not a square anymore. It still has adjacent sides. We did it. Now it does not have right angles. [Figure 8]

In this Day 6 task of creating a rhombus that is not a square, the students began to display understanding of hierarchical relationship between rhombus and square. Initially, the group tried to create the prototypical rhombus with sides that are horizontal (Figure 5). After Matt noticed that the monitors did not display 2 pairs of congruent adjacent sides and 2 pairs of congruent
opposite sides (which makes it all sides equal), the group tried to create another quadrilateral (Figure 6). After some failed attempts at creating the prototypical rhombus, Matt and Alan remembered that they had previously constructed a diamond that was also a rhombus. After they had constructed the diamond (Figure 7), Brad noticed that there were still four 90 degree angles, so it was still a square. Alan then moved up his point and Dan moved down his point to create a shape that still had four sides equal but no 90 degree angles (Figure 8). This episode shows the group negotiating and demonstrating their knowledge of which features are essential for a rhombus and which are not. This is an important part of beginning to develop their knowledge of hierarchical relationships between shapes, which is characteristic of thinking at van Hiele level 3.

Figures 5 and 6. Quadrilaterals students mistook as rhombi

Figures 7 and 8. Quadrilaterals created during episode 3

Discussion and Further Research

This paper presented a computer environment designed to help students to move from simply viewing shapes as prototypical images, to noticing the shapes’ features, to understanding the hierarchical categorization of the various shapes. We presented episodes from the three variations of activities to highlight how the different aspects in the technology drew students’ attention to particular aspects of the shapes. In the first variation, the students at times still demonstrated views of the shapes as gestalts but gradually began to notice the features. During the second variation, the students began to pay more attention to the values of the angles and lengths as displayed on their individual calculator screens. The last set of activities helped students to move beyond noticing the individual features to beginning to talk about general properties of the shapes. Although this paper focused on students’ interactions with those features of the designed environment that were intended to highlight properties of shapes, further research and analysis of these data will also examine the forms of student collaboration supported by this interactive design.

ELEMENTARY-LEVEL CONCEPTUALIZATION OF VOLUME USING NUMERIC TOP-VIEW CODING WITHIN A 3D VISUALIZATION DEVELOPMENT PROGRAM

Jacqueline Sack  
University of Houston-Downtown  
sackj@uhd.edu

Irma Vazquez  
Houston Independent School District  
irmavazquez@sbcglobal.net

This paper focuses on a learning trajectory that deals with connections between top-view numeric coding and the concept of volume. The study’s Year-1 elementary-grades children initially became proficient at top-view numeric coding of 3D block structures. The following year, the same children unexpectedly applied this knowledge to the concept of volume of 3D rectangular arrays. As a result, a refinement of the learning trajectory brought these connections to younger children during Year 3 of this on-going study.

Introduction

The National Research Council’s (NRC) report, Learning to Think Spatially (2006), identifies spatial thinking as a significant gap in the K-12 curriculum, which NRC claims is presumed throughout the curriculum but is formally and systematically taught nowhere. This research team intends to fill this gap by developing new and modified curricular activities guided by the Spatial Operational Capacity (SOC) framework developed by van Niekerk (1997) based on Yakimanskaya’s (1991) work. Using design-research (Cobb, et al, 2003) principles this study’s immediate goal is to describe children’s mathematical sense making of these activities. It is conducted in a dual-language urban elementary school within one of the largest public school districts in the mid-southwestern United States. This paper focuses on the refinement of learning trajectories to support children’s conceptual understanding of the volume formula for rectangular 3D arrays using top-view numeric coding.

Theoretical Frameworks

Spatial Visualization

The National Council of Teachers of Mathematics’ Principles and Standards for School Mathematics (NCTM, 2000) prescribes that in their early years of schooling, students should develop visualization skills through hands-on experiences with a variety of geometric objects and use technology to dynamically transform simulations of 2D and 3D objects. Later, they should analyze and draw perspective views, count component parts, and describe attributes that cannot be seen but can be inferred. Students need to learn to physically and mentally transform objects in systematic ways as they develop spatial knowledge. From a purely academic perspective, the importance of visual processing has been documented by researchers who have examined students’ performance in higher-level mathematics. For example, Tall, et al (2001) found that to be successful in abstract axiomatic mathematics, students should be proficient in both symbolic and visual cognition; Dreyfus (1991) calls for integration across algebraic, visual and verbal abilities; and, Presmeg (1992) believes that imagistic processing is an essential component in one’s development of abstraction and generalization.

Spatial Operational Capacity Framework

The spatial operation capacity (SOC) framework (Yakimanskaya, 1991; van Niekerk, 1997; Sack & van Niekerk, 2009) that guides this study exposes children to activities that require them...
to act on a variety of physical and mental objects and transformations to develop the skills necessary for solving spatial problems. The SOC model (see Figure 1) uses:

- full-scale figures, that, in this study, are created from loose cubes or Soma figures, made from 27 unit cubes glued together in different 3- or 4-cube arrangements (see Figure 2);
- conventional graphic 2D pictures that resemble the 3D figures;
- semiotic representations (Freudenthal, 1991) such as front, top and side views or numeric top-view codings that do not obviously resemble the 3D figures; and,
- verbal descriptions using appropriate mathematical language (Sack & Vazquez, 2008).

The study utilizes a dynamic computer interface, Geocadabra (Lecluse, 2005), a tool that was not available when the SOC framework was originally formulated. Through its Construction Box module, complex, multi-cube structures can be viewed as 2-D conventional representations or as top, side and front views or numeric top-view grid codings (see Figure 3). Whereas one can move around a 3-D model to see it from other vantage points, one may see various views of a dynamic computer-generated figure through its ability to be rotated in real time.

---

Methodology and context

The design research methodology (Cobb, et al, 2003) guiding this study’s instructional decisions is based on learning trajectories developed from an instrumentalist standpoint (Baroody, et al, 2004). This conceptual and problem-solving approach aims for “mastery of basic skills, conceptual learning, and mathematical thinking” (p. 228). Within this approach, “teachers are concerned about students’ understanding and promote the use of any relatively efficient and effective procedure as opposed to a predetermined or standard one” (p. 228). Each lesson is part of a design experiment followed by a retrospective analysis in which the research team determines the actual outcomes and then plans the next lesson. This may be an iteration of the last lesson to improve the outcomes, a rejection of the last lesson if it failed to produce adequate progress toward the desired outcomes, or a change in direction if unexpected, but interesting, outcomes arose that are deemed worthy of more attention.

During the 2007-2008 academic year, a university-based researcher and two teacher-researchers formed the research team that worked with a 3rd-grade and then a 4th-grade group of children weekly (one hour per group) in teacher-researcher, Vazquez’ 3rd-grade classroom within the school’s existing after-school program. English and Spanish parent/guardian and student consent-to-participate forms were sent home to parents of all after-school 3rd- and 4th-graders. All respondents were accepted into the program. The research team adopted social-constructivist instructional approaches, supporting a problem-solving environment that fostered students’ creativity according to readiness and interest. To make sense of student understanding of 3D structures the research team used the following data sources: formal and informal interviews, video-recordings and transcriptions, field notes, student products and lesson notes.

Results

During introductory lessons the children interact with loose cubes and the Soma figures solving problems with the 3D models and with 2D task cards that illustrate combinations of the Soma figures requiring figure identification and classification. By the middle of the second month, the children begin to use the Geocadabra Construction Box to digitally reproduce figures printed in a customized manual as shown in Figure 4. These activities provide the children opportunities to coordinate numeric top-view codings with 2D conventional pictures. Children who need scaffolding may first build the 3D figures using loose wooden cubes.

During Years 1 and 2, in line with their constructivist leanings, the research team’s instructional planning was guided by the children’s interest in top-view coding. Using Geocadabra, the children created their own 2D task-cards of structures they had assembled with two Soma figures. Using these task cards, they drew coding puzzles for peers to decode and check. Later, they developed their own ways of coding Soma assemblies that had holes or overhangs and negotiated a non-conventional coding system for the whole class to use (Sack & Vazquez, 2009). The children became very proficient at moving among the 2D conventional pictures, top-view numerical coding and 3D digital dynamic representations on Geocadabra.

During Year 2, an unexpected and interesting event occurred when five Year-1 children returned. They were struggling with the concept of rectangular volume in their regular academic classes where they were required to use the formula. Using an initial learning trajectory based on the work of Battista (1999), the children attempted to solve volume problems by folding nets drawn on grid paper. They struggled to connect the dimensions of the flaps of each net with the height of its corresponding 3D figure. Within the study’s problem-solving environment, using a contextual scenario, “Ms. Moral’s Shoes,” 24 shoeboxes must be shipped to a nearby city. The children, using loose wooden cubes to model the shoeboxes, were expected to find all possible combinations of rectangular arrays with 24-cubic-unit volumes. The research team was surprised to see them record their findings as numeric top-view codings rather than directly with the length-width-height formula. Connections between top-view coding and the volume formula evolved through guided discussion among the teacher and participant children. Figure 5 shows how the children recorded their work.

Excerpts from field notes, November 5, 2008 (All of the children’s names in the following descriptive sections have been changed to protect identity).

Erin built a prism and then proceeded to record it as a top-view coding. She also wrote in the formula and substituted measurements.

---

She then created other permutations of the same prism by standing it on different faces. [An example of a permutation is shown to the right.]

Following Erin’s lead, Dani created a 3 by 4 by 2 prism and drew her top-view coding with its associated formula.

This occurrence led to a new Year-3 learning trajectory, more closely aligned to the elementary academic curriculum, to develop pre-formula volume conceptualization for a new group of third-grade children. The objectives were 1) to coordinate the number of cubes in a 2D conventional picture with the sum of the numbers in its numeric top-view coding; and, 2) to discover and integrate the numeric top-view coding representation with the volume formula for 3D rectangular arrays using and reinforcing emergent multiplication skills.

During the children’s initial work with the computer and the Geocadabra manual, they were individually challenged to determine how many unit cubes made up the figure in Task 1f (see Figure 4). After the research team noticed wide discrepancies in children’s interpretations, they asked Evan to use Geocadabra’s Construction Box to build the figure in Task 1f, which was projected to enable whole-class discussion.

Excerpts from field notes, November 2, 2009:

[The teacher] asked the class how many cubes were in the figure. Most said 24, but some said 25, 13 and 11. The whole class was invited to explain what was going on. Those who said 24 seemed to add the numbers in the [numeric top-view] grid. . . . They pointed out that the top row (of the grid) had $4 + 3 + 2 + 1 = 10$ cubes, and then $8 [3 + 3 + 2]$ in front of that [row] and so on until they determined 24 cubes in all. The child who said 25 had enumerated incorrectly, but was able to explain where the 13 came from. He labeled his picture [shown to the left] as follows: 1, 2, 3, 5, 6, 7, . . . (he skipped #4 and got 14 instead of 13).

Of note: He clearly counts each cube rather than visible faces. This is an exceptional step that may be supported by the fact that they have used the actual 3D cubes for the past 6 lessons in conjunction with 2D pictures.

Several children said that 13 came from looking at only the visible cubes in the picture and that there are several more hidden behind and/or below what is visible.

Evan had said 11 and also 24. He showed how he obtained 11 by counting only the grid squares that had non-zero numbers in them [i.e., he counted squares rather than the number of cubes in the squares]. Alan said that 11 came from counting only the cubes with black (top) faces in the picture.

The research team was surprised that none of the children had declared 30 or 20 cubes, based on counting all visible cube faces or all visible lateral faces, since this was found to be a common counting misconception reported in Battista’s study on 3D-array enumeration (1999). This activity demonstrates the importance of whole-class discussion. The children were able to hear various explanations dealing with their understanding of the 2D conventional picture and the numeric top-view representation. Those who counted only visible cubes or non-zero grid positions were convinced that there were more cubes when Evan rotated the figure to show the initially-hidden cubes on the left side and back of the figure, demonstrating the impact of the software’s dynamic Control-line-of-view function.
Following this discussion and for the next lesson, the children worked at their own computer stations to create figures that had exactly 24 cubes. This activity required coordination of the numbers in the numeric top-view Construction Box grid with the 2D figure each had created on the screen. Some used the Control-line-of-view option to rotate the screen figure to verify the 24-cube sum. These figures were formatted into task cards and were used in the subsequent lesson to reinforce their coordination of the numeric top-view grid with the 2D picture. Each child drew a grid on blank paper and, using a task card with someone else’s 2D figure, determined its numeric coding. Then, using only the written coding, each child built the figure on the computer to verify his or her numeric solution. Examples of children’s work are shown in Figure 6.

![Figure 6. Children’s numeric top-view coding of peers’ task cards](image)

To address the second objective (integrating top-view coding with the volume formula), the teacher presented a 12-cube rectangular array. Children volunteered to demonstrate how to code different orientations of this model. Then, the class was asked to build a rectangular array using 24 loose cubes. After successfully building and coding one 24-cube array, they were challenged to find as many different 24-cube arrays as possible. Figure 7 shows examples of two solutions that students presented to the class.

![Figure 7. Children’s representations and enumeration of 3D arrays](image)

In the following transcript (November 30, 2009), Jose explains the meaning of the 3s in the first example in Figure 7. This interaction was transcribed from a video-recording of a whole-class discussion that occurred when the children were shown the video-clip that was recorded the previous week.

Teacher: What does the 2 mean [referring to the 2 x 4 = 8 above the 8 x 3 expression]?
Evan: The 2 I think are the two lines [unclear] right over there [pointing at the 2-by-4 array projected on the board].
Teacher: Two rows. Okay, and what is the 4?
Evan: The 4 is the groups.
Teacher: Okay, there are 4… Four what?
Evan: Four squares.
Teacher: Four squares in each …?

Evan: Each row.
Teacher: Okay, so that’s a 2-by-4 [array]. Do you all agree that that’s 8?
Class: Yes.
Teacher: And why do you have … times 3?
Jose: Because there’s 3 in each … There’s 3 in each square.
Teacher: Three what?
Jose: Three cubes [gesturing layers].
Teacher: In each square … stacked up.

Jose’s gesturing indicated that he had formed a mental image of the three layers in the array. Holding his hand flat toward and parallel to the table top, he lifts it up three times to show three stacks or layers.

The children continued to find other combinations of 24-cube 3D arrays including their permutations as shown in Figure 8.

Figure 8. 2X3X4 arrays

Conclusions

Activities designed to help third-grade children move fluently to-and-fro among three visual SOC representations, namely, 3D cube models, their 2D pictures and their more abstract numeric top-view codings, facilitated their conceptualization of the volume formula for rectangular prisms. The initial coding activities that involved non-specific cube structures (e.g., Figure 4) were refined during Year 3 of the study to include a focus on “how many?” Through group discussion, the children described different ways of enumerating the cubes in these figures. In one method, they added the numbers in the top view coding. In others, they used their visual skills on the 2D pictures, by cumulating the number of cubes in each layer or in each stack of cubes. They justified the result by use of an alternate approach. Later, they were able to apply the “how many?” concept to rectangular arrays, fostering their understanding of the volume formula in concert with their emerging multiplication skills (e.g., Figure 8). The 24-cube problem also connected to their emerging understanding of combinations and permutations through concrete (3D) and abstract (semiotic) representations.

The results of this study reinforce other researchers’ findings about the importance of imagistic development (e.g., Dreyfus, 1991; Presmeg, 1992; Tall, et al, 2001). Outhred, et al, (2003), referring to the complexity of representing volume measurement compared to rectangular area measurement, state that “the process is more complex because students have to coordinate three dimensions and diagrams cannot show the layer structure clearly” (p, 84). That these young children in this study were easily able to transfer their knowledge of top-view coding to representation and to enumeration of 3D arrays is significant. Using mental imagery, they explain that each number in the rectangular grid represents the height of a stack of cubes on a
space, a measurement rather than a numeracy construct. Battista (1999) reports a common miscounting error when children enumerate cubes in arrays shown in conventional 2D pictures. He reports that they may count the same cube three times if it is located on a vertex or twice if located on an edge based on the number of visible faces. When presented figures, such as that in Task 1f (Figure 4), none of the children in this study counted all visible faces when asked to find the total number of cubes. This result shows that this misconception may be averted, believed to be due to the Year-3 children’s prior experiences with identification and reproduction activities requiring them to move to-and-fro among the SOC visual representations.

Finally, the after-school environment for this project carries particular advantages in that academic day constraints are not imposed on the instructors or children. Accountability testing at the district, state and federal levels has eroded instructional time with additional mandated test preparation and testing across all grade levels in the public school system. This project has enabled the children to experience authentic mathematics learning outside of the testing shroud.

NAVIGATING GEOMETRIES WITH DIFFERENT METRICS: COLLEGE STUDENTS’ UNDERSTANDING OF TAXICAB-GEOMETRY

Iwan Elstak  
Georgia State University  
matixe@langate.gsu.edu

Draga Vidakovic  
Georgia State University  
dvidakovic@gsu.edu

Mariana Montiel  
Georgia State University  
mmontiel@gsu.edu

Four college students’ understanding of taxicab geometry is examined. Written responses to eight questions on various aspects of Taxicab-Geometry (T-geometry) and their verbal explanations in interviews are analyzed. A proof comprehension and explanation question concludes the sessions. The students had a semester of college geometry that included a significant study of T-geometry including T-circles, T-bisectors of segments, isosceles and equilateral triangles, T-ellipses, and T-parabolas with the taxicab metric. Results indicate that the learning of T-Geometry is by no means a straightforward process where students are able to move effortlessly from Euclidean to T-geometry. Congruence, similarity, distance between (parallel) lines, the interpretation of the metric, (Euclidean) constructions of T-circles and T-angles all pose problems of varying degrees to students.

Introduction

In taxicab-geometry (to be designated as T-Geometry or T-G) points, lines and other objects are embedded in the Cartesian (coordinate) system. The metric between two points is the sum of the absolute values of the differences between the x and y coordinates of the two points. The parallel postulate is still valid and angles are constructed and measured as in Euclidean geometry.

In this study we examine how four mature undergraduate students (mathematics) understand taxicab geometry. More specifically, we investigate: how do these students understand the unfolding of the metric in terms of circles, isosceles triangles, congruence, similarity and the use of circles in geometry to solve problems? Do students distinguish between the concepts of lines, segments between points and distance between points? Are students aware of the analogy between solutions as given in Euclidean geometry and similar problems in T-geometry? Do students understand what methods from Euclidean geometry can be used to find T-geometry solutions?

Data collection and analysis processes center around the following three board questions:
1. How do participants use their knowledge to study T-geometry?
2. How do participants understand T-geometry?
3. What are the main problems the participants exhibit in their solutions to specific assigned problems?

Theoretical Framework

The basic perspective for this study is the model for the development of Euclidean geometric knowledge formulated by the Van Hiele couple since 1958 (van Hiele & van Hiele-Geldof, 1958; 1986). In this model Euclidean geometric knowledge generally grows from one qualitatively different level to the next through five (counting from zero) discernible stages. We are especially interested in the third and fourth levels: Level Three, informal deduction, is characterized by an awareness in the student of the role of definitions, the relations between figures and an ability to deduce claims and facts from given properties and known facts. Level four is the level of axiomatic deduction where a student understands the way theorems are...
proved from definitions, axioms and other theorems (Flores, 1993). The students in our study seem to be able to reason with definitions and properties of objects. In the van Hiele framework they should be at level three at least. We hypothesize that some of the students are still mainly at this level. Moreover, we think that when alternative geometries like taxicab geometry is studied that a new branch (or domain) of knowledge is established that may not fit the formal levels of van Hiele yet, but requires an autonomous path of development from level three or within level three.

The next perspective for understanding the growth of knowledge of T-geometry is the model of dynamical growth of mathematical understanding proposed by Pirie and Kieren (1994). In this model mathematical knowledge is proposed to go through several levels or modes of understanding starting with "primitive" knowing (which can be any existing knowledge). The model has an "image making" mode, an "image having" mode, a property noticing mode (or level), a "formalizing", mode, an "observing" mode, a "structuring" mode, and finally an "inventising" mode. For the finer details of the model we refer to the article referenced below.

What is of importance here is the emphasis of this model on image making, image having, property noticing and the idea that there is a constant restructuring of previous existing knowledge. This process can take the form of folding back in which one tries to understand some mathematics by going back to an earlier area of knowledge. This action of going back is motivated by a desire to understand some mathematical problem or concept from another, higher level than the one folded back to.

With the van Hiele levels we will have a framework for understanding the Euclidean geometry type of knowledge we assume to be present in our students, while the Pirie–Kieren model of dynamic growth provided us with a framework for understanding how the students dealt with the new T-geometry they were studying, and why certain events and problems were observed in their work. The combination, the shift from the first to the second is necessary to explain what the effects were of the original Euclidean knowledge on the students' success or struggle to understand the theorems of T-geometry that departs considerably from the Euclidean original.

**Research Context and Methods**

Four mature students (a mathematics BS close to graduation, a teacher completing requirements for mathematics education, a graduate mathematics student, and a graduate student in mathematics education) were interviewed for this study. They were part of a larger group of thirteen students who took a college geometry class at a southern university in the USA in 2009. Ten students participated in a study to investigate the nature of their understanding of the T-geometry part of the course in College geometry. This study reports on four students from that group.

T-geometry was studied for seven weeks in the course. Content covered in that part included T-circles, the T-bisector of an arbitrary line segment in T-geometry, isosceles triangles in T-geometry, some congruence relations, T-ellipses, T-parabolas, angles in T-geometry, and parallel lines. The group of four studied in this paper are the first group and in the future a paper will be presented on the findings of the whole group of ten students. The students were selected on the basis of their willingness to come back to campus after their final examination to work on a problem solving task followed by an interview with one of the researchers who was also their professor. The students will be designated as Alvin, Louisa, Sandra, and Richard (all names are pseudonyms).

<tbody>
<tr>
<td>Q1: What are the main differences between Euclidean and T-Geometry?</td>
<td>Metric, Circles, ellipse, parabola different. Construction different</td>
<td>Metric depends on orientation. Definitions of objects same as in E-G</td>
<td>Metric changes shape of circle</td>
<td>Congruence is different, and shapes of circle, ellipse, parabola different</td>
</tr>
<tr>
<td>Q2: What is the shortest line segment that connects A to B?</td>
<td>Correct construction using T-circles: center connected to points on perimeter</td>
<td>Triangle with horizontal base, using segment bisector; no consideration of oriented base</td>
<td>Attempt with diagonal base; then horizontal base with Euclidean bisector</td>
<td>Line segment from A to B. But unsure of response.</td>
</tr>
<tr>
<td>Q3: How can we construct isosceles triangles in T-Geometry?</td>
<td>Identical to E-G definitions</td>
<td>Same as E-G, but no clear image of what rectangle looks like in T-G</td>
<td>Identical to E-G definitions</td>
<td>Identical to E-G definitions</td>
</tr>
<tr>
<td>Q4: Parallel postulate in T-Geometry: How many parallel lines can we draw through point P?</td>
<td>Metric does not affect parallel properties. Just one line!</td>
<td>One unique parallel line, bec. rise over run is independent of metric.</td>
<td>Rise over run does not change so only one line.</td>
<td>There is only one line</td>
</tr>
<tr>
<td>Q5: How would you define rectangles and squares in T-Geometry?</td>
<td>Exact copies of triangles, taking orientation into account</td>
<td>Vertical or horizontal segments</td>
<td>Vertical and horizontal distances should be equal</td>
<td>T-length of perpendicular segment between lines</td>
</tr>
<tr>
<td>Q6: How would you define congruent and similar triangles in T-Geometry</td>
<td>Constructed Euclidean bisector, but wondered if a construction was possible without using Euclidean circles, based only on T-circles and lines</td>
<td>Tried to use midpoint of opposite side to construct angle bisector. It worked for right angles.</td>
<td>Tried to use T-circles to construct angle bisector, analogous to the tangent circles in E-G</td>
<td>Euclidean construction with Euclidean circles</td>
</tr>
<tr>
<td>Q7: How would you define the distance between parallel lines in T-Geometry. Shortest distance between par. lines</td>
<td>Explained the steps of the proof correctly and identified the main argument in similarity reasoning to compare metrics</td>
<td>Understood first steps of arguments. Did not know how similarity worked in the two metrics</td>
<td>Understood how ratio of T-length and E-length of a rectangle are reproduced through similarity of right triangles</td>
<td>Understood that ratio between T-length and E-length is preserved through similarity of right triangles</td>
</tr>
</tbody>
</table>

Method of Inquiry

The method of inquiry was twofold. First the students were presented with eight questions on T-geometry ranging from introductory to more conceptual questions. The students wrote their responses and solutions on the worksheets provided. After that they sat for a one on one interview with the researcher where they explained how they had responded to the questions and why they solved problems a certain way or not. These interviews lasted an average of 1.5 hours. All interviews were audio-taped and transcribed later. Data consisted of the worksheets on which the students had written their work and the transcribed interviews with the four students. The transcribed interviews were analyzed and coded per question on the basis of the type of student thinking that was evident, and the forms of conceptual obstacles that were identified. A qualitative analysis of the worksheets, and interviews, was conducted and an explanation of the students’ understanding was formulated using the Pirie-Kieren model.

Questions

The questions posed to the students were: (1) What are the main differences between Euclidean and T-geometry? (2) Suppose I have a point A and a point B in the T-plane. What is the shortest line segment that connects A to B? (3) How can we construct (Using Euclidean tools) isosceles triangles in T-geometry? (4) Two lines in T-geometry are parallel if they do not intersect. Suppose we have a line \( m \) and a point \( P \) not on \( m \). How many lines can we draw through a point P (not on the line) parallel to the given line \( m \)? (5) How would you define rectangles and squares in T-geometry? (6) How would you define congruent and similar triangles in T-geometry? (7) How would you define the distance between parallel lines in T-geometry? (8) How can we construct an angle bisector in T-geometry? This series of questions was then followed by a proof comprehension question (Conradie & Frith, 2000) dealing with a proof that T-squares and Euclidean squares are identical. The main argument of the proof was that every Euclidean rectangle that is not a square is always a T-rectangle that cannot be a square in T-geometry. The students were asked to explain how the main arguments in the proof were grounded and if they were valid.

Results of the Analysis

First we will present the results from the written part of the study in Table 1. The first column of Table 1 represents the problems from the questionnaire. Subsequent columns contain the students’ key responses for each question in brief format. Next we will review the results from the interviews where the students explain their written work. In the discussion of research questions we present an analysis of the data.

The Students’ Explanations From The Interviews

On question two Alvin, Louisa and Sandra mentioned in their explanations that they were confused on this question. After connecting A and B Sandra said: "…so that was a little tricky." (...indicates here deleted dialogue; "I" stand for the interviewer)

I: "OK. And the trick was what?" Sandra: "In my head!"

I: "In your head? In what sense?" S: "The trick was in my head! Well, because I have to remember that they’re the same thing. Going diagonally from A to B is the distance from what you call that horizontally, C- point". (I: She is pointing now to the 90 degree angle, where the horizontal and vertical parts meet). S: "Right. Those--- (pause) it’s the same, either going diagonally or if I go across and then up". The student seemed to hesitate between thinking of the
The comments from Alvin on congruence in question six were similar to his written work. Sandra however said: "Congruent! I said since the angle measures were the same, you see, now you blew me out of the water by telling me I can’t do Side-Angle-Side and all that (laughs). Mainly I said that they had the same angle measures; and I can prove that a side has the same distance". After the interviewer tried to focus on the definition of congruence, Sandra continues: "Well, I was kind of thinking proving them by Side-Angle–Side. Or: Angle-Side-Angle, the basic ways of congruency." When reminded again that she was at the theorem stage, but the definition stage was still not completed, she stated: "OK. So I don’t really know about congruency."

Louisa first hesitated how to explain congruence but eventually claimed that sides and angles need to stay equal for congruence to exist. To get this insight the interviewer made her cut a triangle from the worksheet and place the paper copy in a different position on the grid system. She then states "I mean, if somebody shows me how sides have remained the same but they look different, then I would have expected, then I could understand that and agree with that, but I can’t seem to visualize or construct that myself."

As to similarity in question six, Alvin, Sandra and Louisa all stated initially that proportionality of corresponding sides must go with similar triangles. Only after one or several hints did they realize that proportionality of corresponding sides is a Euclidean consequence of similarity, not a basic general property. In the proof comprehension question Alvin and Richard showed a good understanding of the gist of the proof, but Sandra and Louisa both admitted not to understand the crucial part of the proof. The part where the proof moves from showing that two unequal T-distances lead to a claim about two unequal Euclidean distances, using similar triangles, confused them. They didn’t understand the connection with the initial question of why E-squares and T-squares are identical.

**Discussion of Research Questions**

_How Do Students Use Their Knowledge To Study T-Geometry?_

The main source for the notions of the students seems to be what they know from concepts in Euclidean geometry. The Euclidean concepts are adapted to the conditions of T-geometry, modifying distance considerations to accommodate the T-metric. Students seem to use a naïve form of transfer to navigate from Euclidean formats to T-geometry. In the case of the shortest segment between points A and B we see a superficial interpretation of the question where the focus shifts from the segment to the distance. In the case of the isosceles triangle construction the segment bisector method seems to be a preferred choice, leading only to a solution if the base is horizontal. The angle bisector methods are transfers from Euclidean geometry based on equal distances to legs that do not guarantee equal angles in T-geometry.

_How Do These Students Understand T-geometry?_

It seems clear that Euclidean geometry knowledge informs most of their notions on initial T-geometry. They seem to think about T-geometry through the lens of what they already know from earlier studies of Euclidean conditions. This can help or it can hurt their understanding of T-geometry. However all the students are aware that things change in terms of circles, side
lengths, congruence, similarity, angles, bisectors etc. They have a focus on definitions to guide them through the new geometry. Congruence and similarity are problematic for two of the four students. Definitions of congruence and similarity and theorems of congruence and similarity are taken as one whole from Euclidean contexts. All four students included proportionality in their concept of similarity of triangles.

To explain these observations we look at both the van Hiele (van Hiele, 1986) and the Pirie Kieren (Pirie & Kieren 1994) models. Both stress the importance of a phase in learning (van Hiele, at level two, the level of logically connecting previously noticed properties, assuming the first level to be level zero, and the Pirie-Kieren level of property noticing in learning concepts) where the learner is able to notice how individual properties of objects relate to each other and to definitions. We assume that the students are relatively versed in Euclidean geometry. These students studied T-Geometry which differs from the Euclidean version in the existing metric but not in axioms like the important parallel postulate etc. Euclidean geometric knowledge is therefore proposed as the Pirie-Kieren domain of Primitive Knowing, meaning that we assume that the person doing the understanding can do Euclidean geometry as their initial basis of knowledge before studying T-Geometry (Pirie & Kieren, 1994). The students need to build their knowledge of T-geometry concept by concept. It seems that this process has to be repeated one by one for circles, for lines, for segments, bisectors (angle and segment bisectors), for parallel lines, for triangles in various positions, distances between lines, and for the whole body of congruence and similarity.

What Are The Problems They Exhibit In Their Solutions To Problems Posed?

One observes that the habit from E-geometry to place diagrams of triangles and lines such that there is usually a horizontal component can impact the students’ awareness that in T-geometry, this horizontal orientation amounts to a special case that may not yield a general method of solution for the problem in question. We see this when students try to construct isosceles triangles, where segment bisectors are used with horizontal bases for the initial construction. For the construction of isosceles triangles the students had a choice between a method using T-circles, which was applied by only one student, and a method using generalized segment bisectors, which was not used by any of the students. The segment bisectors in T-geometry were discussed extensively in class, covering all possible orientations of the segment to show the peculiar segment bisectors. The possibility exists that when the question is framed as: ‘construct, using Euclidean tools’ students are overwhelmed by the question and wonder if every E-circle must be replaced by a T-circle. The responses from the interviews suggest that this is the case.

In the Pirie-Kieren model the recursive nature of the learning process is central to the theory. The student will go back repeatedly to their First knowledge, but every time with some added portion of information or some extra mental image or schema. The dynamic image making and image having processes of learning in the Pirie-Kieren theory in particular seem to be very relevant in understanding how T-geometry evolves in the mind of the four students. While a student may have a clear idea of how to construct an angle bisector with Euclidean circles, and execute this flawlessly, the same student (Richard) may not understand yet that the T-distance between parallel lines cannot be literally transferred from the E-geometry context by finding the T-distance of the perpendicular Euclidean distance. If the student did not develop her/his own image of the distance between parallel lines in T-geometry, she/he may not have noticed the
specific properties involved in the question of identifying the correct distance between parallel lines.

For T-squares we notice a similar gap: no clear image apparently of T-squares. Squares in T-geometry were not represented or understood in their most general T-geometry shape or orientation. From the comments of the interviews it was also clear that students had quite clear ideas about what a definition of rectangles should be in T-geometry, but two students did not see how in the comprehension test for showing that E-squares and T-squares are identical how the ratio between E-length of sides is carried over from E-geometry to T-geometry and back.

Constructing isosceles triangles was not placed in its basic (or logical) context of T-circles by two of the four students. A third student constructed an isosceles triangle Euclidean circles but with a horizontal base. Three of the four students tried to adapt Euclidean methods of construction based on perpendicular bisectors of a segment without sufficient consideration of the specific T-geometry implications.

Geometry is a system of related concepts that need to be understood one by one and in relation to one another. The students in this study had to develop their notions of circles in T-geometry, angle bisectors in T-geometry, segment bisectors, triangle congruence, and then find out how distance and length are related to angles and shapes and what could be transferred from the domain of E-geometry into the domain of T-geometry. In particular, the students needed to develop an understanding of when constructions from E-geometry could be applied or modified into a T-geometry construction. The data suggest that this process was incomplete after the seven weeks of study, for most of the objects and concepts mentioned.

Generalizations in mathematics do not occur without reflection. What we observe in the students’ work with T-geometry in relation to their knowledge of E-geometry is consistent with the findings that a systematic study of various different sources of knowledge may be a precondition for successful transfer of concepts from one domain to the next (Wagner, 2006). This seems to apply even when the analogy between systems seems obvious from the context of the problem posed (construction of isosceles triangles or construction of angle bisectors in T-geometry). However, the students showed signs of creative and diverse modes of thinking: there was not one model of behavior or one single type of student performance. Richard had a strong command of some principles but missed a clear picture of how to express the distance between parallel lines in T-geometry concepts. Alvin had a very good overall grasp of T-geometry concepts but did not see that angle bisectors could be constructed simply with classical Euclidean tools and Euclidean circles. The main problem in the students’ solutions was the lack of consistent and well argued transfers of knowledge from the Euclidean sphere to the T-geometry plane with its different metric.

**Conclusion**

In light of the van Hiele theory of growth of geometric knowledge and the Pirie-Kieren concept of levels of dynamic growth of mathematical knowledge it seems that the growth of T-geometry knowledge also passes through various phases of development. One trait of this development seems to be that students have to go through a phase of experiencing how to navigate between E-geometry and the corresponding T-geometry concepts and back. Can we draw a Euclidean circle in T-geometry? Such questions may seem trivial to an outsider, but what we observe is that such questions are far from obvious to students of T-geometry when placed in the context of constructions with straightedge and compass in T-geometry. Studying the effects of change of metric in geometry, T-geometry offers a way to understand and clarify this change.

---

of axioms that differs from a change as we know it in traditional non-Euclidean geometry.
Euclidean geometry and T-geometry are related as mathematical systems. Learning how to
navigate from one world to the other is an excellent exercise in mathematical generalization and
concept building. College students and future teachers could benefit from a thorough study of the
similarities and differences between the two systems (Martin, Towers, & Pirie, 2006) by
expanding their experience with generalizing geometric structures through the study of
geometries with alternative metrics.

PROPORTION AND DISTORTION: EXPLORING THE POTENTIAL OF COMPLEX FIGURES TO DEVELOP REASONING ON SIMILARITY TASKS

Dana C. Cox
Miami University
Dana.cox@muohio.edu

Why is it so difficult for students to transcend visual strategies into preproportional or proportional thinking in the context of similarity? This study is focused on identifying and describing potential extenders for visual intuitions about scale. Described here are 11 strategies that students used during clinical interview to differentiate similar and non-similar figures. There is evidence to suggest that distortion-detection is a skill that enables students to reflect upon and evaluate the validity and accuracy of differentiation.

Introduction

Research literature suggests that students struggle to develop abilities to reason proportionally and to make sense of similarity (Lamon, 2007) yet children as young as third grade have intuitions about what it means for two figures to be the “same shape” (Lehrer et al., 2002; Swoboda & Tocki, 2002; Van den Brink & Streefland, 1979). These intuitions are based on visual perception, which Swoboda and Tocki (2002) describe as a “natural” occurrence. The ability, documented by Van den Brink and Streefland (1979), to visually perceive the relational size of objects and extrapolate the size of such objects in a new context is largely unexplained. Also of interest is an answer to why it is so difficult for students to transcend visual strategies into preproportional or proportional thinking in the context of similarity. What is it about these tasks that prevent students from advancing into the quantitative realm, even after they have done so in other contexts for proportional thinking?

The answers to these questions lie in bridging the previous work characterizing similarity tasks with an analysis of where students access them visually, and what barriers exist preventing more sophisticated solution strategies from being used. Furthermore, it would be important to identify how visual perception is related to other preproportional and proportional strategies. Understanding the nature of visual perception and the boundaries of qualitative and quantitative proportional reasoning will provide important information about how intermediate tasks might be designed to support conceptual growth. This study is focused on identifying and describing potential extenders for visual intuitions about scale by analyzing the strategies that students use during clinical interview to differentiate similar and non-similar figures. Results are shared here in answer to the questions:

1. What strategies do students use to differentiate similar figures and what types of geometric and numeric reasoning are indicated by these strategies?
2. How does the complexity of the figure to be differentiated influence student reasoning about proportion?

Theoretical Perspective

This study assumes a constructivist perspective on the inquiry into student conceptions and the modeling process. This has two implications for the study at hand. First, there is the direct implication that without observations of students themselves, no theory can stand apart from the limitations of the mathematical understanding and biases of the researcher (Cobb & Steffe, 1983).
By observing students interacting with the ideas behind the theory, we open the theory up to the unexpected (Cobb & Steffe, 1983). Thus, the method of clinical interview was chosen as the primary method of data collection.

The second implication is in registering the significance of the data that are collected. It is possible to have as a goal the empirical vetting of a theory, marking instances where the predictive power is great and where it is not. However, another goal, responds to Vergnaud’s (1987) challenge to “understand better the processes by which students learn, construct or discover mathematics and to help teachers, curriculum and test devisers, and other actors in mathematics education to make better decisions” (as quoted in Confrey & Kazak, 2006, p. 311).

**Literature Review**

Proportional reasoning has been investigated through two major types of tasks: comparison tasks and missing value tasks (Lamon, 1993, 2007). Lamon (1993) outlined a conceptual progression for the development of proportional reasoning that stemmed from visual and intuitive solutions growing through successful preproportional strategies up into mature proportional reasoning. This progression was useful in describing and organizing the numeric strategies that were used by students during interviews. However, because of the geometric nature of the tasks it was insufficient to focus only on instances of numerical proportional reasoning in student strategies. In order to capture other forms of reasoning that students used on similarity tasks, it was imperative that a geometric lens also be used.

**Data Collection**

**Population**

A population of students in a Midwestern, urban school district was identified to target racial, economical, and academic diversity. The inclusion of diversity in the sample for study was not intended to highlight differences between groups of students, but rather to ensure that a broader extent of prior student experience and knowledge is included in the results.

**Instrumentation**

*Revised Similarity Perception Test (rSPT).* The rSPT was designed to mark differences in visual perceptions of geometric proportion. It coarsely differentiates students by their ability to visualize geometric proportional growth as well as their likely understanding of scaling and the relationships between similar figures. The part of the test relevant to this paper is made up of 23 yes/no items divided into four sections (1-4) where students are asked if two given images are different sizes of the same shape.

![Figure 1. U-shape, Simple Convex, and Complex Figures Used on rSPT Tasks](image)

Three distinct classes of figures are featured on the rSPT items and were included in the subsets given to each student. These distinctive classes are the U-shape, simple convex, and complex figures, which are illustrated with examples in Figure 1. The U-shape is an eight-sided concave polygon with all right angles. All of the simple convex figures are rectangles (as the one shown) or parallelograms. The complex figure class includes figures that were created by setting a second image (stars, cartoon girls, or parallelograms similar to the exterior) inside of a
parallelogram. The variation in figure type included in the rSPT items meant that different arrays of characteristics such as lengths within the figure were available to students on each item.

Five questions in Section 1 identify student perceptions of distortion in the general shape. For example, students are shown the letter A in two different fonts. The seven questions in Section 2 identify visual perceptions of distortion in terms of simultaneous horizontal and vertical growth. The seven questions in Section 3 identify visual perceptions of zooming and perceptions of distortion as changing the perspective of the image. These items feature a figure framed by a parallelogram. On some items, such as Item 3.2 shown in Figure 2, different scale factors are applied to the interior figure and exterior frame to give the illusion of zooming in or out on the figure. The last four items in Section 4 identify visual perceptions of continuous all-over growth by varying the scale factor on different components of one figure.

Figure 2. Item 3.2 from the rSPT

The rSPT was administered in entirety to a group of 91 seventh-grade students for sampling purposes. This instrument provided information about students’ visual perception of shape, correspondence, and size transformation and helped to divide students into subgroups according to their responses. A stratified purposeful sample (n=21) that included the most common as well as unique response patterns was selected for task-based interviews. This method of sampling intentionally included individuals who exhibited varying abilities, perceptions, and strategies.

Interview Protocol. As a part of a larger interview protocol, students were asked to revisit a subset of the rSPT items from sections 1-4 and think aloud as they responded again to the items. They had just finished a unit of instruction on similarity and the opening prompt was changed to, “Are these figures mathematically similar?” Students were not made aware of their original responses before responding, even if they asked. As time did not permit the review of every item on the rSPT with every student, students were given individually selected subsets of the items. These subsets were chosen carefully to include a variety of items. The goal was to capture the most diverse reasoning possible from each student.

Data Analysis

From the interviews, student responses to rSPT items were transcribed using Transana (Fassnacht & Woods, 2005), a software package used to transcribe and organize data. Student think-aloud responses to rSPT items during the interviews were analyzed using a constant comparative strategy, the unit of analysis being an individual’s response to one item on the rSPT. The responses were analyzed for themes, first by student and second by item.

After the framework emerged from analysis, it was used on the data. Each response given by each student was coded according to the strategy type used. In the event that a student used multiple strategies on one item, that response was broken into multiple units so that each received one code. The nonspecific code was only used if a student gave no indication of a strategy at all on an item, thus it is impossible that a student’s response could be broken up into non-specific and then specific components. In total, 559 units were analyzed and coded.

Results

Framework

The framework that emerged to describe the types of strategies that students were using to differentiate proportional from non-proportional pairings of figures is oriented toward the types of characteristics that caught student’s attention or were useful in justifying a response. It was initially intuitive to include characteristics such as “angle” or “side length” in this framework. In the traditional analytic sense, these are the characteristics by which similar figures are defined. However, other characteristics such as the overall appearance of the figures, variety in the types of lengths students referred to, or types of relationships between the two figures emerged during the analysis of student responses. Four main characteristic types encompassed the overall variety that was documented: Appearance, Angle, Length, and Relationship. In 39 cases, or roughly 7% of total responses, a student’s response was not specific enough to ascertain what characteristics of the shape the student perceived, or how the student arrived at a conclusion about similarity. For example, Elijah responded to an item from Section 2, “They are the same. I forgot what I was going to say.” A fifth category, Nonspecific was added to include all responses that did not reference specific characteristics.

As responses were sorted according to characteristic, it was possible to parse out the strategies that students were using to differentiate the figures. The characteristics that students note are highly intertwined with the strategies that students are using, but they are not necessarily one-to-one; students utilize the characteristics of the figures in very different ways. From those responses where a strategy was evident, a framework of eleven unique strategies emerged from analysis. These are summarized in Table 1.

Appearance-type Strategies. Three types of responses regarding the general appearance of shapes were made: (1) descriptions of cosmetic features of figures such as color or blur, (2) comparisons of shape type such as “rectangle,” and (3) the relative positions of subshapes within a figure. These holistic descriptions of the shape did not reference specific components of the figures, but did help students describe their visual perceptions of figures and were indicative of different levels of sophistication even within the broader category of Appearance-type strategies.

Angle-type Strategy. Angle was not a differentiating factor for most of the figure pairs on the rSPT, although it was a factor on Item 1.2, which features non-similar parallelograms. Most students successfully determined that these two figures were non-similar using the non-equality of corresponding angles as evidence. Anna responded, “I could tell the difference between these two because it’s got more of an angle. Like, it’s angled more over. This one is up...er...bent over more. I can’t really explain it,” (Anna, 1.2, Non-similar). In the language that students used and methods of angle comparison, there were subtle differences in the ways angles were invoked.

Length-type Strategies. Three distinct length measures were noticed and compared by students while differentiating figures: primary, secondary, and gap lengths. One of each of the three measures are illustrated in the case of the U-shape in Figure 3. Primary and secondary lengths are both measurements of drawn lines within the figure, generally edges. A primary length is a length that defines the height or width of the entire figure. In the case of a parallelogram, all four edges were defined as primary because they frame the figure and determine both horizontal width and a “slant height,” which most students referred to as “height.” All other lengths including remaining edges or drawn lines within the figure are secondary. A gap length measures the width of a gap in the figure not represented by a drawn line. As with the Appearance-type characteristics that students noticed, students compared and used these lengths...
in a myriad of ways. Two particular Length-type strategies were documented: *Corresponding Length Comparison* and *The Constant Gap Strategy*.

*Figure 3. Illustration of Length Subtypes*

*Corresponding Length Comparison* indicated that a student made a decision about similarity based on the comparison of two (and only two) lengths. Arguments that students used that indicate this strategy sound like “these figures are similar, one is just taller than the other.” In most of the cases, the lengths to be compared were primary or secondary lengths. In the case of the *Constant Gap Strategy*, it is not. For some students, there is a conceptual difference between

---

a gap length and one that is represented by a drawn line. The difference lies in the fact that a drawn line can be perceived as an object that has properties such as length. A space length is not as easily perceived as an object, although it can be represented as the unmarked distance between two points. In this sense, space lengths can be classified by students differently from drawn lengths, and may not be expected to scale in the same way. The constant gap strategy was based on the expectation that while lengths may get longer (or even scale multiplicatively), gaps remained constant.

**Relationship-type Strategies.** Three other strategies that relied on a student’s perception of relationships within the pair of figures were identified in this study. Two of these strategies were numerical in nature (one additive and the other multiplicative), while the third relied on a qualitative assessment of the relationships. The *Constant Difference* strategy is often seen characterized as a misconception or immature numeric reasoning. Students using this strategy are not yet focused on proportion as a multiplicative concept. The *Constant Ratio Strategy* is familiar, based on numeric reasoning and often taught explicitly in the classroom. Its use by a student named Tom in this study is noteworthy.

Tom was one student who consistently used extrinsic ratios of primary and secondary side lengths to determine similarity. On most items, he chose to compare between two and four pairs of lengths. Tom used this strategy on almost all items yet came to some incorrect conclusions. For example, Tom’s method was unreliable on items featuring U-shapes. Tom would often compare the ratio of two pairs of corresponding sides. On one particular item he compared three ratios and when questioned, Tom made a statement that unintentionally explained why his method was unreliable:

**Interviewer:** You coordinated three things there: the width, then the width of this leg thing, then the height. Is that because this is a different kind of shape? How come three things?

**Tom:** On the other ones you've chose, you have...There's really not much you can...You can go like that [compares the overall height gesturally] which I kinda did. You, but, you can’t really measure...The more complicated the shape, the different you...the more different ways you could change it to look similar but it could be different (Tom, 2.4, Similar).

Students using transformative strategies (*dilation* and *tiling*) decided if two shapes were similar/non-similar based on whether one could/could not be transformed into the other. Both strategies were used by students who perceived a dynamic relationship between the two figures in the item and imagined one as transformed from or into the other either by dilation or by tiling. For example, David used a dilating action radiating from the lower corner to describe the relationship between two parallelograms. As he drew, David said, “I tried to fit that in that and make it bigger. And see...kinda picture it,” (David, 1.3, similar).

David uses qualifying language such as “like” or “kinda” (kind of) with a tentative tone, as if he is searching for a way to describe what he imagines and is trying words out. Students used common phrases like “fit it in” or “filling up,” and prior experiences became tools by which to identify specific perceptions. It was also common for students to make sketches of one shape inside of the other, as David did above with the parallelograms. To highlight the use of many of these tools in a slightly more difficult context than the parallelograms above, the following
transcript was taken from David’s description of why he thought two U-shapes were similar. David interpreted the larger and smaller shapes as related by dilation.

David: I think I said these are the same. Like, these are parallel. Just the same shape as it. Kinda like just tried to fit [the small leg] in [the large leg].

Interviewer: How does this one fit in there?
David: It kinda doesn't.

Interviewer: What do you imagine?
David: I kinda just imagined like...[David draws a sketch.] I try to picture it as it getting bigger and fitting.

Interviewer: Filling it up?
David: Yeah! This, like, this corner go into this corner. (David, 2.4, similar)

Although the language used is not formal language typically associated with dilation, it is not lacking in sophistication. David used drawn dots to describe the destinations within the larger U-shape of specific points within the smaller U-shape. This illustrated a very sophisticated conception of correspondence and continuous all-directional growth, even if this conception did not translate into a strategy that was easily verbalized or uniformly applied.

Patterns in Student Strategies

Even students who were capable of analytic reasoning used visual judgment to mediate their responses to items. The use of this visual judgment, particularly to identify distortions between figures, supports Swoboda and Tocki’s (2002) hypothesis that students regard distortion as a property of shapes in this context. Two findings are particular supportive: (1) there is preliminary evidence that whether two figures are similar or not impacts student strategy choices, and (2) the presence of different types of distortion has a further impact on student strategies when figures are non-similar. Due to space limitations, only the first finding is explicated here.

![Figure 4. Comparison of Strategy Types Used on Perceived Similar and Non-similar Pairs](image)

**Discussion**

In Figure 4, the types of strategies used by students are organized. 203 units were ‘Yes’ responses where a student had decided that the two shown figures were similar (whether or not this was the mathematically correct response). The remaining 356 units were ‘No’ responses. It

---

is interesting to note that 14.78% of ‘Yes’ responses were Nonspecific, while only 2.53% of ‘No’ responses were Nonspecific. There is also a significant gain in the percentage of Relationship-type strategies used when a student did not think the figures were similar compared to when they thought they were. There is evidence to suggest that distortion-detection is a skill that enables students to reflect upon and evaluate the validity and accuracy of differentiation. On simple differentiation items such as those incorporated in the rSPT, students’ decisions were more evidence-based on items where they perceived distortion than when they perceived none. Of the 39 non-specific responses, almost six times as many were related to figures students perceived as non-similar.

Taking a purely analytical or numerical approach to differentiation tasks can be limiting and in some cases debilitating, especially when the task is to prove that two shapes are similar. When proving two complex figures or U-shapes are similar, a student taking a purely analytical approach must compare each and every possible length including primary and secondary edges, but also space lengths. It is difficult for students to know when enough is enough. In the case of non-similar figures, a student could make multiple comparisons and still miss the one pair that deviates from the pattern. Visual judgment can greatly reduce the analytical workload by indicating to a student where to look to find likely counterevidence to similarity and help support the student in determining a sufficient argument. For example, instead of constructing all possible ratios of corresponding lengths to test for equality, Tom could have used visual judgment to detect distortions in particular components of the U-shape before deciding which ratios to compare.

David was remarkable in his ability to explain his Transformative strategy of imagining the small figure slowly filling up the larger while maintaining its shape. David’s understanding of continuous all-directional growth is quite well developed and is evident in his visualization. The correspondences that he saw indicated that he was, indeed, visualizing dilation. He concluded with a dynamic hand gesture as if he was holding a beach ball as it filled with air. This gesture could also be interpreted as a method of describing continuous all-directional growth. David’s description did not include analytic reasoning, yet it illustrated deeper understanding than Tom’s accurate but incomplete use of the Constant Ratio strategy.

This is not to elevate all visual judgment to extreme levels of sophistication. Certainly there were examples of visual strategies that alluded to more basic conceptions. Nor is this argument intended to deny the importance of analytic reasoning. Visual judgments provide structure for mathematical description, but are not themselves numerical descriptions. In order completely mathematize and abstract the act of classifying or scaling figures, analytical reasoning is required. However, what has been observed in this study suggests that visual perception is not entirely guess-related and primitive, that the consideration of visual perception as a powerful indicator and supportive extender of conceptual understanding in this area might be warranted.

This report describes a collection of instructional tasks developed and piloted with students from second through fourth grade as part of a four-year longitudinal study. These tasks were developed to help students progress to higher levels of thinking in measurement. In addition to describing the tasks and their purpose, we provide student responses to these tasks from individual interviews with eight students. The process of developing and piloting these tasks has been beneficial for us as a research team and has caused us to reorganize our thinking about the teaching and learning of measurement.

Introduction

The technical skills needed to measure accurately and precisely are important in many aspects of our everyday lives. We as teachers should strive to help students develop these necessary skills so that they can function well as adults. However, to focus only on the procedure of measurement is not sufficient. The conceptual understanding required to comprehend the foundations of measurement is imperative to developing a coherent and flexible notion of a unit, which applies not only to length, area, and volume but also to less physical measurements including rates and ratios in general. Unfortunately, many students struggle with even the most basic of measurement tools, the ruler (Lehrer & Schauble, 2000, Bragg & Outhred, 2004, & Cannon, 1992), that suggests a disconnect between numerical measurements and the unit iteration process. This disconnect should be seen as a warning to researchers to “question the depth of students’ understanding of coordinate systems, function graphing, locus problems, and theorems about lengths or distances” (Battista, 2007, p. 902).

Although this report discusses a set of measurement tasks and student responses to these tasks, our main purpose is to describe a framework for developing measurement tasks based on reflective analysis of student responses. The tasks we present here have been developed as the result of our work testing and modifying a set of hypothetical learning trajectories for measurement (Clements & Sarama, 2009). According to Simon (1995), a hypothetical learning trajectory consists of three components: “the learning goal, the learning activities, and the thinking and learning in which the students might engage” (p. 133). We used the learning trajectory to focus our attention on key ideas in measurement, such as unit, comparison, quantification, and ratio, as we designed tasks.

Methodology

The learning activities described in this report were developed as part of a teaching experiment (Steffe & Thompson, 2000). The teaching experiment consisted of multiple teaching episodes in which the research team developed a set of tasks for the student, made predictions.
about how the student would respond to the tasks and checked our predictions against student responses. This cycle of the teaching episode was repeated multiple times over several years making up a teaching experiment. The data reported here reflect our teaching experiments with eight students as they moved from second grade through fourth grade.

Length

Bent Path Comparison Task

In the Bent Path Comparison Task, we provided students with a sheet of paper containing two separate bent paths with a start and ending point (Figure 1). We asked the students to imagine a bug walking along each path from the start to the end before prompting them to compare the length of the paths. Students were asked to respond to this task without touching the paper and without a measurement tool. This comparison was intended to be a qualitative comparison with the student predicting that one path was longer. After the student predicted which path was longer, we asked if they could check this. We anticipated that the students would use a ruler to measure the length of each path and subtract to find the difference.

![Figure 1](image)

This task was designed to explore two misconceptions, making a comparison based on the number of turns or confusing distance traveled with displacement. This task also allowed us to determine how students would deal with partial units because the paths were composed of segments made up of non-integer lengths when measured in inches. We also wanted to see how the students would visually compare the path lengths and if they could understand and deal with the fact that the sum of the lengths of the individual parts was the length of the entire path.

Student responses. For the initial comparison, several students relied on a mental straightening or stretching of the paths. Drew said “I'm thinking just about that if you stretched this one out in a straight line”, at the same time pretending to hold and pull two ends of a string apart. Sara, who typically struggled more than the others, based her comparison on the number of turns in the paths. Surprisingly Ryan verified that the longer path was indeed longer by reconstructing the two paths using the ruler. He copied each individual section of the path and translated it off to the side, adding the next part so that the pieces formed a straight path. Using this method, the student was able to reduce the task to a simple direct comparison between the two reconstructed straight paths. We felt that using this method allowed the student to avoid any measuring because he never assigned a quantity to any of the lengths.
Wrap Comparison Task

For the Wrap Comparison Task, we began by demonstrating to each student that a pipe cleaner could be bent to fit perfectly around the four edges of a 1-inch square tile. Then we build another shape out of a collection of 1-inch tiles and asked the student to compare the length of the path around the set of tiles to the length of the pipe cleaner. For example, if the distance around one square tile was called 1 pipe cleaner, then the distance around the image in Figure 2 would be two pipe cleaners. At times we directed students into dealing with equivalent fractions by asking them to report their measures in different ways. For example, if a student reported that the length of the path around a set of tiles was two and a half wraps, we asked them to tell us how many half wraps this would be. We hoped that students would report things like the path length is two and a half wraps or five half wraps.

The purpose of this task was to present students with a measurement task that would require the use of a composite unit. In this case, one “wrap” around the square tile was made up of four “sides.” We envisioned this as a way for students to experience one-fourth as a unit with four fourths composing one unit or a wrap. This way of introducing students to a fourth allows them to avoid decomposing a unit into four equal parts to create a fourth. This task also lends itself to proportional reasoning (i.e. four sides is to one wrap as 12 sides is to three wraps) and equivalent fractions.

Student responses. Generally speaking, students responded very well to this task once they understood what was being asked of them. Initially, some students interpreted the task incorrectly and found the perimeter of the set of tiles by counting the sides rather than counting the number of wraps or pipe cleaners. Once the task was clear, most students counted the number of sides around the set of tiles, grouping sides into fours as they went. Some students, however, eventually started counting up the total number of sides and dividing by four to calculate the number of wraps that it would take to be as long as the path around the collection of tiles. Although we felt this was an important move towards proportional reasoning, we found the students’ ability to deal with equivalent fractions in this context to be far more exciting.

While working with the collection of tiles in Figure 3, if a student responded that it would take one and a half wraps to be as long as the path around the set of tiles, then we asked them, “How many half-wraps would it take to be as long as the path around the set of tiles?” To our surprise, most students were able to respond that it would take three half-wraps. As we extended this idea, students were able to tell us that the path around the set of tiles was as long as one and a half wraps or three half-wraps or six quarter-wraps, essentially building equivalent fractions. Although we are not certain that students completely understood all of the mathematical consequences of their responses, we were pleased with their ability to change their unit of measure.

Construction Paper Cut Out Comparison Task

The students were given two figures at a time and asked to compare the areas. The figures were cut from construction paper prior to the interview. The first pair was a square and the
triangle formed by cutting a congruent square in half along its diagonal (Figure 4). The second pair was the same square and the rectangle formed by cutting a congruent square in half vertically (Figure 5). Then the students were given the two halves to compare (Figure 6). This process was repeated with a triangular quarter and square quarter of the original square (Figure 7).

This task lends itself to three different approaches: reasoning numerically that two shapes that have half the area of a third shape necessarily have equal areas, making an intuitive visual comparison between two different shapes, or mentally decomposing and recomposing one half onto the other. The purpose of this task was to explore student reasoning and to determine which of the three techniques students would use to explain their answers.

*Student responses.* Surprisingly only two students, Anselm and David, determined that the two halves in Figure 6 had the same area. One reasoned numerically while the other relied on decomposing and recomposing. Anselm easily recognized that the two halves were equivalent, stating that because they were both halves of the same whole, the rectangle and triangle would have the same area. He gave a similar argument for the two quarters. In contrast, David compared the two halves (and the two quarters) by lining up the corners and talking about how the uncovered parts could be rearranged so that both figures were the same and therefore had the same area. Most students did not see that the two halves (and the two quarters) had the same area. Instead, they thought that the triangle’s area was larger based on an intuitive visual comparison.

*Compare Marked Rectangles*
For this task, students were presented with two rectangles, one 5 x 8 inches and the other 4 x 9 inches (Figure 8). Both rectangles had tick marks along the sides revealing the dimensions, but neither rectangle had numerals labeling the dimensions. The students were asked to compare the area of the two rectangles and to explain how they determined which rectangle had the larger area.

This task was designed to force students to structure the empty space inside the rectangles to compare the areas. The textbook series that these students use provides structured square units for almost all area tasks, thus reducing the task to one of counting a set of discrete objects. The rectangles for this task were designed so that the perimeters were equal but the areas were not. We were also interested in exploring how students dealt with the presence of two different units, length and area. The tick marks along the side of the rectangle were designed to draw students’ attention to the units of length around the perimeter of the rectangles, but they needed to use those length units to construct area units inside the rectangles.

**Student responses.** The students demonstrated unique counting strategies for this task. Some seemed to invent rules. For example, Drew counted the tick marks around the figure and did not count the corners. He could not give a clear answer for why, but seemed like he was attempting to avoid double counting the square units in the corners. When the interviewer asked Drew if his response of 22 squares would fill the entire rectangle, he realized there would be some unfilled part in the middle. To take care of that, he said he would add half of 22 to get the inside. Drew’s final answer for the area was 22+11. He seemed to have an idea of space-filling, but his spiraling concentric circle method was not accurate.

Others had inefficient counting techniques for determining length, which in turn caused errors when computing area. Anselm and David both made their counting errors when determining side lengths of a figure when only tick marks were present. Several students confounded perimeter and area concepts for this task. These students incorrectly reasoned that figures with the same perimeter necessarily have the same area.

**Volume**

**Cube Comparison Task**

In the Cube Comparison Task, we presented students with two rectangular prisms built out of different sized cubes. The first prism was 2 x 2 x 4 made out of 1-inch cubes; the second prism was 2 x 3 x 4 made out of 1-centimeter cubes (Figure 9). We told the students that another child said the figure made out of the 1-centimeter cubes had a larger volume because it was made up of more cubes. The students were asked if they agreed with this decision. Visually, it was clear that the structure made out of 1-inch cubes had a larger volume even though it was made from fewer discrete cubes.

The purpose of this task was to determine our students’ understanding of the word volume. We were concerned that our students misunderstood the volume of an object to be a function of only the number of cubes it would take to build the object without any consideration of the size of the individual cubic units. If this was the case, then students would be willing to agree that the volume of the smaller prism was larger based on a count of the number of cubes.

**Student responses.** Most of the students recognized that the structures were made out of different sized cubes. If the student thought that the figure with more blocks had a larger volume, it gave us an opportunity to introduce another way of thinking about volume. Ryan was convinced by the “other student” saying, “This makes sense because the cubes are way tinier, even though the yellow cube only makes up about two cubes, it's still way more 'cause they're
just tons of tiny cubes put together.” We asked the student to imagine both structures made of ice and to imagine that the ice melted. Then we asked which pile would turn into more water. With this illustration of volume, the students could get beyond the idea of counting cubes in order to compare the volumes.

![Figure 9](image)

Besides comparing the volume of the figures, many students also compared the units. Ryan realized that the unit size mattered when he said, “Come to think of it, on the yellow brick, is only about two or three cubes on that one [larger structure made of 1-inch cubes]. This only makes up two or three wooden cubes.” The student placed two of the wooden cubes next to the entire centimeter structure, and the student continued, “If all this melted, and two cubes melted, it'd be about the same amount of water.” The student was making a comparison between the centimeter cube structure and two 1-inch cubes, saying they were about the same volume.

Drew recognized that one cube had a height and width of one inch, and the other had a height and width of one centimeter. It was important that he noticed this characteristic of the cubes. We decided to call them “inch cubes” and “centimeter cubes.” Owen immediately focused on the size of the units and did not agree with the “other student” at all. It was also interesting that Abby and Owen related the 24 1-centimeter cubes to two of the 1-inch cubes without prompting. They used this relationship to justify that although the 1-inch cube structure was made up of fewer cubes, it had a greater volume.

**Prism Volume Comparison**

For this task, we presented students with two rectangular prisms with capacities in a ratio of one to two (Figure 10).

![Figure 10](image)
We asked the students to compare the volume of the larger prism to the smaller. If the students did not understand the wording, we asked them how many times they would have to fill the smaller prism in order to fill the larger prism. After the students made a prediction, we demonstrated that the smaller prism could be filled and emptied into the larger prism twice. Next, we shifted our attention to the larger prism and asked the students to fill this container with water so that it would fill the smaller prism exactly once.

Our goal for this activity was to explore student thinking about volume for a task when cubic units were not present. Essentially, we were asking students to compare the volume (capacity) of the two containers, first with the larger prism as the unit and then with the smaller prism as the unit.

**Student responses.** Most students knew which prism had the larger volume but did not always know how to answer a question with the word compare. One student Ryan said, “It looks like two of these would make up this one [larger].” Some students were not able to think about the containers themselves as units. Instead, they tried to compare the volume of the prisms by imagining them filled with little cubes, essentially comparing the volume of the two objects indirectly by using a third object as the unit. Drew, for example, provided inconsistent responses until we let him fill the containers with water over a sink. Other students, however, were able to cope with the shift in the assignment of the unit, correctly stating that when the smaller object was the unit the larger had a volume of two, and when the larger object was the unit, then the smaller had a volume of one-half.

**Discussion**

As a research team, we have been engaged in designing and implementing tasks focused on measurement. Through refining and reflecting on this process, we have come to re-organize our thinking. We have created a framework for ourselves that guides the generation of measurement tasks. These tasks help our students develop a solid foundation of the concepts in measurement. Our basic outline for a measurement task has two main components.

In the first step, we ask students to compare two objects by some identified attribute. Here we anticipate only a qualitative response that will help us to determine if the student is able to abstract the correct attribute for comparison. This idea is best illustrated by the *Cube Comparison Task*. When a student was asked to compare the volume of the two prisms in Figure 9, if they did so based solely on the number of cubes, then we would have revealed a misconception that would need to be addressed before prompting the student for a quantitative comparison.

If the student was able to provide a correct comparison of the two objects based on the identified attribute, our second step would be to ask the student how much more of this attribute is contained in the “larger” object. This quantitative comparison would require the student to identify and use a unit to produce a ratio. At this point, the student would have to decide if they would select one of the two objects as a unit or a third object as a unit to quantify the comparison between the two objects. In the *Prism Volume Comparison* task, for example, we wanted the students to select one of the objects as the unit and to produce a ratio between the two objects based on the amount of liquid that the two prisms could hold. In contrast the *Bent Path Comparison* task was better suited to the selection of a third object as a unit. In this case, most students selected, as anticipated, an inch as their unit and constructed two separate ratios by measuring the lengths of the two bent paths. From these two separate measurements, the students could then provide a quantitative comparison. In the form of the task presented here, we did not

---

ask the students how much longer the longer path was. This allowed one student to avoid quantifying the lengths by reconstructing the bent paths into straight paths and making a simple direct comparison. Although this technique allowed the student to answer the question posed, we felt we missed an opportunity by not asking how much longer the longer path was.

Conclusions

As we move forward, continuing to think about the teaching and learning of measurement, we will use our two steps described above to guide our development of tasks and encourage other educators to do the same. By presenting students with two different objects and asking them to compare the objects by an identified attribute and then prompting the student to provide a quantitative comparison (How much longer…), we feel that students’ attention will be directed to some of the major ideas in measurement. These ideas include comparison, attribute identification, unit, and ratio. We anticipate that this process will develop students’ general understanding of units and ratios by laying a solid foundation for proportional reasoning.

Although we have only discussed measurement of length, area, and volume, we anticipate that these ideas can be applied to less physical measurements such as rates. We do not claim that all measurement tasks should be designed based on these two steps but rather these two steps are helpful in directing attention to major ideas in measurement. We are also aware that the tasks presented in this report do not all follow these two steps and in some cases this allowed our students to avoid the intention of the task.

THE MAINTAINING DRAGGING SCHEME AND THE NOTION OF INSTRUMENTED ABDUCTION

Anna Baccaglini-Frank
Università degli Studi di Siena (Italy)1 & University of New Hampshire (USA)
abaccaglinifrank@gmail.com

Research has shown that the tools provided by dynamic geometry systems (DGSs) impact students’ approach to investigating open problems in Euclidean geometry. This paper presents results from a study on how a particular dragging modality, maintaining dragging (MD), can be used for generating conjectures in open problem situations. The study served to test and refine a model describing a utilization scheme (the MDS) associated with MD. In particular the paper discusses the abductive nature of the MDS leading to the new notion of instrumented abduction. Moreover the paper provides evidence that solvers can “free” the MDS from the physical dragging-support, developing a powerful psychological tool.

Introduction

Mathematics education supervisors and leaders have been encouraging the use of technology in the classroom to foster mathematical habits of mind (Noss & Hoyles, 1996; NCTM, 2000, 2006; Mariotti, 2006; Cuoco, 2008). Several studies in the teaching and learning of geometry (for example, Noss & Hoyles, 1996; Mariotti, 2006) have shown that a dynamic geometry system (DGS) can foster the learners’ constructions and ways of thinking, and how, thanks to the dragging tool, a DGS can be powerful for explorations in an open problem situation (Laborde et al., 2006; Arzarello et al., 2002; Lopez-Real & Leung, 2006).

Research carried out by Arzarello et al. (2002) and Olivero (2002) led to the description of a hierarchy of dragging modalities, classified through an a posteriori analysis of solvers’ work that can be observed while a solver is producing a conjecture in a DGS. A key moment of the process of conjecture-generation is described in Arzarello et al.’s model as an abduction that seems to be related to the use of dummy locus dragging. The study we report on in this paper (Baccaglini-Frank & Mariotti, 2009, in press) was designed to shed light onto this delicate moment; we proceeded by elaborating (from Arzarello et al.’s classification) four dragging modalities – in particular maintaining dragging (MD), developed from dummy locus dragging – and developing and testing a model that describes a process of conjecture-generation.

The study makes use of two more notions present in the literature: abduction, and instrument. Peirce was the first to introduce the notion of abduction as the “inference, which allows the construction of a claim starting from some data and a rule,” (Peirce, 1960). Recently, there has been renewed interest in the concept of abduction, with a number of studies focused on its various uses in mathematics education (for example, Simon, 1996; Cifarelli, 1999; Ferrando, 2006), and generating new definitions. In particular, Magnani describes abduction as:

the process of inferring certain facts and/or laws and hypotheses that render some sentences plausible, that explain or discover some (eventually new) phenomenon or observation; it is the process of reasoning in which explanatory hypotheses are formed and evaluated (Magnani, 2001, pp. 17-18).
In the current study we consider “dragging” in a DGS after the instrumentation approach (Vérillon & Rabardel, 1995; Rabardel & Samurçay, 2001), as has been done fruitfully by other researchers (for example, Lopez-Real & Leung, 2006; Leung, 2008; Strässer, 2009). A particular way of dragging, in our case MD, may be considered an artifact that can be used to solve a particular task (in our case that of formulating a conjecture). When the user has developed particular utilization schemes for the artifact, we say that it has become an instrument for the user. We will call the utilization schemes developed by the user in relation to particular ways of dragging, “dragging schemes”.

The general experimental design was articulated in two phases, a pilot study followed by a refinement and revision phase that preceded the full-blown study. For both the pilot study and the full-blown study subjects were high school students in Italian “licei scientifici”, 9 (3 single students and 3 pairs) students for the pilot study and 22 (11 pairs) for the final study. Since according to the literature (Olivero, 2002), spontaneous use of dummy locus dragging does not seem to occur frequently, first, we introduced four dragging modalities to the subjects during two lessons. We then interviewed students while working on open-problem activities. Data collected included: audio and video tapes and transcriptions of the introductory lessons; Cabri-files worked on by the instructor and the students during the classroom activities; audio and video tapes, screenshots (using the software “HyperCam”) of the students’ explorations, transcriptions of the task-based interviews, and the students’ work on paper that was produced during the interviews.

This paper presents, through a first paradigmatic example, the maintaining dragging scheme (MDS) developed in our model, and through a second example it sheds light onto difficulties which can arise for a solver trying to making sense of what may appear during an exploration when MD is performed. This leads to an introduction of our notion of instrumented abduction, and finally to our third example that shows how the MDS may become a psychological tool.

**Formulating A Conjecture Using The Maintaining Dragging Scheme (MDS)**

This section illustrates, through a paradigmatic example, how the main ingredients of the MDS described in the model we developed come into play in the analysis of two students’ exploration. James and Simon were given the following open-problem activity:

“Construct three points A, B, and C on the screen, the line through A and B, and the line through A and C. Then construct the parallel line l to AB through C, and the perpendicular line to l through B. Call the point of intersection of these last two lines D. Consider the quadrilateral ABCD. Make conjectures on the kinds of quadrilaterals can it become, trying to describe all the ways it can become a particular kind of quadrilateral.”

The solvers followed the steps that led to the construction of ABCD, as shown in Figure 1, and soon noticed that it could become a rectangle. Simon was holding the mouse (as shown by his name being in bold letters in the excerpts below), and followed James’ suggestion to use MD to “see what happens” when trying to maintain the property “ABCD rectangle” while dragging the base point A. In such situation the selected property “ABCD rectangle”, according to our model (Baccaglini-Frank & Mariotti, in press), is called intentionally induced invariant. As Simon was focused on performing MD, James’ attention seemed to shift to the movement of the dragged-base-point, as shown in Excerpt 1 below.

---

Excerpt 1

1  I: James, what are you seeing?
2  James: Uhm, I don't know...I thought it was making a pretty precise curve...but it's hard to...to understand. We could try to do “trace”.
3  Sim: trace!
4  James: This way at least we can see if...

James seems to be looking for something, which he describes for the time being as a “pretty precise curve” ([2]). This intention seems to indicate that James has conceived an object along which dragging the base point A will guarantee that the intentionally induced invariant is visually verified. This is what we call a path (Baccaglini-Frank & Mariotti, in press). Moreover he is trying to “understand” ([2]) what such path might be. In other words he is searching for a geometric description of the path. To do this he suggests activating the trace tool.

The solvers activate trace on A and Simon performs MD again. James seems to be searching for a geometric description of the path by interpreting the trace mark on the screen (Figure 2).

Excerpt 2

15  I: and you, James what are you looking at?
16  James: That it seems to be a circle...
17  Sim: I'm not sure if it is a circle...
18  James: It's an arc of a circle, I think the curvature suggests that.
...
24  James: Ok, do half and then more or less you understand it, where it goes through.
25  Sim: But C is staying there, so it could be that BC is...is
26  James: right! because considering BC a diameter of a circle...

They construct the circle and drag A along it, and then they write the conjecture: “ABCD is a rectangle when A is on the circle with diameter BC.”

In this Excerpt James seems to be searching for a geometric description of the path and identifies some regularity in the movement of the dragged-base-point, “a pretty precise curve” ([2]), then “a circle” ([16], [17]) “considering BC a diameter” ([26]). Moreover, there seems to be the intention of looking for something, which we interpret as an attempt at “making the path explicit”. This can lead to perceiving a second invariant, that we call it the invariant observed during dragging, as a regular movement of the dragged-base-point. Both invariants are perceived within the phenomenological domain of the DGS, where a relationship of “causality” may also be perceived between them. Our model refers to this first relationship of causality as a Critical Link. Of course such relationship can be formulated within the domain of Euclidean Geometry as a Conditional Link between geometrical properties corresponding to the invariants, provided that the solver gives an appropriate geometrical interpretation.

Making Sense Of The Findings Of An Exploration

Using MD the perception of a second invariant, the invariant observed during dragging, can occur in a rather “automatic” way. As a matter of fact, when MD is possible, the invariant observed during dragging may automatically become “the regular movement of the dragged-base-point along the curve” recognized through the trace mark, and this can be interpreted...
geometrically as the property “dragged-base-point belongs to the curve”. In the previous excerpts James and Simon seem to behave in this automatic way, that is, the solvers proceed smoothly through the perception of the invariants and immediately interpret them appropriately, as conclusion and premise in the final conjecture. We refer to solvers who exploit the MDS like James and Simon as experts. From the perspective of the instrumental approach (Vérillon & Rabardel, 1995), the MDS may be considered a utilization scheme for expert users of the MD-artifact thus making MD an instrument (the MD-instrument) for the solver with respect to the task for producing a conjecture.

However reaching expert behavior is not trivial, as shown by the fact that many solvers we interviewed did not seem able to make sense of their discoveries even when they appeared to be using MD in a way that seemed coherent with our model. In particular, even when invariants are properly perceived (Baccaglini-Frank et al., 2009) it seems that their simultaneous perception does not guarantee the interpretation of such phenomenon in causal terms. The Excerpt below shows a case in which two solvers have used MD maintaining the property “ABCD rectangle” as their intentionally induced invariant dragging A, they have provided a geometric description of the path and perceived the invariant “A on the circle”. However they do not seem to make sense of what they have discovered, and they are not able to reach a conjecture linking the invariants.

Excerpt 3

1  Val:  Move A on the circle.
2  Ilia:  You look to check that it stays...
3  Val:  There, it remains, it remains a parallelogram.
4  Val:  Yes, I mean a parallelo...it remains a rectangle.
5  Ilia:  a rectangle.
6  Val:  Yes, more or less.
7  Ilia:  Yes, ok. But...
8  Val:  Ok....why?
9  Ilia:  Because...
10 Val:  Why?
11 Val:  So...I know that, uh, so
12 Ilia:  But B has to always be in that point there.
13 Val:  Where?
14 Val:  So I think...this remains a rectangle...when AB is perpendicular to DC, ok but in this case it would also be BA is equ, perpendicular to CA.

The solvers have constructed a circle corresponding to their geometric description of the path, and seem to clearly perceive the simultaneity of the invariants perceived (“A on the circle” [1] and “it remains a parallelogram” [3]). However the solvers do not seem to be able to make sense of their findings: they repeatedly ask themselves “why” ([8], [9]) and resort to an explanation which has nothing to do with the invariant observed during dragging, but that instead goes back to the definition of a rectangle as a quadrilateral with four right angles ([14]). Note that in the rest of this exploration the solvers will never produce a conjecture using “A on the circle”.

Having to base our assumptions exclusively on indirect evidence, it is impossible to say whether the solvers have conceived a Critical Link between the invariants, in the phenomenology of the DGS, but we can definitely say that they are not able to reach a Conditional Link by interpreting their findings geometrically. It is unclear whether the difficulty for them lies in...
perceiving the invariant observed during dragging as a “cause” of the intentionally induced invariant within the phenomenology of the DGS (so in conceiving a Critical Link), or in interpreting the Critical Link geometrically as a relationship of conditionality between geometrical properties (so in conceiving a Conditional Link).

The Notion of Instrumented Abduction

Unlike Ila and Val, expert solvers seem to withhold the key for “making sense” of their findings, which seems to be conceiving the invariant observed during dragging as a “cause” of the intentionally induced invariant within the phenomenology of the DGS, and then interpreting such cause as a geometrical “condition” for the intentionally induced invariant to be verified. In other words, the solvers establish a causal relationship between the two invariants generating – as Magnani says (2001) – an explanatory hypothesis for the observed phenomenon. Moreover, as soon as they decide to use MD to explore the construction, experts seem to “search for a cause” of the intentionally induced invariant in terms of a regular movement of the dragged-base-point. This idea is key; it seems to lie at a meta-cognitive level with respect to each specific investigation the solvers engage in, and possessing it seems to allow complete exploitation of the MDS, culminating in the formulation of the conjecture. Moreover, as mentioned above, the process of conjecture-generation through MDS seems to become “automatic” for expert solvers.

Automatic use of the MDS seems to condense and hide the abductive process that occurs during the process of conjecture-generation in a specific exploration: the solver proceeds through steps that lead smoothly to the discovery of invariants and the generation of a conjecture, with no apparent abductive ruptures in the process. Thus our research seems to show that, for the expert, the abductive reasoning that previous research described as occurring within the dynamic exploration (Arzarello et al., 1998, 2002) occurs at a meta-level and is concealed within the MDS-instrument. We introduce the new notion of instrumented abduction to refer to the inference the solver makes through the MDS, leading to formulate a conjecture.

MDS as A Psychological Tool

We now take our reflections on the MDS one step further and consider expert use of the MD. We have found evidence that experts may use the MDS as a “way of thinking” freeing it from the physical dragging-support. In the following excerpts we will show how the MDS guided the process of conjecture-generation of Francesco (F) and Gianni (G) even though they were not able to reach an invariant observed during dragging through MD. The solvers were working on the following open-problem activity:

“Draw a point P and a line $r$ through P. Construct the perpendicular line $l$ to $r$ through P, construct a point C on it, and construct the circle with center in C and radius CP. Construct the symmetric point of C with respect to P and call it A. Draw a point D on the semi-plane defined by $r$ that contains A, and construct the line through D and P. Let B be the second intersection with the circle and the line through P and D. Consider the quadrilateral ABCD. Make conjectures on the kinds of quadrilaterals can it become, trying to describe all the ways it can become a particular kind of quadrilateral.”

The solvers have chosen “ABCD parallelogram” as their intentionally induced invariant.

Excerpt 4

1  G: and now what are we doing? Oh yes, for the parallelogram?
Francesco and Gianni seem to have conceived a geometric description of the path ([3]) that does not coincide with the trace mark they see on the screen as Francesco performs MD ([4]). This leads the solvers to reject the original description ([16]) and search for a new condition (“when” [40]). However they are not able to reach such condition using MD because of manual difficulties they encounter as the exploration continues. This leads Gianni, who is not trying to perform the MD, to conceive a condition in his mind, as shown in the following excerpt.

Excerpt 5

43 G: eh, since this is a chord, it’s a chord right? We have to, it means that this has to be an equal cord of another circle, in my opinion with center in A. because I think if you do, like, a circle with center

44 F: A, you say…

45 G: symmetric with respect to this one, you have to make it with center A.

46 F: uh huh

47 G: Do it!

48 F: with center A and radius AP?

49 G: with center A and radius AP. I, I think…

50 F: let’s move D. more or less…

51 G: it looks right doesn’t it?

52 F: yes.

53 G: Maybe we found it!

The solvers’ search for a condition as the belonging of D to a curve defined through other base points of the construction is now complete, as they construct the circle with center in A and radius AP and proceed to link D to it in order to check the Conditional Link. The solvers seem quite satisfied and formulate their conjecture immediately after the dragging test, proceeding coherently with the model.

Although the “search for a cause” through use of MD with the trace activated failed, the solvers are able to overcome the technical difficulties and reach a conjecture by conceiving a new geometric description of the path without dragging-support. In other words the solvers seem to have interiorized the MD-artifact to the extent that it has become a psychological tool which no longer needs external support. Moreover the abductive process supported by MD in the case of an instrumented abduction now occurs internally and is supported by the theory of Euclidean
geometry (BP and PD are conceived as chords of symmetric circles). Taking a Vygotskian perspective (Vygotsky, 1978, p. 52 ff.), we can say that the MD has been internalized and the actual use of the MD-artifact has been transformed becoming internally oriented.

Conclusions

We have seen how the model of the MDS seems appropriate for describing the processes of conjecture-generation when MD is used, providing evidence to a correlation between the introduction of dragging modalities, and MD in particular, and a specific new (with respect to those in literature) cognitive process described by the model. We have referred to such process as a form of *instrumented abduction*, a new notion that we hope can be generalized to other contexts in which abduction is supported by another instrument. Furthermore, we seem to have captured the key idea that may lead to complete appropriation of the MDS, that is searching for a cause, and described how it resides at a meta-level with respect to each specific exploration in which MD is exploited as an instrument for conjecture-generation. Finally we described how for expert solvers the MDS might be transformed into a way of thinking. In this sense it may lead to the construction of fruitful “mathematical habits of mind” (Cuoco, 2008) that may be exploited in various mathematical explorations leading to the generation of conjectures.

When such a way of thinking is developed through internalization of the MD-artifact (and is therefore freed from the dragging-support) the abductive reasoning has the advantage of involving geometrical concepts, like in the case of Francesco and Gianni. The geometrical concepts that emerge in this case can become “bridging elements” with respect to the proving phase, since they can be re-elaborated into the deductive steps of a proof. On the other hand, expert use of the MDS still supported by dragging seems to lead to conjectures in which no geometrical elements arise to “bridge the gap” between the premise and the conclusion. In other words, although expert use of MD seems to offer the possibility of generating “powerful” conjectures that solvers might have trouble reaching without the dragging-support, generating conjectures “automatically” through the MDS with the dragging-support, may hinder the proving phase in which these “bridging elements” are essential.

In this work we catalogued the content of multiple-choice geometry items on the Ohio Achievement Tests for Grades 3, 5 and 8 according to the van Hiele model of development of geometric thought. Using statewide data from 1,418 students, responses on each question were analyzed to trace performance level at different grade levels. The results indicated that the majority of the items at each grade level focused on Levels 1 and 2. Student performance declined as the question level increased.

Introduction

Usiskin (1987) raised public concerns regarding the geometry knowledge of children in US schools and argued that except for the knowledge of shapes (something learned even before first grade), the geometry knowledge of students at the end of elementary school remains minimal. Referencing the results of the 1982 National Assessment, he pointed out that student performance remained low at all levels. He proposed that both the teaching and content of geometry taught in schools must be reconsidered so as to assure that children’s learning is not hindered as a result. Nearly three decades later, results of national and international studies that measure mathematical performance of children at various grade levels continue to highlight the fragile nature of geometry knowledge of children in US schools. These results are disheartening. Geometry is a major connection between informal and formal mathematics, serving as a critical factor in student success in future mathematics classes (Duval, 1999).

In response to the disappointing results of the students’ performance on norm-referenced examinations (achievement tests), some have argued that the results of these tests should not be given much weight since the test items may not be reflective of what students should know and be able to do. This argument is widely used in places where students’ performance on high-stakes tests is used to gauge teacher effectiveness and school ranking. In many states across the country, including Ohio, student results on standardized exams have political and financial ramifications for schools and districts. Schools are evaluated annually according to whether they have met proficiency standards and placed on “emergency” status if they fail to show progress in students’ results in three consecutive years. Ultimately, schools may be shut down if progress, as measured by standardized exams, is inadequate or insufficient. Therefore, the content of exams and validity and reliability of items used to assess knowledge are of great concern. Of particular interest in the study was the quality of geometry knowledge tested as well as student achievement on standardized exams since the subject remains one of the most overlooked mathematical areas in the US.
Chapter 7: Geometry and Measurement

Purpose of the Study

The goal of the study we report here was threefold. First, we aimed to examine the content of the geometry items used on the Ohio Achievement Tests at Grades 3, 5 and 8 according to the van Hiele model to determine what level of geometry knowledge was expected of children. The goal was to see whether the content of the tests agreed with the learning theory.

Second, using data from the performance of 1,418 students from 11 schools across the state of Ohio on each of the items tested, we planned to establish a profile of geometry knowledge of the students. Lastly, by analyzing the common response choices students made on multiple-choice items, we hoped to identify factors inherent in the test items that could have contributed to students’ performance. This report is part of a research project in which children’s mathematical development from 85 schools across Ohio is traced over the course of three years of involvement in a statewide professional development model (Brosnan & Erchick, 2010).

Theoretical Consideration

Concern about geometry learning and teaching is not a recent development and dates back to the 1950s with the pioneering work of two Dutch teachers, Pierre van Hiele and Dina van Hiele-Geldof. The van Hieles proposed a framework that accounts for the development of geometric reasoning in order to explain how people grow in their geometry knowledge. They identified five different levels of understanding through which an individual passes when learning geometry, including visual, descriptive/analytical, informal deductive, formal deductive, and rigor. According to this model, these levels are not dependent on maturation, but on instruction. While this model has been under revision by some scholars in recent years (Battista & Clement, 1992, 2007) and criticized by some scholars for its inability to trace “in between levels of reasoning” (Burger & Shaughnessy, 1986), it is still widely used in curricula implementation in mathematics classrooms today. For these reasons we opted to use the framework as a lens for our analysis of both the tests and students’ performance. A brief description of each level is presented below.

At the visualization level (Level 1), a learner identifies, names, compares and operates on geometric figures, such as triangles, angles, and parallel lines, according to their appearance. At this level, students may see the difference between triangles and quadrilaterals by focusing on the number of sides of the polygons but may not be able to distinguish different quadrilaterals such as parallelograms and trapeziums.

At the analysis level (Level 2), students can recognize components and properties of a figure. However, they cannot see relationships between properties and figures, nor can they define a figure in terms of its properties. At this level a learner analyzes figures in terms of their parts and the relationships between these parts, establishes the properties of a class of figures empirically, and uses properties to solve problems.

At the informal deduction level (Level 3), students can recognize interrelationships between figures and properties, and they can justify these relationships informally. The learners can understand and use precise definitions and are capable of “if-then” thinking but not producing formal proofs.

At the deduction level (Level 4), students can reason about geometric objects using their defined properties in a deductive pattern. Students at this stage could construct the types of proofs that one would find in a typical high school geometry course.

At the highest level, rigor (Level 5), students can compare different axiom systems. Learners establish theorems in different postulation systems and can analyze and compare these systems.

Participants and Methods

The database for the study consisted of the results of 1,418 students who had completed the Ohio Achievement Tests in May 2009. The sample consisted of 471 third-grade, 644 fifth-grade and 303 eighth-grade students’ responses to the latest released math exams in their grade level, i.e. third grade test in 2005, fifth and eighth grade test in 2006. The students were from 11 low-performing elementary and middle schools. School ranking was designated by the Ohio Department of Education (ODE) according to the percentage of students who had failed to meet the “proficiency” level criteria set by the state. All participating schools were involved in a statewide professional development program which aimed to raise the mathematical knowledge of both teachers and learners in these schools. Student results were compiled by each school and submitted to the research team online. Student and school identities were removed.

Students’ responses to each multiple-choice question on each of the three grade level exams were formatted in Excel spreadsheets. Results were then compared and analyzed. Across grade levels the percentage of correct answers on questions in each van Hiele level was used as an indicator of students’ progress. In this work we considered only the tests’ multiple-choice questions and students’ responses to them in order to avoid potential inconsistencies that could exist when scoring the tests’ open-ended response items, of which only one for each grade related to geometry. Since the student responses were not scored by the research team, we were not in a position to assure inter-reliability ratings of open-ended responses.

Analysis of the Tests

We identified the van Hiele level of each question by examining its content. We agreed that although higher levels of reasoning can always be adopted to solve lower-level questions, this did not change the level of difficulty of the question in itself. Hence, we used the highest van Hiele level of geometry reasoning required to solve the problem as a means to rank the level of the question on each of the tests. Additionally, we acknowledged that distinguishing one-step reasoning from identification was not always possible since this kind of reasoning is usually a deduction from definition to its sufficient and necessary condition. Nevertheless, the van Hiele level of thinking is based on experience and the instruction received (Crowley, 1987). For instance, if students are taught to identify parallel lines by using corresponding angles, a question concerning this relationship may be viewed as a Level 2 item; whereas if other ways of identifying parallel lines had been taught and the congruence of the angles was then shown to be a consequence, then this question may be classified as a Level 3 item. Therefore, without information on the actual experience of students, judging the level of question according to the van Hiele model (solely on the basis of its content) may not be adequate. However, in our analysis no subcategory between the levels was defined. Therefore, in places where disagreements occurred among the research team regarding the level of a question, we identified the question to be in the “closer” level by intuition. For example, consider the following example from the eighth-grade test:

(Eighth grade) In the figure, lines j and k are parallel.
Which angle is congruent to 1?
A. 2   B. 3   C. 4   D. 5

While it could be argued that the above question measures Level 3 thinking since the congruence of 1 and 3 is a conclusion following the statement of parallel lines, i.e. “If j and k
are parallel, then \(1\) and \(3\) are equal”, asserting then that reasoning from lines to angles is involved. Nevertheless, it is also legitimate to argue that congruence of \(1\) and \(3\) can be viewed as an identifier of parallel lines; hence the question can be ranked as an “identification” task instead of reasoning that leads to the solution. In this case, we classified the question as Level 2 since we believed one-step reasoning to be “closer” to description than to relation.

Table 1 offers a blueprint of the test items at each grade. As illustrated, all but one question on the third-grade test are in Level 1. These items measure knowledge of triangles, quadrilaterals and the number of their sides and angles. The only Level 2 question on the third-grade test refers to a basic identifier, i.e. convention to describe locations in the coordinate grid. No other properties of the grid, such as the parallel or perpendicular lines, are involved in the question.

In 1992, Clements and Battista concluded that, in geometry, students are extremely unsuccessful with formal proof (upper Level 3 and Level 4). We noticed that (as shown in Table 1), tests were mostly measuring low levels of knowledge. More than 85% of the test items are designed to measure Level 1 thinking in Grade 3, and a large percentage of questions on fifth- and eighth-grade tests were also ranked at Levels 1 and 2 (75% and 67%, respectively).

The van Hiele levels of questions used on the fifth-grade test were higher than those on the third-grade test. The two Level 1 questions were about three-dimensional shapes. The figures are more difficult to visualize than two-dimensional figures when drawn on paper. Therefore, the questions are of a higher Level 1 compared to the third-grade items. The four Level 2 questions asked students to find the relative location of lines, symmetry of a circle by its diameter, and geometric properties in the coordinate. These concepts are more difficult than the concepts of sides and angles since they are described by more advanced geometric concepts. The two Level 3 questions measured students’ understanding of the angle sum formula of a triangle. Students were asked to find the degree measure of an angle given the measures of the other two angles.

On the eighth-grade test, only one Level 1 question was noted and it required three-dimensional thinking. The three Level 2 questions measured knowledge of parallel lines’ angle-related properties, identification of figures and their transformation in the coordinate plane. The two Level 3 questions were also more sophisticated than Level 3 questions in the fifth-grade test. One question tested students’ perception of the similarity of triangles and required calculating the index of proportionality of figures. The second question required the use of algebra in calculating the area of a triangle.

As the blueprint illustrates, the van Hiele levels of the questions asked on the three tests increased according to grade level, though not at the same rate. Therefore, the design of the geometry questions on achievement tests we studied was consistent with the developmental sequence of geometry reasoning according to the van Hiele model. Nonetheless, the significant portion of each test at each grade level focused on low levels of geometry reasoning. We will address the significance of this issue in the discussion section of this article.
Analysis of Students’ Performance

Tables 2-5 summarize the percentage of students who chose the correct response on each geometry question on each of the achievement exams. A decrease in the percentage of correct responses to higher-level questions compared to correct lower-level responses within every grade level is detectable. In the van Hiele model, as with most developmental theories, a student must proceed through the levels in order, and to function successfully at a particular level, a learner must have acquired the strategies of the preceding levels (Crowley, 1987). Therefore, students who reached higher levels would be fewer than those who only achieved a lower level. Thus, the decrease in performance is consistent with the sequence of development in van Hiele’s theory.

The third graders’ average percentage score for the 6 items that were ranked at Level 1 of geometric reasoning was 61%. This average score decreased to 51% for Level 2 questions. Similarly, the fifth graders’ average percentage scores on Levels 1, 2 and 3 items were 46%, 36% and 30%, respectively. Lastly, eighth graders’ average scores declined from 55% to 44%, and 32% as the level of question increased from 1 to 3. For the entire sample, the average percentage score on Level 1 items was 55%. This number declined to 44% for all items ranked as Level 2. Finally, the average percentage score for Level 3 items was 32%. The results indicate low student performance in all three levels. More importantly, as a group, the performance also declined as the level of geometric thinking increased on the tests. In order to better understand the results, a close examination of items and factors that could have influenced children’s choices of wrong answers was conducted. After having done so, we propose three conjectures regarding students’ performance based on the language and form of the questions used.
Conjecture 1: Inferences can be drawn based on past experiences and concept images developed during instruction.

As an example, let us consider an item from the third-grade test. The question asked students to identify a picture that showed a right angle with the following images provided:

(Third grade) Which picture shows a right angle?  
A.  B.  C.

Among the 471 third graders, 171 chose “A,” 174 chose “B” and 123 students chose “C” as their answer. Small differences among the total students who made each choice indicate they were confused since none of the choices met their image of a right angle. We argue that since teachers usually draw a right angle in their instruction as the intersection of a vertical ray and a horizontal one, the students failed to see the picture turned by 45° as the same figure.

Another similar example was noted on the fifth-grade test. The problem asked students to identify the measure of the missing angle in the image when the measures of two other angles were given, as shown below.

(Fifth grade) Triangle ABC is shown. What is the measure of angle C?  
A. 50°  B. 65°  C. 90°  D. 180°

The most common choice was “B”, selected by 202 of 644 (31%) fifth-grade students whose responses were examined. It is plausible that the students assumed the figure represented an equilateral triangle and every angle of it should be equal accordingly. This image is consistent, again, with what is frequently used in class in teachers’ demonstrations of concepts. The imagery could have evoked strong concept images, directing students to incorrect conclusions.

Conjecture 2: Inferences might be drawn due to linguistic clues, i.e. appearance of numbers more than once in the same problem context.

In considering the fifth graders’ common response to the test item that asked them to identify the length of the diameter of a circle given the measure of the radius, 34% of the 644 students selected “10” as their response option. Note that in this question the numeral “10” appeared in both the figure and also in the option “A.”

(Fifth grade) Point F is the center of the circle shown. What is the diameter of this circle?  
A. 10 feet  B. 20 feet  C. 30 feet  D. 100 feet

When considering the eighth graders’ responses to the question below which asked them to find the ratio of the areas of two circles with the radius of one circle twice the radius of the other, the common response option “B” selected by 42% of the sample...
can be explained in a similar manner. In this question “twice” appeared both in the condition and in option “B.”

(Eighth grade) Circle A has a radius that is twice the length of the radius of Circle B. Which is an accurate statement about the relationship of the areas of Circles A and B?

A. The area of Circle A is four times the area of Circle B.
B. The area of Circle A is twice the area of Circle B.
C. The area of Circle A is one-half the area of Circle B.
D. The area of Circle A is one-fourth the area of Circle B.

Conjecture 3: Inferences might be drawn due to linguistic clues or meanings students attached to words from personal experiences.

In elaborating on the influence of language on students’ choices, let us consider two examples from third- and fifth-grade achievement tests, as shown below. Note that in response to the first example (third-grade test: “Which shape is three-dimensional?”), 53% of the third graders selected “B” (the triangle) as the response option. In retrospect, students could have associated the “three” in “three-dimensional” with “three” as in “three-sided figure.” In this context, students could identify the triangle (option “B”) as the object with “three” sides. This knowledge was previously tested with the use of another question on the same test that 87% of the sample answered correctly. The language of the text could have provided the wrong hint for selection of the response. The recall from that context could have certainly influenced the children’s choice in this problem space.

(Third grade) Which shape is three-dimensional?
A. B. C.

In reading and interpreting mathematical problems, students draw from multiple resources including their own experiences from real life and how terms are used in their daily lives. An example of such an influence is evidenced in the fifth graders’ popular response to the problem below.

(Fifth grade) Malcolm needed to measure the distance across a circular tablecloth. He folded the tablecloth in half as shown. Malcolm measured the length of a folded side. Which part of the circular tablecloth did Malcolm measure?
A. center B. circumference C. diameter D. radius

The most commonly selected response option to this question was “A” (center). This option was chosen by 222 (34%) of the fifth graders in our sample. The student might have interpreted the folding of the circle in half as finding the center of the circle. That is, the folded side is in the middle of the circle, dividing the tablecloth into two equal parts; hence, it is the center of the tablecloth. We conjecture that such contextual interpretation may have contributed to the students’ choice, assuming middle to be the center.

Our data are certainly limited both in quality and quantity to permit conclusive inferences regarding children’s thinking or influences that could have impacted their choices. We agree that more detailed, descriptive data might provide some direction in better understanding the contributing factors to the children’s choices.

**Discussion**

Analysis of students’ performance at three different grade levels on geometry items used on Ohio Achievement Tests clearly speak to problems associated with school geometry learning. Students in all three grade levels had difficulty with visual identification of geometric concepts. Indeed, as specific features were added to a figure, students’ performance declined by a much larger margin. Collectively, the students’ perception of geometric concepts was underdeveloped at both the visual and descriptive levels. Data further indicated that students had difficulty recalling mathematical terms and definitions.

There is no doubt that student performance on standardized exams is influenced by a variety of instructional and non-instructional factors. From the point of view of instruction, there is always the potential for existence of a mismatch between what is tested and what is taught in the classroom. It is certainly plausible that performance on items that test children’s knowledge of basic facts may not be as high when instructional focus is on inquiry and conceptual development. Hence, while we are cautious about making general instructional recommendations based on the findings from this study, we posit that considering that we examined geometry knowledge of the sample using a well-established theory of learning geometry, the results should be considered independent of specific instructional contexts.

Analysis of the test items make explicit the need for a careful consideration of what is included on tests, both in language and content, in order to adequately measure student development. This is particularly important since a “teaching to the test” framework can limit children’s mathematical experiences in classrooms, focusing teachers’ attention to only lower cognitive level tasks. Analysis of the test items and student achievement also highlight the need to devote greater attention to how geometry is taught in schools.

**Endnotes**

We concur that regardless of how carefully we may define the levels, debates on their borderlines always exist. As a result, findings of the study should be considered with respect to these flexibilities.

NON-EUCLIDEAN GEOMETRIES: PRESENT IN NATURE AND ART, ABSENT IN NON-HIGHER AND HIGHER EDUCATION

Cristina Alexandra dos Santos Sousa
Universidade Portucalense Infante D. Henrique
crisalex@netcabo.pt

This analysis begins with an historical view of Geometry, ending in the Parallel Postulate. Next, are presented new geometric worlds beyond the fifth postulate, discovered as a result of the flaw that many mathematicians encountered when they attempted to prove Euclid’s Parallel Postulate. After this brief perspective, a reflection is made on the presence of Non-Euclidean Geometries in Nature and Art and some philosophical implications. Finally, it is analyzed the study of Geometry in Portuguese Secondary Education and the absence of Non-Euclidean Geometries in Higher Education curricula in Portugal.

Introduction

Geometry: From its Origins to Euclid

It is impossible to follow the early evolution of Geometry but it is assumed that, from the observation of Nature, Man created the concept of forms, figures, bodies, volumes and distances. It was in Greece that geometrical concepts have acquired a scientific form, achieving its splendor with Euclid. Euclid’s Elements, one of the most important works of all time, contains the teachings which are still the basis of modern Geometry. The Elements is based on five logical postulates. Four of these postulates seem to come accordingly to our experience. However, the 5th Postulate does not sound so obvious and intuitive, and is considered a Euclid's own invention. This is the point of controversy that led to centuries of discussion in the scientific community and served as the motto for this particular work.

New Geometric Worlds Beyond the 5th Postulate

Several mathematicians tried to prove the correctness of Euclid’s 5th Postulate for a long time. Although they could get close to real conclusions, they failed, as its primary objective was to prove the Postulate, and not conclude that this could be false (Saccheri – Acute Angle Hipothesis, Legendre, Farkas Bolyai, Gauss). As Greenberg said, it is delightfully instructive to observe the mistakes made by capable people as they struggled with the strange possibility that they or their culture might not accept their conclusions.

It was finally with the courage and determination of János Bolyai and Nikolai Lobachevsky that the Non-Euclidean Geometries were finally acknowledged in Mathematics. Although working separately, both mathematicians developed a new Geometry that exists in spaces of constant negative curvature, which became known as Hyperbolic Geometry.

Later, Bernhard Riemann also developed a similar Geometry to the one of Bolyai and Lobachevsky, creating the concept of Elliptic Geometry, which exists in areas of constant positive curvature. Now, let us try and define each one of these Geometries.

The Hyperbolic Geometry exists in spaces of constant negative curvature. The fundamental difference between this and the Euclidean Geometry is that the Parallel Postulate is replaced by the Hyperbolic Axiom that says that for a point outside a given line there is a multitude of straight lines parallel to it. It is also known that in the hyperbolic surface the sum of the internal angles of a triangle is always less than and there are no squares or rectangles, since the sum of

---

its interior angles is less than. On the other hand, if the surface has constant positive curvature, i.e., is spherical, and since the lines are geodesics on the surface (such as the globe’s longitude lines), they always meet in two points (the poles), with no place for parallel lines. Again falls to the ground the validity of the Parallel Postulate. In these surfaces the sum of the internal angles of a triangle is always greater than.

![Hyperbolic Geometry](image1.png)  ![Elliptic Surface](image2.png)

**Figure 1. Hyperbolic surface**  **Figure 2. Elliptic Surface**

The Presence of Non-Euclidean Geometries in the Real and its Absence in the Study of Geometry

We are now arrived to the last part of this work were will be analysed the presence of the Non-Euclidean Geometries in the real and its absence in the study of Geometry.

We are faced by many phenomena in Nature considered as authentic forms of Art. A crucial difference between human Art and animal Art is the intention with which it is created. The animals create what seems to be more practical and functional to them. Humans create it just for aesthetic enjoyment.

There are names in Art History that are synonymous of the combination of Art and Science. As an example, one can refer the great Renaissance artist, Leonardo Da Vinci. Da Vinci produced thousands of drawings where artistic and scientific investigations meet.

![Cobweb](image3.png)  ![Honeycomb](image4.png)  ![Circle limit IV by M. C. Escher](image5.png)

**Figure 3. Cobweb**  **Figure 4. Honeycomb**  **Figure 5. Circle limit IV by M. C. Escher**

Another unavoidable figure is M. C. Escher which became par excellence the creator of impossible worlds. In particular, the regular division of a surface facilitated his approach to infinity. This surface is no more than one model of representation of the hyperbolic disk. Escher, during his work, developed a true glorification of reality, interpreting mathematically patterns and rhythms of Nature forms. But of all forms of Art, the one which is more closely related to Geometry is undoubtedly Architecture. The architectural structures are the result of geometric
principles and the final result may come to be a solid figure. Despite the great speed of advancement of societies and technology and the demand for new architectural styles, Euclidean Geometry is still present in most buildings. However, newer concepts from the Non-Euclidean Geometries began to contribute to changes. Antoni Gaudí can, in this field, be considered the great master of Organic Architecture that is the Architecture which is based on principles and forms based on Nature. Gaudí will forever be an icon of world Architecture.

Geometric Structures Independent of Human Intervention

Taking into account the knowledge of common sense, easily we assume that the Geometry of Nature is Euclidean. However, there is no basis for this, partly because concepts such as infinity have no place in the real world, so that in itself brings us to abstract concepts.

There is in Nature an infinite number of elements that cannot be defined by traditional Euclidean Geometry. Examples of that are some trees, clouds, mountains, rivers, the system of blood vessels, nerve structures, etc., which have the name of fractals.

Now, a figure of Mathematics and Physics that cannot be forgotten is Albert Einstein. Since the pioneer work of Einstein, we now have a different view of space and time. For Einstein the Universe was not flat nor time was absolute and both were combined in a curved space-time. The particularity of his work was to have added to the already known three dimensions (width, height and depth), the dimension of time.

Let’s now consider a problem, perhaps already known to all: "From a certain point on Earth, a hunter walked 10 km to the South, 10 km to the East and 10 km to the North, thus returning to the starting point. There he found a bear. What colour was the bear?"

At first glance it might seem impossible. However, since it is known by all that the Earth is not flat, the solution is imminent. If the three movements of the hunter are perpendicular to each other and he returns to the starting point, he can only be found in one of Earth's poles. If he encountered a bear, it can only be white and the location is the North Pole.

We can now say that there is no doubt about the presence of Non-Euclidean Geometries in the world. Also notable is its use by various artists. For this reasons, one tried to investigate the "state of play" on the study of Geometry in Secondary Education and of Non-Euclidean Geometries in Higher Education in Portugal. The general perception that students are required to devote more time to Mathematics is a false one. Rather, the syllabus steadily decreases both the amount of subjects and their difficulty. For its part, the study of Geometry suffers the consequences, as it is repeatedly put on hold and, when studied, there is no depth or consistency and, therefore, no logical understanding by students. As a result, it appears that students don’t have proficient skills of autonomy in their work, preventing them from acquiring a more accurate and comprehensive learning. In addition, in University Education students don’t have, in most cases, any knowledge of Geometries other than Euclidean. The reverse situation could positively

influence the way students comprehend the world around them, by broadening their geometrical horizons.

Concerning the study of Non-Euclidean Geometries in Higher Education, there was done a demonstrative analysis, although not exhaustive, of the presence of Non-Euclidean Geometries in the curricula at senior level in Portuguese Universities. In about two dozen of courses, only five contained references to the study of Non-Euclidean Geometries. It is a bit unacceptable the absence to its study even in courses of Mathematics, as occurs in the University of Coimbra and the University of Minho.

And it is also unacceptable that in all the courses analyzed, only seven had references to the study of traditional Geometry. This study is absent in courses that could benefit greatly by its presence, as is the case of Arts and Civil and Environmental Engineering.

In a simple and clear way, I tried to demonstrate that, despite the popularized idea that Euclidean Geometry is the only current Geometry in the world, the Non-Euclidean Geometries are present in numerous events that surrounds us. It is expected, therefore, the generalization of knowledge on these issues so that we can look at the reality in a more complete way.

According to the philosopher Immanuel Kant, the reality is synthesized in accordance, not with the real world, but with our mind and its limitations. But as Russell said, Mathematics is the discipline that we don’t know what we are talking about nor whether what we say is true...

SPATIAL STRUCTURING THROUGH AN EMBODIED LENS

Lynn M. McGarvey
University of Alberta
lynn.mcgarvey@ualberta.ca

Jennifer S. Thom
University of Victoria
jethom@uvic.ca

In much of the spatial reasoning literature, concrete activities are assumed to develop into more sophisticated and purely mental concepts. In this paper, we offer a contrasting viewpoint of one spatial reasoning construct—spatial structuring—by examining the intersection of two different data sets (i.e., preschoolers and fifth graders) through an embodied cognition lens. Our analysis and discussion of the students’ work reveal the inter-actions of the body are integral to mathematics knowing—not precursors to more sophisticated mental conceptions. In this manner, our paper attends to the complexity of learning by highlighting an ecological perspective.

Introduction

Spatial structuring is described in the literature as “the mental operation of constructing an organization or form for an object or set of objects” (Battista, 1999, p. 418). The construct, like many in the spatial reasoning literature, assumes children’s concrete activities such as arranging, building, counting and drawing develop into more sophisticated mental concepts that do not require physical movement (Battista & Clements, 1996; Battista, Clements, Arnoff, Battista & Borrow 1998; Mulligan, Mitchelmore & Prescott, 2005; Outhred & Mitchelmore, 2004). In this paper, we provide a contrasting viewpoint and contribute to the understanding of children’s spatial reasoning by examining the intersection of two contextually different data sets through an embodied cognition lens. In the first set of data we examined young children’s (ages 4-5) two-dimensional spatial structuring in extending and drawing a growing rectangular pattern. In the second data set we explored fifth grade students’ three-dimensional spatial structuring in response to a pyramid building patterning task. Our analysis and discussion articulate a view of spatial reasoning whereby inter-actions of the body are integral to mathematics knowing—not simply precursors to more sophisticated mental images or concepts. In this manner, our paper attends to the complexity of learning by highlighting an ecological perspective of individual and collective knowing as it occurred within and across time and space.

Theoretical Framework

Our research draws on contemporary studies in cognitive science and mathematics education which reveal knowing to be a dynamic, contextually contingent, and body-centered phenomenon (Lakoff & Núñez, 2000). Such a theoretical perspective conceives our cognitive structures and processes to extend throughout our bodies and further into the biological, social and cultural environment in which our bodies are embedded. “[C]ontext-dependent know-how [is viewed] not as a residual artifact that can be progressively eliminated by the discovery of more sophisticated rules, but as, in fact, the very essence of creative cognition” (Varela, Thompson & Rosch, 1991, p. 148). Learning, then, is not assumed to be a process of converging onto pre-established truth, but a divergent, recursive process of expanding possibilities for action (Davis, 2004).

From an embodied perspective, cognition occurs “all at once” and not on a continuum from concrete to abstract or from particular to general (Maturana & Varela, 1992; Varela, et al., 1991). Knowing is dialectically abstract|concrete, general|particular and contextually contingent (Roth...
& Hwang, 2006). Actions with objects are not assumed to potentially lead to knowledge but instead, are acts of knowing in and of themselves (Varela, et al., 1991). Thus, children as competent beings, bring forth worlds of significance through reasoning and using all of the perceptual resources situationally available to them (Roth & Thom, 2009). The unit of “analysis of learning [moves] beyond a narrow focus on individual and ‘internal’ cognitive processes” (Núñez, Edwards & Matos, 1999, p. 46) to the biological and experiential contexts brought forth in moments of being.

**Modes of Inquiry**

The analysis of the two data sets relied heavily on the videotapes such that we attended to the students’ verbalizations, gestures, actions with objects, interactions with others, and their drawing processes. Analysing both sets involved viewing the video data repeatedly while comparing and verifying our conjectures with each other and against the collected artifacts and relevant theoretical literature. We identified the children’s physical sense making activities, their efforts to verbalize their actions, their spatial and numerical structures, and also the relationship(s) among these aspects (Pirie, 1997). In particular, we analyzed and interpreted the data for the following themes related to spatial structuring:

- **Modes of physical activities.** Analysis involved attention to the particular ways that the children physically acted and interacted in response to the geometric tasks.
- **Geometric, arithmetic, and/or geometric-arithmetic structure.** Analysis entailed the spatial and/or numerical conceptualizations that the students demonstrated while working on the geometric tasks.

**Data Sources**

*Data Set 1: Polygon Pictures*

Situated at a learning centre, children (ages 4-5) in pairs were asked to watch carefully as we built the first three images of a growing rectangle (i.e., 1x2; 2x2; 3x2). The children were prompted to build the next image and later draw the two-dimensional images of all four pattern elements. Each child responded in different ways to the extension and drawing prompts provided by the researchers. Three exemplars were selected illustrating three children who produced the same 4x2 structure with the tiles, but through closer examination of their physical interactions, gestures and process of drawings revealed different conceptualizations of the geometric structure produced.

Seina (see Figure 1) watched closely as the first three pattern elements were built. Although she did not respond to the prompts (e.g., “What comes next?”, “How do you know?”), she built two rows of four tiles moving from left to right. When asked, “How many tiles”, she swept her hand over her last set of tiles and answered “eight.” Seina’s drawings reveal a shift from providing details of individual tiles (elements 1 and 2), to drawing a horizontal line cut with vertical lines (element 3), and finally to a generalized rectangular form. Each drawing indicates what she attended to and how her priority of attention changed as the rectangles grew.

Wasif (see Figure 2) and Breanne sat together at the centre. Wasif constructed the fourth element by placing four tiles (bottom two then top two), followed by individual tiles top-bottom-top-bottom. He too started drawing with details of two tiles followed by growing images of generalized rectangles. After both children completed their drawings they were asked if what they made was a pattern. Breanne answered, “No … this (element 1) has two and these (elements 2, 3) have more. Wasif, disagreed and said, “Yes.” When asked why he thought so, without
counting he said, “There are two, four, five, six,” and with his hands he gestured that the rectangles had become progressively longer.

Finally, Hunter (see Figure 3) appeared to anticipate the task, because once the tiles were laid out, he interrupted the researcher and pointed to each element, “two, four, six.” When asked what would be next, he responded physically by building. Like Seina, he built two rows of four, but seemed less concerned about the organization of the tiles. “Okay, eight here.” When asked what would come next, he pointed to each element and whispered, “two, four, six, eight” and said “ten” loudly. When drawing his first image he said, “It’s a rectangle, but …[and drew a line splitting the rectangle].” For the next one he said, “It’s a square, but divided into a window.” At this point in the task he started singing and ceased commentating. His third image began with an outer rectangle and he drew six squares inside of it; and the fourth image he sketched each tile, using

at least one side connected to another tile. The last two tiles were drawn quickly as loops, likely for speed and efficiency rather than accuracy.

![Image of tiles]

**Figure 3. Hunter**

**Data Set 2: Corner Pyramids**

Three fifth grade students worked in a group to solve a series of three-dimensional geometric tasks. Presented with the first three “corner pyramids” (see Figure 4), the group determined how many cubes were in the first pyramid and how many more cubes were required for the second through eighth, thirteenth, and twenty-ninth corner pyramid. After the researcher introduced the first three pyramids and tasks to the students, they were left to work on their own for the remaining prompts.

![Image of three pyramids]

**Figure 4. The first three corner pyramids**

The students worked individually and together building the pattern elements, counting cubes in them, and producing the same solutions. However, there were distinct spatial conceptualizations that specified exactly how they built and counted each pyramid.

Using multi-link cubes, Allan and Veronique created the fourth pyramid by assembling horizontal layers of cubes and counting the 10 ‘steps’ on its front side (Figure 5). William built a vertical rod of 4 cubes, attached another 16 cubes to it, and counted the cubes on its bottom (see Figure 6). The students agreed that the two pyramids were identical even though they had built them differently.
For the fifth pyramid, Veronique took the third pyramid, placed it behind the fourth pyramid and as she examined the outer layer, stated, “the more cubes are the ones that you can see.” She proceeded to “add five” imaginary cubes onto the fourth pyramid’s base and counted on from five with her finger on each of the existing steps to arrive at “fifteen” additional cubes (see Figure 7). William replied that it would be simpler to build the fifth pyramid, turn it over, and count the cubes in its bottom.

As the students moved on to the seventh, eighth, and thirteenth pyramids, Veronique and Allan produced three drawings of what they imagined the bottoms of the pyramids would look like (see Figure 8).

The group began building the seventh and eighth pyramids. Veronique and Allan built the seventh pyramid by attaching two rods of six cubes each onto two adjacent sides of the bottom cube of a vertical rod with seven cubes (see Figure 9) and then attached 65 more cubes. William created the eighth pyramid with a vertical rod of seven cubes and attached to its bottom cube, a
36 cube base (see Figure 10) that resembled Allan’s drawing of the eighth pyramid’s bottom. William then attached the rest of the cubes as steps, constantly turning the pyramid as he built it.

Figure 9. Veronique and Allan’s frame for building the 7th pyramid

Figure 10. William’s frame for building the 8th pyramid

Results

While the children worked in these sessions, their gestures and conversations predominantly directed attention towards their physical activities. This physical work accomplished by the children both individually and collectively emerged as: building, arranging, drawing, and counting. The two data sets and the examples within each set illustrate for us, the diversity of the children’s conceptions of patterns, pattern growth, and the spatial structuring of patterns, as well as the embeddedness of these structures in their physical work. Furthermore, even within the examples we noted that the children conceptualized pattern growth in more than one way. The children’s conceptualizations recursively flowed into how they then built the next element in the pattern—not towards mental abstraction, but continuously contingent on the immediate context.

The growth of the children’s ability to visualize was very clear in their work. We contend however, that physical activities such as counting, drawing, building, and arranging should neither be considered merely as a means of testing or checking—nor should these actions serve as indicators that children are at a less sophisticated level of spatial reasoning simply because they are not purely mental acts. These children’s physical activities were combined with a flexibility of moving between different modes and numerical and spatial images that revealed mathematical sophistication and not its converse. In the episodes, the children’s physical activities may appear on first glance, to be low level ways of knowing, acting, or being mathematical but upon further examination into how the children actually built, arranged, counted, and drew, very sophisticated and complex spatial-numerical structuring is evidenced.

Our review of previous studies on spatial structuring emphasized counting, building and drawing actions as indicative of children’s level of ability. However, we feel that simplicity of mathematical actions is not a clear indicator of what these authors consider to be low level spatial structuring.

Differently and notably observed in the exemplars is that the children’s geometric and arithmetic structures did not exist separately from one another. Further, the children’s thinking neither progressed in a manner from concrete to abstract nor did it exist as a mental product of their physical actions. Given this, the children’s physical activities cannot be viewed as merely
material re-presentations of categorical mental knowings or understandings. Rather, the children’s physical actions in unpredictable yet recursive manners were the children’s spatial and numerical conceptualizations of the two- and three-dimensional pattern growth. As such, their very physical and always contextually grounded conceptualizations must be considered to be fully embodied events; events that emerged, evolved, and grew in complexity as the children engaged in yet other physical activities of building, counting, arranging, and drawing.

SYMMETRY AND CONFIDENCE: THE POWER OF CHILDREN’S MATHEMATICAL AESTHETIC

Robert Scott Eberle
University of Texas at Austin
scott.eberle@mail.utexas.edu

Mathematics is an aesthetic subject and researchers are beginning to take an interest in what this should mean for education. This paper looks at examples of how an aesthetic sense guides fourth grade students in their search for, and evaluation of, geometric tessellations. A child’s aesthetic is different from a mathematician’s, but the child’s aesthetic is well-suited for leading the child to generative paths of inquiry. As an example, I show how children’s aesthetic attraction to symmetry gives them greater confidence and mathematically fruitful ideas when searching for tessellations.

Introduction

The ancient Greeks understood mathematics (and not just its applications to art) as the height of aesthetics. This idea was lost by the time of the Enlightenment, but regained in the late 19th century, when mathematicians again recognized that aesthetics is at the foundation of pure mathematics (Sinclair & Pimm, 2006). Recently there has been a growing awareness of the need to pay explicit attention to mathematical aesthetics in education. The NCTM Standards (2000) call for inclusion of aesthetics in the teaching and learning of mathematics. Nathalie Sinclair (2008) has recently shown how an aesthetic lens can be used to understand certain aspects of classroom interaction.

In this paper, I will look at how children use aesthetics in mathematical inquiry to direct their own search for solutions and to evaluate their own findings. I will show how the aesthetic consideration of symmetry guides children’s thinking when exploring open-ended tasks involving geometric tessellations. In particular, the students’ awareness of different symmetries adds significantly to their confidence that a path of exploration is likely to be fruitful or that a solution is valid.

Background

What is mathematical aesthetics?

Mathematics is often perceived as being a rigorous, logical subject with no room for subjectivity. This is not the perception of mathematicians, most of whom understand mathematics to be an aesthetic subject (Burton, 2001). What is often overlooked in the popular perception of mathematics is that theorems, proofs, and applications are only one part (often the final result) of mathematical work. Before a system of theorems is built up, an axiomatic foundation has to be agreed upon, and this can only be by aesthetic criteria, such as elegance and simplicity. A search for theorems or new areas of study may involve considerable exploration, which is guided by a sense of aesthetics.

Sinclair, in her book Mathematics and Beauty (2006), describes aesthetics as a way of knowing. An artist uses a sense of aesthetics to know how to use colors. In a similar way, mathematicians use aesthetics to know how to explore mathematics. Sinclair defines aesthetics as “A pleasurable sense of fit, which speaks about context and surroundings as well as attributes of the situation in question” (p. 41). She proposes a tripartite model for the role of aesthetics in
mathematics covering the motivation of the choice of problems, the generation of conjectures, and the evaluation of solutions. In short, aesthetics is involved throughout the inquiry process.

**Importance of aesthetics to mathematics education**

Sinclair (2009) has pointed out that many see the consideration of aesthetics for mathematics education as either frivolous or elitist. Those who see it as frivolous believe aesthetics to be peripheral to mathematics rather than the foundation on which mathematics is built. Many see the purpose of mathematics education as the learning of skills needed for life and other coursework—the mere application of what mathematicians have developed. Aesthetics, it is argued, is at best a concern for mathematicians alone. However, Sinclair and others (Sinclair, 2006; Upitis, Phillips, & Higginson, 1997) have convincingly argued that aesthetics is important for meaning and sense-making for students. Others (e.g. Hiebert et al., 1996) have emphasized the importance of incorporating inquiry in mathematics education, which cannot be done without a sense of aesthetics as a guide. Brown, Collins, & Duguid (1989) have argued that learning should be situated in an authentic context. But if students are to experience such an authentic cognitive apprenticeship, their learning must include genuine inquiry guided, not by heuristics, but by aesthetic criteria.

The view that mathematical aesthetics for education is elitist comes from a Platonic view that aesthetics is an inherent property of mathematical objects, independent of culture (Sinclair, 2009). As such, it is believed that aesthetics can be properly evaluated only by experts. Various researchers have shown that students do not always share the same aesthetic appreciation for solutions as mathematicians; such evaluation is therefore believed to be beyond children’s abilities. However, it has been pointed out (Burton, 2001) that aesthetics is in some respects subjective and that different mathematicians have different criteria for what they appreciate as aesthetic in mathematics. Whereas certain aspects of aesthetics are shared among mathematicians, others are variable and contribute in different ways for different mathematical tasks, sometimes even leading to different solutions. Children’s mathematical aesthetics is somewhat different from that of experts, but may serve their needs better than expert aesthetics by focusing on the aspects of mathematical learning that is important to students (Sinclair, 2006) while still leading them to understand powerful mathematical ideas. This paper is an example of how fourth grade children’s sense of aesthetics guides them in their search for solutions to open-ended geometry tasks.

**Tessellations**

A tessellation, or tiling, is a complete covering of the plane by non-overlapping shapes, typically polygons. Tessellations make an ideal context for exploring the aesthetics of geometry with children. The NCTM *Curriculum Focal Points* has recommended that tessellations be studied in the fourth grade in order to learn transformations (NCTM, 2006).

Some educators have found that tessellations can be powerful tools for teaching geometric ideas. Dina van Hiele-Geldof used tessellations to teach 12-year-old children geometric concepts, such as the congruence of corresponding and alternate interior angles, by having her students explore patterns formed by lines in tessellations of rhombi (Fuys et al., 1984). After a fourth grade unit on tessellations, Upitis, Phillips, & Higginson (1997) found evidence of sophisticated visual understanding which transferred to units outside of geometry.
Symmetry
Most commonly studied tessellations have patterns that repeat throughout the plane; that is, they have translation symmetry in at least two independent directions. There are exactly 17 types of patterns with such translation symmetry, as categorized by the orders of the other types of symmetry that a tessellation can possess: reflection symmetry, rotation symmetry, and glide reflection symmetry. It is not required, however, that a tessellation possess even translation symmetry—a tessellation can be aperiodic (never repeating), though such tessellations are complex and have only been studied by mathematicians since the 1970s (Gardner, 1977).

Symmetry is an obvious aesthetic consideration and has been extensively studied in art as well as mathematics. All children perceive symmetry naturally. Sinclair (2006) already noted an example of how a sudden perception of symmetry enabled a child who was stuck on a problem to regain motivation and use the symmetry to find a solution. Children’s perceptions of symmetry may not be highly sophisticated and they may not be able to explain the perceived symmetry mathematically, but symmetry still may be attractive to them and guide their thinking towards generative mathematical ideas.

In my work with fourth grade children, I found several aesthetic considerations in children’s thinking, such as alternating rows and “3D” patterns. These considerations both inspired a sense of wonder and enjoyment in the task and directed their thinking along generative paths. In this paper I will focus on how students’ awareness of symmetry affected their mathematical inquiry.

Methodology

Population
I conducted exploratory clinical interviews (Clement, 2000) with eleven fourth grade children from two schools: a demonstration school for a large state university serving students from underprivileged families, and a small, multilingual private school with accreditation from the French government. Three of the children were French; the rest were American.

Six of the children were interviewed in pairs, the others individually, in whichever language they were comfortable with. Students were given a variety of tiling tasks, usually in the form of “Is it possible to tile a floor with this shape?” The immediate goal of the interviews was to explore how children conceptualized tilings before and after they attempted to create them. Tasks were adjusted according to student interest, performance, and time, so not all students had the same tasks.

Tasks
Several tasks were conducted, three of which will be described in this paper. First, after several tasks that explored tilings with individual pattern blocks, students were given all the squares and triangles in the set of pattern blocks and asked if it were possible to create a tiling with those two shapes together. In another task, students were given dot paper and asked if they could tile by drawing only L-tromino shapes. In their last task, they were asked if it was possible to tile by drawing only T-tetromino shapes on dot paper. (The L-tromino is a shape made with three squares, and the T-tetromino with four squares. See Figure 1.) In the two dot paper tasks, I drew the initial shape and then asked if they could continue the tiling with the same shape.

The tiling with squares and triangles was the most complex task. Though there was no requirement that edges and vertices be matched up, all children attempted to create such tilings in
every task. Of particular interest to mathematicians are two semi-regular tessellations with squares and triangles. (Semi-regular means that every vertex has the same pattern of regular polygons surrounding it.) The easiest one is simply alternating rows of squares and triangles. (See Figure 2a.) Each vertex is surrounded by the pattern triangle-triangle-triangle-square-square, sometimes referred to as 3.3.3.4.4. No one constructed this tiling, though some did organize their tilings partly or completely in rows of some sort. The other semi-regular tessellation is the 3.3.4.3.4 tiling (or snub square tiling; Figure 2b) whose pattern is triangle-triangle-square-triangle-square around each vertex. This tiling is visually complex, but some children found patterns close to it. If we relax the condition of semi-regularity, there are infinitely many possible tessellations with squares and triangles. In this study, no two students found the same pattern.

Data Analysis

The primary motive during the interview was to discover how the children were conceptualizing tiling. There was no deliberate probing concerning the aesthetics of each task. Observations concerning aesthetics were only considered after the data were collected. The interviews were video recorded. Detailed notes of each video were made and then analyzed by coding various factors such as perceived tiling possibility, pattern found, initial confidence, final confidence, solution symmetry, and reasons that justified the tiling. These data were then analyzed using an aesthetic lens as an interpretive framework (Sinclair, 2006).

Results

I will focus on the results from the two dot paper tasks and the squares and triangles tiling task. I will draw from the responses of three students: Arlene, Don, and Alicia (pseudonyms). Don and Alicia worked together; Arlene worked alone.

L-Trominoes

Nine children were asked to tile with the L-tromino on dot paper. I drew the first shape and then asked them to draw the other shapes to make a tiling. All but one student believed it was possible to tile with such a shape, though two expressed some hesitation. Six of the children made rectangular units of the shape. The other three created apparently aperiodic tilings which they either denied could work, or expressed hesitation about.

Arlene did not seem to know at first if such a tiling was possible. She was one of the three children who attempted to make a tiling by drawing shapes
seemingly at random. After drawing eight tiles, she decided that the tiling would be possible. Her explanation depended on the fact that the L-trominoes could be placed symmetrically, though her current drawing displayed no symmetry. When challenged to explain further, Arlene attempted to draw a new pattern with two-fold reflection symmetry. (See Figure 3.) Even though she was not completely successful, the fact that she could place the trominoes somewhat symmetrically, together with the fact that she was able to place 27 trominoes without creating a hole, convinced her that a tiling was possible. In other words, her certainty drew partly from the empirical evidence that the tiling was working so far, and partly from the possible symmetry of a successful tiling.

Don and Alicia quickly saw that a tiling was possible with the L-trominoes by putting two trominoes together to make a rectangular unit. Because the rectangle was easy to tile, a tessellation could quickly be made with these units. Wheatley & Reynolds (1996) have also found that many students solve such tiling tasks by unitizing. After drawing the first rectangular unit, Don and Alicia explicitly used a reflection to create a second unit symmetric to the first. (See Figure 4.) They claimed that further reflections could be used to create an infinite rectangular tiling. Simple translations would have been sufficient for tiling their rectangles, but for some reason, perhaps aesthetic, they preferred using reflections to complete the tessellation.

T-Tetrominoes

Six students were given the T-tetromino tiling task. Two believed the shape could tile; two believed it could not tile; and two were not sure. Only Don successfully created a mathematically valid tiling. Most of the children placed tiles at random in an apparently aperiodic pattern. Arlene was not given the T-tetromino task.

At first, both Don and Alicia were confident that a tiling could be made with the T-tetromino and they tried to make a pattern together. After reaching a few impasses where no new piece would fit, they lost their confidence that the tiling was possible. They continued to work separately on two different patterns. Don succeeded in making a nice row pattern, effectively demonstrating that the tiling was possible. (See Figure 5.) Notice that he used reflection symmetry to create subsequent rows from the first row. Alicia continued with a seemingly random pattern of 26 T-tetrominoes which seemed to fit nicely together. Because the tiling was working so far, Alicia decided that this empirical evidence was enough to conclude that her tiling might work, but she was not confident of her answer.
Squares and Triangles

Nine children were asked if it was possible to tile with squares and triangles together. Students created various patterns and most concluded that such a tiling was possible, though only four students succeeded in making patterns that were clearly extendable in all directions.

Arlene successfully made the snub square tiling up to eight squares and sixteen triangles. She described her pattern as repeatedly combining a square and a diamond (two triangles). Perceiving this pattern helped her to place the pieces—always putting two triangles together next to a square. This was possibly not a case of true unitizing because it is not easy to visualize how such units tile, though there was unitizing of the two triangles as a “diamond.” She then put the seventeenth triangle where a square should have gone without realizing it. After reaching a point where her pattern clearly broke down, she was unsuccessful in locating the source of the problem and decided (without conviction) that the tiling would probably not work after all and that somewhere she would eventually face an arrangement where no tile could fit. (See Figure 6.) She was not sure if the problem was simply that squares and triangles cannot work together, or if she had made a mistake somewhere, though she suspected the former.

Don created a tower of widening rows—each row was one unit wider than the row above it. Though apparently finite, Don said that the rows were meant to continue indefinitely in each direction. The finiteness of the tower width may have been a result of trying to create a pattern with left-right symmetry, an innate aesthetic response.

Alicia and Don then worked together on another pattern that they put together one tile at a time without any clear preconceived structure. With the addition of the fifth piece, the small structure gained simple reflection symmetry. The symmetry was lost for a moment and then regained with the eighth piece. With the thirteenth piece, they managed to form a pattern with two-fold symmetry. Don commented, “I see a star and an X,” pointing to the symmetry of the shapes. (See Figure 7a.) From this point on, they were very careful to plan the structure in a way that conserved the two-fold symmetry, though parts were left undone due to lack of tiles. (See Figure 7b.) They tended to clump the triangles together in regions separated by rows of squares without any clear idea of exactly how the structure would continue. But the pattern was clearly symmetric, simple to understand locally, and aesthetically pleasing. This seemed sufficient to assure them that they would be able to continue some sort of pattern forever.

Discussion and Conclusions

The Power of Symmetry

Finding symmetry enabled children to believe that a tessellation was possible. They did not have the mathematical skills for investigating aperiodic tilings, but symmetric, repeating tilings.
could be seen to continue indefinitely. Translation symmetry (finding a repeating pattern in both dimensions) is the simplest kind of symmetry and one that is necessary for mathematical certainty of tiling at these children’s level of understanding. More interesting is when the children found reflection and even rotation symmetry. Arlene began with a random, aperiodic tiling, and then suddenly saw that it must be possible to arrange the L-trominoes symmetrically. Though she did not quite succeed, she remained convinced that symmetry was possible and therefore a solution was possible. This generative thinking was mathematically correct. With more time, if she had continued to try (perhaps with a little help) to arrange the trominoes with a two-fold symmetric pattern, she could have succeeded.

Children were often convinced by empirical evidence that a tiling was possible, even when a pattern was not found. Alicia’s empirical evidence for the T-tetromino was not sufficient to convince her fully because it lacked symmetry. Don and Alicia were fully convinced by their empirical evidence for the squares and triangles tessellation because of its multiple symmetries. In both cases, the children failed to find a solution that was mathematically complete, though Don’s and Alicia’s symmetric construction was closer to a solution and could have led to one with time and more pattern blocks. Alicia’s sense of aesthetics led her to be dissatisfied with a construction that lacked symmetry because it could not lead her to a fruitful idea for tiling. A mathematician, with a somewhat different aesthetic, might have found this apparent lack of symmetry intriguing and explored the possibility of a sophisticated, aperiodic solution. But Alicia’s aesthetic correctly led her to evaluate the types of solution that would be fruitful for her mathematical abilities at this time. Aperiodic tessellations are mathematically difficult to work with. Thus the aesthetics of symmetry indicated to these children which attempts were mathematically generative for them.

Symmetry was not always necessary in the solution, but it gave a more appealing answer, such as Don’s use of reflection in his T-tetromino rows. The use of reflection symmetry may make the answer clearer, more convincing, and aesthetically appealing.

Symmetry is not a heuristic that inevitably leads to correct solutions. The left-right symmetry of Don’s tower of squares and triangles was irrelevant to the tiling he was trying to visualize and could have led him astray, as in fact it did with two other children who made similar structures. Don and Alicia’s reflections to create an L-tromino tiling were not any mathematically better than simple translations (though not worse either, and perhaps more pleasing). Symmetry serves, not as a logical indicator of the correctness of a tiling, but as an aesthetic device that lends confidence to the children’s solutions by making extensions of their tilings easier to visualize. Even when they could not visualize the extension, the presence of symmetry served as an indicator that they were on the correct path towards a valid solution, an aesthetic conclusion that was more likely correct than not.

Moreover, this aesthetic sense of symmetry can lead to an awareness of mathematical structures expressed in the tiling (cf. Piaget, 1971). Don’s perception of “a star and an X” is the precursor to a more sophisticated understanding of mathematical symmetry.

Looking at how the aesthetics of symmetry guides children’s thinking may seem like a small consideration. But symmetry is only one aspect of aesthetics. There are many other aesthetic considerations which guide both mathematicians and children in mathematical inquiry. We need to begin to look at all the ways aesthetics, and not just logic and heuristics, guide children’s mathematical thinking.

Children’s aesthetics is not mature and could be improved through enculturation in the mathematics classroom. Sinclair (2008) has already observed how such enculturation is taking
place implicitly in some classrooms. Children’s aesthetics could be more finely developed if teachers gave more explicit guidance in the aesthetics of mathematics.

By becoming more aware of the ways aesthetics guides thinking, especially in exploration and evaluation, we can become better able to give explicit guidance to students on the aesthetic aspects of mathematics. More research is needed in this area in order to understand better how aesthetics guides children’s mathematical thinking and how this sense of aesthetics can best be developed in an educational environment.

This paper seeks to complexify a relationship between students' geometric reasoning and diagrams used in geometric instruction. The van Hiele levels are used as a frame through which classroom task diagrams are examined. Possible student interpretations of the diagrams biased on different van Hiele levels are compared with the intended meaning of the diagrams in the task. Future research is recommended to examine this issue.

Introduction

In elementary school textbooks and during enacted lessons, students are shown a picture of a shape such as that in Figure 1 and are expected to name it based on the visual representation. For example, if the quadrilateral does not appear to have equal-length sides, the student is supposed to conclude that it is not a square. The student is not expected to describe the shape in Figure 1 as a parallelogram. Instead, students are expected to pay attention to the shape as a whole and match the shape to others they have seen before.

Figure 1. What is the name of this shape?

In contrast, in high school geometry classrooms, when given the same diagram (Figure 1), students are expected not to claim that the shape is a rectangle. In fact, many geometry teachers, frustrated why students would assume the angles of the shape are right angles, instruct their students not to "trust" geometric diagrams by appearance. For example, students are told that just because two sides look parallel doesn't mean that they are actually parallel, unless markings or a direct statement is provided that indicate that the sides are indeed parallel.

In this paper, we explore this change of how geometric diagrams are used to convey meaning (visual rhetoric) in textbooks from elementary school to high school. We argue that a fundamental shift of the diagram as the shape (an image) versus the diagram as a representation of a shape that is not shown, but imagined occurs in textbooks. We suspect that some students make this transition, while others do not, creating the situation where the diagram is meant to mean one thing (a quadrilateral in which we do not know anything special about the sides or angles), while the student sees another (a rectangle). In this paper, we explore examples of visual rhetoric from textbooks and discuss their potential meanings. Finally, we conclude with recommendations for future study.

Theoretical Framework

The van Hiele framework is a hierarchal framework that describes different levels of students’ reasoning in geometry. The five levels used in the framework describe different ways that
students could reason about geometric topics, from visualization and analysis at lower levels to abstraction, deduction and rigor at higher levels (Burger & Shaughnessy, 1986). The van Hiele framework explains that different individuals (such as the teacher and a student) can use the same words (such as “rectangle”) with different intension, and thus essentially talk past each other. For example, a teacher might want to talk about a quadrilateral with four right angles, but the student might instead think of the image of a rectangle and not even recognize that it has four right angles. Thus, for classroom discourse to be effective, the ways in which topics are discussed in the classroom should coincide with the van Hiele levels that students are reasoning at. For example, discussions about the definitions and properties of shapes may not be effective if students have only begun to reason about shape by comparing pictures of shapes to real world objects that look similar.

This paper uses the van Hiele levels as a lens through which to compare the visual rhetoric used in elementary textbooks compared to that found in high school textbooks. In the same way that the effectiveness of words can be hampered by differing van Hiele levels, we look at how the geometric diagrams used in mathematics at different grade levels might be affected by differing van Hiele levels. To do this, we focus on the three lowest of the van Hiele levels, denoted here as levels 0, 1, and 2. Burger and Shaughnessy (1986) identified different indicators that suggest a student may be reasoning at a particular. For the purposes of this paper, we included descriptions of some (but not all) of the indicators at these three lowest levels.

**Level 0**

Students recognize shapes by their by appearance alone. The figure is perceived as a whole, and the properties of the shape are not recognized.

**Level 1**

Students are able to sort shapes by single attributes and are able to recognize properties of the shapes, but do not recognize relationships between the shapes.

**Level 2**

Students are able to define shapes and recognize that different criteria may be used to define shapes. Students can sort shapes by a variety of mathematically precise attributes and can recognize relationships between shapes (such as understanding that a square is a special rectangle).

**Task Descriptions and Student Reasoning**

So what are the different ways that geometric diagrams are used in mathematics textbooks to convey information? In this section, we examine three different tasks adapted from actual prompts found in a variety of United States texts across different grade levels. For each, we discuss the diagram(s) provided in the task, as well as how it might be perceived by students of different van Hiele levels.

**van Hiele Level 0 Reasoning Task**

The task in Figure 2 was adapted from an activity in a text intended for a kindergarten classroom. As part of the task, students are presented with pictures of real world objects. We note here that the pictures do not include any additional markings added to indicate additional information about the objects. The only information students have to rely upon are the visual images of the objects. Students are asked to identify the objects that are circles as well as rectangles.
Directions: Have students mark an X on the objects that are circles. Then have them put a circle around the objects that are rectangles.

**Figure 2. A kindergarten task adapted from a United States math textbook**

This task seems to fit very well with a type of reasoning about geometry that is described in the Level 0 of the van Hiele framework. Here, students are expected to use the visual qualities of the pictures of the objects to identify and sort the shapes. These prototypes of the shapes are being used to help students pay attention to certain characteristics of the objects. Thus, the student is expected to identify the dinner plate as a circle and the clipboard as a rectangle based on appearance. However at this point, students might not recognize the framed picture as a rectangle.

While this task seems fairly straightforward for someone who is reasoning at Level 0, how might students at other levels of understanding of geometry interpret these shapes? For students at Level 1, who begin to pay attention to the attributes of shapes, they might be critical of the CD and the dinner plate, measuring the several different diameters to check that it really is a circle and not an oval. These students might also argue that the briefcase and the clipboard do not have straight sides, so therefore they are not rectangles. However, students reasoning at Level 2, who begin to use mathematical definitions and pay attention to mathematically precise attributes, may require additional information about the shapes before they would classify the objects. They may want to know if the sides of the clipboard are really parallel, or if the framed picture indeed has equal-length sides.

In each group of triangles, circle the one that doesn’t belong. Explain how you know that it doesn’t belong.

   ![Triangle](image2)
   ![Triangle](image3)

2. ![Triangle](image4)
   ![Triangle](image5)
   ![Triangle](image6)

**Figure 3. A second grade task adapted from a United States math textbook**

van Hiele Level 1 Reasoning Task

The task in Figure 3 was adapted from a textbook intended for second grade mathematics. Students are given a set of three triangles and asked to circle the one that “doesn’t belong.” Again we note that the images of the triangles are only the three sides of the triangles, no additional information about the triangles are included.

This task seems to be aimed at those students who are reasoning in ways similar to the ways described in van Hiele level 1. Here students may be sorting shapes based on a single attribute, while ignoring other attributes. Indeed in each line of this task, two of the triangles contain apparent right angles, while one triangle contains angles that appear to measure 90°. This task seems to expect to have students identify the non-right triangle as the figure that “doesn’t belong.”

Next, we consider how students who reason at a Level 0 might use these diagrams. In the first line, students might identify the middle triangle as the one that does not belong since its base is not horizontal, a common way that the image of triangles are portrayed. A student reasoning at Level 2 might require additional information about the triangles, and will not assume that angles that appear to measure 90° do.

Classify quadrilateral ABCD using the given information.

1. $\overline{AC}$ and $\overline{BD}$ bisect each other.
2. $\overline{AC}$ and $\overline{BD}$ bisect each other, and $\overline{AC} \cong \overline{BD}$.
3. $\overline{AC}$ and $\overline{BD}$ bisect each other, and $\overline{AC} \perp \overline{BD}$.
4. $\overline{AC}$ and $\overline{BD}$ bisect each other, $\overline{AC} \perp \overline{BD}$, and $\overline{AC} \cong \overline{BD}$.

Figure 4. A high school geometry task adapted from a United States math textbook

van Hiele Level 2 Reasoning Task

The task in Figure 4 was adapted from a textbook intended for secondary school geometry. In this task, students are given one diagram for several questions. In each question, certain relationships between parts of the figure are stated. From these criteria, students are expected to name the shape. It is noted that the diagram used does not appear to satisfy any of the criteria of any of the questions. Also, while the questions all refer to the same figure, some criteria are given for certain questions, while excluded from other questions.

This question appears to require reasoning that is similar to the kind described in van Hiele level 2. Students are expected to pay attention to the definitions of different shapes, and

explicitly reference them. They are also expected to sort shapes according to their mathematically precise attributes. This prompt seems to expect students to pay attention to the relationships described in each question, and not the visual shape of the diagram, in determining the different shapes.

Consider how someone reasoning in a manner similar to Level 0 would engage with this task. For this student, they have not yet begun to consider formal mathematical definitions of shapes, or consider the implications of describing parts of the figure as bisecting each other. Instead they might look at the diagram and conclude that the shape does not look like any of the shapes they have special names for, regardless of the verbal information printed in the text. Someone reasoning at a Level 1 might not be able to consider a definition of figure in terms of its diagonals, instead of its sides.

**Discussion**

An alignment between student reasoning of geometry and reasoning about a diagram is, undoubtedly, preferred. However, several interesting things can occur when there is a non-alignment in the ways that students are reasoning about geometry and the reasoning required to use a diagram in its intended way. If a student is at a lower van Hiele reasoning level than what the diagram is requiring, students may end up using empirical evidence from the diagram in their justifications of naming the shape. The diagram may not be intended to be used in this manner, especially if it is not drawn to scale. As stated previously, this may occur when students try to claim a figure is a rectangle, while a problem may be set up only to indicate that the figure is a quadrilateral.

The mismatch of visual rhetoric for different van Hiele levels can also occur in the other direction as well. Students may be at a higher van Hiele reasoning level than the reasoning intended to use a diagram. In this situation, students may be intentional trying to avoid using visual, empirical evidence from a diagram. The question, however, may be intending for students to generalize based on only visual clues from a diagram.

There is a transition in school geometry of which students and teachers may not be explicitly aware. Early elementary geometry often relies of visual evidence of figure, wanting students to generalize from pictures. High-school geometry often relies on logical conclusions drawn from an axiomatic structure. In this system, diagrams are not utilized as justifications. There is a transition here between these two extremes that still remains unstudied.

This research identifies the potential confusion that can exist when the meaning of a geometric diagram requires a different level of van Hiele level than that of the student. This appears to be an area where further research would not only be fruitful, it would also be important. Students often struggle with geometry and reasoning around diagrams could be involved. How aware are teachers of the reasoning necessary to use a diagram? And how might teachers use diagrams in the classroom during lessons or on assessments? How does student reasoning around diagrams change as students progress through elementary school and into high school? How do we support students who might not have adopted new reasoning levels? How is this change of visual rhetoric related, or unrelated, to changes in verbal rhetoric? These are just a sample of questions that future research can attempt to address.

YOUNG CHILDREN’S INTUITIVE KNOWLEDGE OF REFLECTIVE SYMMETRY

Hyun Jung Kang

skim118@asu.edu

The goal of this study is to investigate young children’s intuitive knowledge about reflective symmetry concept and their performance in reflective symmetry tasks. The study was conducted with 15 second graders. The result indicated that 2 out of 15 second graders were able to create a reflective symmetry design successfully. The study suggested the idea of a mirror image appears to be of a higher developmental level than the translation of shapes. We found that knowing the orientation of the shapes seemed to be a more important predictor than finding the distance to the axis to perform reflective symmetry tasks.

Introduction

Geometry and spatial thinking are important ideas to develop because they involve the space where the children live, breath and move (National Council of Teachers of Mathematics – NCTM–, 1989). Clements and Brista (1992) addressed spatial reasoning, which is the ability to “see” and reflect on spatial objects, images, relationships, and transformation as the fundamental constructions in geometry thoughts. Transformation includes the operation of images; such as rotation, reflection and sliding of shapes and symmetry as one of the concepts that are connected to transformational geometry. Children’s beginning concept of geometry is not just about shapes, but also about symmetry, congruence, and transformation (Clements & Sarama, 2007). Research studies that addressed young children, stated that they develop preference of symmetry as early as 12 months (Clements & Sarama, 1992; Vurpillot, 1976).

Despite young children’s cognitive development of symmetry, little work has been done regarding the intuitive knowledge, which children have when they are presented with geometric tasks. Almost no research study has been conducted to investigate the relationships between elementary students’ intuitive knowledge and reflective symmetry tasks.

The authors of this paper investigate the intuitive ideas of symmetry of second grade students. Knowing how children think about geometry will help us understand solutions to a variety of problems in mathematics by using pictures, a common aid children used to solve different kinds of problems.

Theoretical Framework

Palmer and Hemenway (1978) documented that there seem to be two phases in recognition of symmetry. The first stage is to select potential axis of symmetry in all orientations simultaneously defined by mirror-similar parts, and then perform a detailed evaluation of symmetry about the selected axis by comparing the two halves for mirror-identity. With respect to the symmetry axis, many studies indicate that bilateral (or “mirror-image”) symmetries which axis is a vertical line are perceptually most prominent, horizontal on the other hand is less dominant, and the diagonal line of symmetry is the most difficult (Hoyles & Healy, 1997; Palmer & Hemenway, 1978; Vurpillot, 1976).

Meanwhile, Vurpillot (1976) reported that mirror images were particularly difficult for young children to distinguish compared to other types of transformations. The task of his study was to distinguish figures between simple rotation (e.g. 90 degree rotation) in a single plane from
inversions or rotations in vertical/horizontal presentations. He also reported regardless that they were mirror images or not, the transformation from top toward bottom is easier for the children than the change from left to right.

As with symmetry, the children were asked to compare two objects which were similar but not physically identical. Vurpillot (1976) stated that many young children judged congruence based on whether the objects are more similar than different. Another study (Rosser, 1994) documented that orientation was a significant feature for the kindergarteners to judge whether the shown pairs of figures (some congruent but all rotated) were different. Rosser’s study indicated that in addition to the congruency of shape and sizes, and understanding the rotation of a shape is a critical feature in reflective symmetry. However, research showed that children’s concept of equivalence may develop as young as 18 months but the consideration of its spatial relationships gradually develops later (Vurpillot, 1976).

Hoyles and Healy (1997) analyzed students’ thinking-in-change of reflective symmetry. They stated that it is important to know the property of symmetry in order to understand the concept of symmetry. The study noted the property as the reflective image having the same size and shape as the original, it is at the same distance away from the mirror (symmetry line), and is “opposite” or “reversed”. Holyes and Healy indicated that without clear understanding of this property students are more likely to make an error when they create symmetrical shapes.

The goal of this study is to investigate second graders’ intuitive knowledge about the concept of reflective symmetry and their performance in creating reflective symmetry tasks. We chose this subject for two reasons. First, limited research has focused on elementary students’ intuitive knowledge of this concept. Second, the concept of symmetry is fairly simple and can be readily learned by young children, but it is not typically taught until upper elementary grades.

The research questions are:
1. What are young children’ intuitive knowledge about reflective symmetry?
2. What types of knowledge do children need to learn in order to understand this concept?

Method

Participants

The subjects for this study were 15 second grade students (eight girls and seven boys) from three classrooms (five students per each classroom) in two different schools. These schools are located in an urban area of the Southwest of the United States and are currently participating on a National Science Foundation (NSF) professional development project for elementary mathematics. More than 90 % of the student population of both schools is Hispanic and receiving free lunch. Under the district policy, the classes were grouped by English proficiency level. Students’ English proficiency level was a selection criterion because communication was necessary to investigate the students’ thinking process through interviewing. All participants were Hispanic.

Data collection

Two types of data were collected in preparation of this paper: 1) individual interviews with students using paper and glue to create symmetrical designs, and 2) paper and pencil tasks.

Tasks

Each student was asked to participate in three different tasks. The first task included interviewing the student about what he or she saw when creating symmetrical designs with glue.
while folding paper. The interviewer drew odd shapes including a dot, a curvy line and a straight line with liquid color glue on the left side of a paper. Next, the interviewer folded the paper in half to produce the symmetrical shape on the right side (see Figure 1).

The interviewer opened the paper carefully after asking the student to predict what would happen, and asked the student following questions about the new design: What do you think about this shape? Can you explain more about this? Can you describe it for me? Can you compare the two halves? How do you know these are the same? Can you find other shapes which are the same? Are there any differences between these two? How can you know those are different?

Figure 1. Example of task 1

Figure 2. Example of task 3

The second task was similar to the first, however, children were asked to draw a shape by their own and fold the paper in half to produce the symmetrical shape, and observed the result. After folding and unfolding the paper, the interviewer encouraged the student to describe what they saw and tell why they thought these shapes were the same or not. When the students had a difficult time explaining, the interviewer asked similar questions as the ones listed above.

In the third and final task the students were instructed to draw with a pencil on the right side of the paper showing what s/he expected to see if the paper was folded (see Figure 2). During this task, the students were asked to explain how and why they expected such a figure. Students were allowed to use mirrors, pop-sickle sticks, or strip papers to help them measure in order to aid themselves to accomplish their goal.

Interview

The authors interviewed the second graders during the month of May, which is at the end of the school year. Since each interviewer observed students' mathematics classroom regularly for the entire school year as part of the NSF Project, they were familiar with the interviewers. Each child was interviewed individually for approximately thirty minutes. The entire interview was audio recorded and transcribed for the analysis. Each student’s work from the three activities was collected. The interviewers took notes as the students were solving the tasks. If the interviewer did not understand what the child explained, she asked the student to explain further until it was understood what method she or he was using to solve the task.

Data Analysis

Children’s explanations were coded in terms of whether they were correct or not, and if their drawings for the third task were right or wrong. According to the children's explanations and drawings, their thinking about symmetry was analyzed. Children’s symmetry understandings were categorized by 1) size, 2) shape, 3) distance, 4) copy, and 5) mirror image. Each category is explained in the table 1 below.

Results

The careful analysis of the interviews and the drawing resulted in the discrimination of the following categories: size, shapes, distance, copy and mirror image. The “size” category shows if children identified the figures on each side of the symmetry by axis or by flipping lines to discover if the figure was the same size or not. In the “shape” category, the information collected tells us if children realized the shapes were the same on each side of the axis, or if they failed to realize that due to the flipping nature of one of the halves. In the category for “distance”, the authors coded those students that placed the figures on the right spot relative to the symmetry side, but they failed to “orient” the figures, not obtaining a mirror image. Dots are a special case inside this category and will be discussed separately. As one can imagine, under “copy” fell all of the drawings made by the children that failed to place the figures in the right position relative to the axis, and that were not flipped either, but that as a whole, the children drew it as a copy of the original, what could have been a translation of a vector with a magnitude equal to half the page. Finally, in the “mirror image”, we found those students that succeeded in drawing a symmetric picture of the original design they were presented with.

Considering the categories mentioned before, the following results were obtained:

Size and Shape

When children were presented with the symmetric design, in almost 100% of the time they said that the two halves were “the same”. The students who focused their attention on the shapes of each side said that what was presented on the left side was also in the right half. Eighty percent of the students agreed that the sides were “the same”. In one case, student number three, pointed out that the sides “look the same, they are the same”, to explain how the two halves compared to each other. In another case, student number five, was prompted to describe the differences between the two sides of the first design with glue and responded by saying: “everything is the same”. This idea that the two sides were “the same”, even though they didn't exactly look that way, is linked with the category “copy” and will be further discussed in the coming section.

Another aspect of the glue design according to the second graders was the size of the shapes. In most cases, 80% again, they told the interviewers how shapes and lines were, or should be, the same size. On the third task, where the students were asked to make a symmetric drawing, they showed a conscious effort to reproduce the figures and lines by making sure they had the same size as the original. Students took measures with the provided paper rulers, their fingers, and sticks. In some cases they made sure that the interviewer knew that even though their work didn’t reflect the same size, it should have, and told how they were trying to reproduce the same measures without a graduated ruler.
Figure 3. Student’s work example of copy

Copy

On task three, 9 out of 15 students copied the original, to the other side of the axis or flipping line. Interestingly, this reproduction of the original matches what they described in task one: they mentioned both sides of the first glue picture were the same, although they weren't since once was a mirror image. On task three, by making a copy of the given design, they made sure both sides were actually the same. Students who made a copy of the last activity, and that were asked if they wanted to fix or change any detail of their work, focused again on the size the figures they drew, not on the fact that they were not mirror images.

Distance

Only two cases out of 15 students fell into the Distance category. These two students, who mentioned that both sides of the figure were the same, and that the respective sizes were equal as well, placed lines, figures and dots in the relative correct spot; however, they failed to “flip” the figures or lines. On the other hand, the dots they reproduce on the third task were perfectly symmetrical to the original ones.

In the presence of this data the authors make two hypotheses regarding this category and how children behave when trying to reproduce a mirror image of a given figure.

First hypotheses: Children are able to reproduce a mirror image when they are not distracted by lines or orientation. Children were correct almost 100% of the times in their prediction when they were asked to “guess” where one dot of glue was going to “appear” if we closed the paper and the two halves touch.

In two cases, when two different second graders were prompted to talk about how they knew where the dot was going to be, they said that they imagined a “straight line” and showed with their hands a line perpendicular to the axis, from the original to the symmetric side.

Second hypotheses: Children who are able to draw objects and place them in the correct relative position of the paper (distance), but not flipping, are one level closer to being able to obtain a mirror image, compared to those children who did a copy.
Student 15 copied all the shapes as the other students but while explaining to the interviewer, he corrected himself. He said he was wrong because the dots were not going to touch each other if he folded the paper. He wanted to do it again and figure 4 is the result of his second trial. The placement of the dot was correct but the orientation of other shape remained the same including the inside dot.

The results indicated that most students were able to predict where the symmetrical of one single dot was going to be, but none of the second graders were able to do this with a more complicated design, nor did they place a set of dots when the dot was presented with or inside the figures.

Mirror Image

When the interviewers prompted the students to talk about the differences, they learned that when looking at both sides of the glue designs, one student mentioned that one of the sides was “flipped”, but this student was not able to reproduce this idea on the third task. Student number three, said: “This is the same... but... kinda like (motioning a rotation with her hand) the same but don't.” This student also failed to reproduce a mirror image on the last task. What is interesting in this case, as well as in another two cases, is that students appeared to realize that the two halves were not actually the same, but lacked the vocabulary to describe what they saw. Being this the first time they are asked to do so, and considering these students were in their majority considered English Language Learners (ELL), the authors questioned what kind of information would have been shared if they could have explained it in their native language.

![Figure 5. Student’s work example of mirror](image)

Two out of the 15 students made a better attempt, to draw a mirror image, than the rest. In the case of student number one, the work was totally successful, and in case of student number eight, the work was partially successful, with some problems keeping the size of the figures equal to their originals. This student had pointed out that the sizes were the same, but it is assumed that due to his motor skills not being refined yet, the drawing came out smaller than what he was observing in the original.

Student number one, whose drawing is shown left, (see Figure 5) started his work as a copy, and then taking a second look exclaimed “Oh! It had to be the other way” and asked for a new piece of paper to draw what was his final work. The numbers that appeared in the picture were numbers that the student wrote to symbolize how the distances between two sets of points were the same. In this example, he said that if the distance between the extremes of the line were 5, no unit given, then on the other side, on his drawing, it had to be 5 as well. And his second example was one side of the quadrilateral: he told the interviewer how that side had to be the same in the corresponding figures. The student explained that if the side of the original was 4, then it had to be 4 on his side of the drawing as well.

Conclusion and Discussion

The result of this study indicated two features of young children’s intuitive knowledge about reflective symmetry concepts. The first one is that the idea of a mirror image appears to be of a higher developmental level than the translation of the shapes. The majority of second graders did very good copies of the original, sliding the shapes and almost achieving a translation of them, but only two students were able to create a mirror image.

Another finding revealed that the orientation of the shapes seemed to be the most difficult task for the young children to produce reflective symmetry successfully. Although they considered perpendicular lines to the axis to locate the figures on the other side, and they were successful locating single dots, the images of figures didn't have the right orientation. When the children had to think about the distance to the axis of single dots, they were much better able to predict the reflective symmetry position. It is generally assumed that the distance to the axis is critical in learning reflective symmetry, because finding the same distance from the axis is the first step to draw a symmetrical design. Nevertheless, this study indicated that the orientation of shapes is a more difficult concept for young children than finding the distance.

The implications for future practice involve teachers prompting students to explain what they mean by “the same” and work more deeply on what the differences are in two symmetric designs, original and image. The idea that the figures appeared “flipped”, in respect to one another, should be highlighted and explored further in the classrooms with young children. Teachers should work in depth with the idea of “orientation” of figures, and also with the notion of distances to the sides and the middle, in our case, the axis.

Future research should focus on how labeling “the same” in the symmetric design influenced the production of a copy instead of a mirror image. The researchers also recommend that future projects observe if children can find the symmetry of a single dot, a dot embedded in a design, and a dot that is a part of a figure, for instance, a vertex.

DYNAMIC GEOMETRY IN HIGH SCHOOL MATHEMATICS CLASSROOMS

Zhonghong Jiang
Texas State University San Marcos
zj10@txstate.edu

This four-year research project funded by the National Science Foundation compares effects of an approach to high school geometry that utilizes Dynamic Geometry (DG) software with standard instruction that does not make use of computer exploration/drawing tools. The basic hypothesis of the study is that use of DG software to engage students in constructing mathematical ideas through experimentation, observation, data recording, conjecturing, conjecture testing, and proof results in better geometry learning for most students.

Building upon previous studies, this study will seek to answer the following research questions: 1) How do students in the experimental condition perform in comparison with students in the control condition on measures of geometry standardized test and geometry conjecturing-proving test? 2) How does the DG intervention affect student beliefs about the nature of geometry and their beliefs about the nature of mathematics in general? 3) How does the DG intervention contribute to narrowing the achievement gap between students receiving free or reduced price lunch and other students? and 4) How is students' learning related to the fidelity and intensity with which the teachers implement the DG approach in their classrooms?

The research study follows a mixed methods, multi-site randomized cluster design. The population from which the participants of this efficacy trial are sampled are the 10th grade geometry teachers and their students at all high schools in Central Texas at which 50% or more of the students are eligible for free or reduced lunch. For determining the sample size, a power analysis has been conducted. Taking an attrition rate (20%) into consideration, 76 teachers are randomly selected from that population for the study.

Randomized assignment is used, with teachers as the unit of randomization. The 76 teachers selected are randomly assigned to two groups. Each teacher is represented in the study with measurements from only one classroom of students, and the classroom and teacher unit of analysis will overlap, yielding the design where the students are nested within teachers/classrooms, which are nested within schools. Teachers in both treatment and control groups receive relevant professional development. Fidelity of implementation for the experimental treatment is monitored carefully.

The implementation plan for the project is: Year 1: Preparation (All research instruments, DG instructional materials, recruitment and training of participants, etc.); Year 2: The first implementation of DG treatment, and related data collection and initial data analysis; Year 3: The second implementation of the DG treatment, and related data collection and continued data analysis; Year 4: Careful and detailed data analysis and reporting.

GEOMETRIZATION OF PERCEPTION: VISUAL CULTURE AND MATHEMATICAL VISUALIZATION FOR PROFESSIONAL TEACHER DEVELOPMENT

Claudia Flores
The Federal University of Santa Catarina
crf@mbox1.ufsc.br

Visualization has been considered as an essential factor in learning and teaching mathematics. Thus, the issue of visualization in the teaching of geometry has been a main research focus for several groups, as they recognize its importance for student understanding of mathematical and geometrical knowledge. However, bringing up such questions implies putting together concepts related to the construction of geometrical knowledge and primacy of perception. This research project focuses on the analysis of one way of looking at and representing military plans, architectural designs and military engineering treaties. The empirical work will be done on military plans or architectural designs of the American fortifications in the seventeenth and eighteenth centuries, in accordance with the teachings and rules found in the treaties of military engineering. Theoretical assumptions come from the reflections on the construction and representation of militarized space in mathematical activity, to understand how the operation of perception has become geometrical and how they have created and used mathematical knowledge to represent with the technical perspective theory. This theoretical study is based on Foucault (1989, 2000), Certeau (2007), Flores (2007) and Meneses (2003). As a possible result, mathematical knowledge applied to historical practice can be an exercise in the professional teacher development as a means to design activities related to visualization in the teaching and learning of mathematics.

Endnotes

References
This study sought to identify the predictors of the Geometry Achievement (GA) of the Grade 10 Science & Technology students of Charles Herbert Flowers High School (CHFHS) of Prince George’s County Public Schools (PGCPS), State of Maryland, United States of America (USA).

The predictors in this study were the entry competence (verbal comprehension, verbal reasoning, figural reasoning, quantitative reasoning and the overall entry competence ratings), middle school achievement (non-mathematics courses, mathematics courses, Middle School Assessment, geometry pretest and overall middle school grades) and grade 9 achievement (non-mathematics courses, mathematics courses, High School Assessment and overall grade 9 grade). The criterion variable was the Geometry achievement.

Multiple correlation analysis of all predictor variables yielded a significant large positive correlation of 0.599. The aforementioned predictor variables if taken simultaneously explained 30.68% of the variance in the Geometry achievement. This suggested that there might be other variables aside from those included in this study, which predict Geometry achievement. The strongest predictor variable was the overall entry competence rating.

CONCLUSIONS WITHIN MATHEMATICAL TASK ENACTMENTS: A NEW PHASE OF ANALYSIS

Samuel Otten
Michigan State University
ottensam@msu.edu

This study builds on the mathematical tasks framework developed during the QUASAR project by considering the ways in which enacted mathematical tasks are concluded. Though the framework originated from a cognitive tradition, this study takes a sociocultural perspective and reinterprets task phases through the lens of activity structure. Based on observations of 84 middle-school class periods and 4 detailed task conclusion analyses, a modification of the mathematical tasks framework to include a separate conclusion phase is proposed. Implications for analysis of cognitive demand are discussed, as is the relationship between task conclusions and characterizations of the nature of mathematics.

Introduction

Students’ engagement with mathematical tasks is widely recognized as a central component of mathematics education at all levels. For the middle school level in particular, Stein and her colleagues (Stein, Grover, & Henningsen, 1996) built on the work of Doyle (1988) and earlier cognitive science to develop the mathematical tasks framework (see Figure 1). Within this framework, the definition of a mathematical task is based on the earlier concept of an academic task but is broadened in duration to align with the mathematical idea under consideration. In other words, a new mathematical task has not begun until the mathematical idea being focused on has shifted, which means that a single mathematical task may contain several academic tasks. The mathematical tasks framework utilizes the key notion of cognitive demand, the kind of thinking processes entailed in solving the task, which has been found to correlate with student performance (Stein & Lane, 1996). The framework becomes valuable as a research tool because its phases allow the level of cognitive demand to be tracked throughout the enactment of the task. For example, during the set-up phase, teachers may cast a task written to be procedures-with-connections as procedures-without-connections; or during the implementation phase, a doing-mathematics task may descend into unsystematic exploration or nonmathematical activity. Overall, we know that it is difficult for teachers to enact mathematical tasks in ways that authentically engage students in the thought processes of mathematics, even when a task is written with a high level of cognitive demand (Henningsen & Stein, 1997).

![Figure 1. The mathematical tasks framework (adapted from Stein & Smith, 1998)](image)
More recent work in mathematics education has brought to the foreground the sociocultural aspects of mathematics teaching and learning. This view implies that mathematical task enactments involve not only students’ cognitive processes but also their participation in the activities and discourses of mathematics (Chapman, 2003; O’Connor, 2001; Otten & Herbel-Eisenmann, 2009). The current study views task enactments through the lens of classroom activity structures for the purpose of examining the alignment between the existing mathematical tasks framework and the nature of the classroom activity. In particular, I examine middle school level task enactments, as did the framework developers, and argue that this activity lens reveals a distinct phase of task enactments—the task conclusion—that has thus far been unrecognized by the framework. As is shown below, this conclusion phase is significant from an activity perspective but also has implications with respect to trajectories of cognitive demand. Thus a revised framework is proposed.

**Theoretical Perspective**

Within the broad realm of sociocultural theory, I employed Halliday’s (Halliday & Matthiessen, 2003) theory of systemic functional linguistics (SFL) to examine discourse practices in middle school mathematics classrooms. SFL recognizes three metafunctions of language—ideational, interpersonal, and textual. Language is used to make sense of experience and in so doing serves the ideational metafunction; that is, it provides cues and clues regarding the meaning of what is being talked about. Language is also a means for acting out the social relationships of those who are using the language, thus serving the interpersonal metafunction. The textual metafunction refers to aspects of the organization of the language itself. Any use of language involves all three metafunctions, though not always to the same degree.

Within SFL, language is viewed as a system in which various sets of options exist with different meaning-making potentials. When someone is producing a text—written, verbal, or otherwise—they make many (possibly unconscious) choices about their language use, each of which influences subsequent choices and the potential ways in which the text will be construed. This language-in-use simultaneously shapes and is shaped by the context of the interaction. For example, a teacher closing the door and addressing the class in a full voice is serving the textual metafunction of marking the beginning of a lesson, but the local context (e.g., the bell ringing, students taking their seats and expecting a lesson to begin) are simultaneously influencing the teacher’s discourse. This is closely related to Lemke’s (1990) discussion of activity structures:

[A classroom lesson] has a pattern of organization, a structure… In real life you never know for sure what is coming next, but if you can recognize that you are in the midst of a patterned, organized kind of social activity, like a lesson, you know the probabilities for what is likely to come next. (pp. 2–3)

Thus the various language options noted by SFL are restricted in a patterned way when the language is occurring within an activity structure such as lecture, going over homework, or small-group work. Furthermore, activity structures can be recognized by analyzing discursive cues and their textual functions marking the activity structure.

**Method**

Data for the present study consisted of task enactments drawn from a larger project involving eight middle grades (6–10) mathematics teachers engaged in literature study groups and cycles.
of action research around classroom discourse. The videotaped class periods in which these task enactments occurred come from the baseline year of the larger project, before any interventions with the teachers had taken place. The present study is focused on the middle-school level, so two of the eight teachers were excluded because they taught high-school content. This left 84 classroom observations from six middle school mathematics teachers as the full corpus for the present study. (Note that there were less mathematical task enactments than class periods because many tasks continued over multiple class periods, and I excluded any tasks whose enactments were not entirely captured within the observed class periods.)

I reviewed all transcripts and watched video clips from the 84 selected observations. I took notes on discursive markings of the task phases (e.g., “teacher addresses class from the front of the room”), general features of the classroom events (e.g., "students worked in pairs on a handout for 20 minutes"), mathematical content of the tasks (e.g., "area of triangles"), and general impressions of what I perceived to be the task conclusion (e.g., "short conclusion with the teacher emphasizing main points"). Using these notes, I then selected four tasks to undergo detailed analysis. The selections were made based on several criteria (i.e., varied teachers, varied mathematical content, varied curriculum materials, varied features of the task conclusion), all intended to lead to a variety of task conclusions in the detailed analysis phase.

The four selected task enactments were analyzed using three different tools from SFL. First, discourse markers and their textual functions were coded with respect to the activity structures of the task enactment. This analysis is the centerpiece of the current study, which focuses on the alignment between the activity structures and the original enactment phases. Second, lexical chains (Christie, 2002) were created to map the semantic progressions of the task conclusions. Third, various linguistic analyses (e.g., theme analysis, amplification analysis, agency analysis; Martin, 2009) were performed with each of the four task conclusions to better understand their discursive nature. These latter analyses are only peripherally reported on here.

**Results**

Within the full corpus of examined task enactments, a strong alignment existed between the set-up phase of the mathematical tasks framework and the activity structure of “setting up” in-class work. This phase was characterized by the teacher addressing the entire class, usually from the front of the room, and directing student attention to the written task (often in a textbook, but also appearing on hand-outs, overhead transparencies, or the board). Examples of teacher talk marking the beginning of this phase are the following: “Take a look at the three triangles on the top of page fifty-eight…”; “OK, the first part of the assignment I’m handing out to you says…”; and “When you get this worksheet, I would expect to see…”. This phase continued with teachers maintaining the floor (Edelsky, 1993) of the interaction as they describe or clarify the written task and communicate what the students will be expected to do. The students during this activity are typically expected to sit quietly, listen, and possibly ask clarifying questions (e.g., “Are we going to turn this in today?”).

There was also a strong alignment between the start of the implementation phase and a shift in activity structure. In particular, the shift from the set-up phase to the implementation phase was cued discursively by the teacher, who indicated that the students should begin working on the task (e.g., “So go ahead and get started”), and by the students, who began working (often after physically rearranging themselves into pairs or small groups). The teacher relinquished the floor and the discourse separated into several smaller interactions (in the case of partner or group work) or relatively few interactions at all (in the case of individual seatwork). Within this activity
structure, the teachers typically circulated the room, listening and observing students as they worked and also talking quietly with students if they had questions or if the teacher had a question for them. Students were expected to be actively engaging with the task and, when appropriate, interacting with one another around the mathematical ideas.

These results show that, as was expected, the set-up phase of the mathematical tasks framework is strongly aligned with the classroom activity structure at that point in the task enactment. Moreover, the beginning of the implementation phase corresponds with a marked shift in activity structure. Further analysis reveals, however, that an additional activity structure shift takes place later in the task enactment that does not correspond with a phase of the mathematical tasks framework. Specifically, an activity structure that may be described as a conclusion phase of the task enactment occurred throughout the corpus. I now turn to the results regarding this phase, first describing general trends before turning to the detailed findings of the four selected task enactments.

The beginning of a task conclusion is generally marked by the teacher’s reclamation of the floor. Physically, teachers who have been circulating the room or working at their desk return to the front of the room. They also may turn on the overhead projector or write something on the board, drawing student attention from their own work back to the front of the room. Discursively, teachers raise their voice and address the entire class, typically communicating that work time on the task is complete, either explicitly (e.g., “OK, it’s almost time to go, so please pass your papers to the left”) or implicitly by indicating that something else is about to happen (e.g., “We’re going to go over a few of them now”). The activity structure is teacher-led (though students may be called on to give extended explanations) but is distinct from the activity of the set-up phase since students are expected to answer questions, share solutions, or ask questions about mathematical ideas (rather than just about classroom procedures or task expectations).

The functions of the task conclusion and the relationship of the conclusion to the written task are also distinct from both the set-up phase and the implementation phase. The full corpus examination revealed that, within the conclusion activity structure, many different instructional functions existed. In many task conclusions, the teacher presented the answers to the written task, either verbally or on the board, and solicited questions from the students over any part that was not clear. Alternatively, teachers called on students to present their answers. In addition to this answer-presenting function, task conclusions often involved the sharing of various solutions. In some cases, this activity went beyond mere sharing into comparing or connecting different strategies. The task conclusion was also a place where the teachers highlighted or summarized main ideas and possibly asked students to reflect back on their work. There were instances of teachers prompting for generalizations of the solution strategies and of teachers using the task conclusion as an opportunity to practice previously developed skills. In a small number of cases, the task conclusion was the site of concept formalization or mathematical conjecture. In other cases (typically at the end of a class period), the task conclusion was brief, consisting only of the teacher asking the students to write their name on their work and “pass it forward.”

This overview of functions of the conclusion phase points to differing relationships between the enactment phases and the written task. In the set-up phase, the teacher is typically clarifying the written task and describing what the students are expected to do in the implementation phase. In other words, the set-up phase consists of talk about what will be happening in the implementation phase. In the implementation phase, the students are actually working on the mathematical task, that is, the work is happening. In the conclusion phase, the teacher is typically leading the class in a consideration of what happened during the implementation phase.

There were cases of students continuing to work solving the written task during the conclusion phase, but generally such activity ceased in favor of sharing, reflecting on, comparing, or connecting solutions.

To provide more insight into the nature of task conclusions, I now turn to a more detailed examination of four task enactments. I focus elsewhere (Otten, 2010) on the mathematical and discursive functions and content of these four enactments, but focus here particularly on the discursive evidence with respect to activity structure pointing to the separability of the task conclusion as a phase.

Mr. Nicks, an eighth grade teacher in an urban school district, enacted a task over the course of two class periods involving the determination of perimeters and areas of various polygons. The set-up phase and implementation phase occurred on the first day of the task enactment. The following day of class began with Mr. Nicks asking five students to write on the front blackboard their work for one of the task items each. Thus the students were no longer working to solve the task items but were beginning the task conclusion. After the students at the board had finished writing and everyone had taken their seats, Mr. Nicks addressed the class, “So you should have a pen out; you should have that green worksheet out.” Mr. Nicks then called out item numbers (e.g., “Number one. Number one comes out to be…” ) to focus the students’ attention as they went over the handout. When Mr. Nicks arrived at items that had been written on the board, he explained the solutions, gesturing to the student work, and asked for any questions from the class. The activity structure of this conclusion phase was distinct from the implementation phase in that Mr. Nicks took a leading role from the front of the classroom and the students were expected to be sitting quietly, unless called upon, with their desks arranged in separate rows rather than together in pairs. The task conclusion lasted approximately 20 minutes and 30 seconds, slightly longer than the set up phase and implementation phase combined (or 53% of the entire enacted task). The conclusion phase ended when the students passed in their work and Mr. Nicks asked them to open their textbooks to a new section.

Ms. Doss, a sixth grade teacher in a rural school district using a reform textbook series, enacted a task over the course of three class periods involving the use of fraction strips to determine the filled portions of fundraising thermometers. On the first day, Ms. Doss set up the task and had the students work on it, and on the second day she reprised her set-up and had the students continue to work. Ms. Doss then used the entirety of the third day for the task conclusion. She began the task conclusion by addressing the class, “OK, then get out problem one-point-three from yesterday. (…) You should have problem one-point-three out, ready to go. That’s the one we did with thermometers, OK?” She then said that they would “get started summarizing problem one-point-three.” Ms. Doss continued, “We’re going to work through each of those thermometers.” She then asked for student volunteers to come up to the overhead projector, where the thermometers were displayed, to “explain how they found” the fractions for each thermometer. Ms. Doss pushed not only for the students’ answers but for descriptions of how they arrived at those answered. She also used the task conclusion to emphasize the main ideas of numerators and denominators and what they meant in the context of the task. This conclusion phase was distinct from the implementation phase in that Ms. Doss was positioned near the overhead projector, where the thermometers were displayed, to “explain how they found” the fractions for each thermometer. Ms. Doss pushed not only for the students’ answers but for descriptions of how they arrived at those answered. She also used the task conclusion to emphasize the main ideas of numerators and denominators and what they meant in the context of the task. This conclusion phase lasted approximately 31 minutes, nearly an entire class period (37% of the entire enacted task). The conclusion phase ended when Ms. Doss asked the students to put their work into their mathematics notebook and take out their homework assignment from the previous day.
Mr. Ewing, a sixth grade teacher from an urban school district, enacted a task over the course of two class periods involving the naming and ordering of decimal numbers. The context of the task was that the students were serving as baseball managers in developing a batting order based on fictional players’ statistics. The task conclusion took place during the latter part of the second day of the task enactment. Mr. Ewing, who had been circulating amongst the groups, returned to the front of the room and gathered whole-class attention by asking the students to move their desks back into rows. He said that they would “take some time and talk about our batting orders.” He further signaled the beginning of the conclusion by turning on the overhead projector and displaying a blank transparency. Mr. Ewing proceeded to solicit batting orders from the groups, recording them on the transparency. He then asked the students which players were easiest to place in the order and which portions of the lineup were open to managerial discretion. The task conclusion lasted approximately 12 minutes and 35 seconds (26% of the entire enacted task). The conclusion phase ended when the dismissal tone sounded and Mr. Ewing asked the students to “pass [their] papers up, please.”

Ms. Tibilar, a seventh grade teacher in the same school district as Ms. Doss, enacted a task over the course of two class periods involving the determination of various triangles with the same area. Relative to the previous three cases in this study, the task conclusion in Ms. Tibilar’s case was more difficult to analyze. The difficulty was not because the task conclusion lacked a clear beginning or ending, but because it contained the set-up and implementation of a sub-task within itself and thus had a complex activity structure. During the second day of the task enactment, Ms. Tibilar began the task conclusion by addressing the class from the front of the room, “OK, so what we have to do then is just go ahead and talk about a couple of them on there, and see if everybody’s looks the same or if we’ve got some different ones.” She continued by stating that she did not want to go over every part of the written task, only to “talk about a couple of things that I think are important from it.” Ms. Tibilar then led a whole-class discussion focusing on the students’ work creating different triangles with an area of 15 square centimeters. The relationship between the (fixed) area and the (variable) perimeter was uncovered and explored. This phase was distinct from the implementation phase because the students were no longer actively working on the written task but were instead discussing the work they had done during the previous class period and using it as a basis for making sense of the mathematical ideas of area and perimeter. The task conclusion ended with Ms. Tibilar evaluating the discussion (“Absolutely amazing discussion”) and directing the students to place their written work in their journals. The task conclusion lasted approximately 60 minutes and 25 seconds (78% of the entire enacted task), though approximately 21 minutes of the task conclusion were spent working on a sub-task. (The sub-task was a refinement of the original task that was designed to answer a concern that had arisen in the conclusion discussion. Since it focused on the same mathematical idea as the broader mathematical task and fed back into the original task conclusion, I have characterized it as a sub-task rather than a separate task.)

Discussion

This study examined mathematical task enactments at the middle school level using the sociocultural lens of activity structure (Lemke, 1990) as a means of validating and extending the mathematical tasks framework of Stein and her colleagues (Stein, Grover, & Henningsen, 1996). The set-up phase of task enactments were found to align strongly with a “setting up” activity structure, and the shift to the implementation phase corresponded with a shift in activity structure as the students began working to solve the written task. This analysis revealed, however, an
additional conclusion phase in which the teacher reclaims the discursive floor and leads the class in a “looking back” or “sharing out” of work done during the implementation phase. The phase is also distinguished by its relationship to the task itself which is typically no longer being worked on but instead is being looked back upon, forming a sort of symmetry with the set-up phase wherein the work on the task lies ahead. This identification of the conclusion as a separate phase is corroborated by other research such as that of Shimizu (2006) who found that teachers in countries across the globe engage in the activity of “summing up” the main ideas of their lessons or connecting between mathematical concepts, utilizing public talk for this activity. (It should be noted that Shimizu’s work is on the lesson-level rather than the task-level and does not connect to the mathematical tasks framework.) Figure 2 presents the revised mathematical tasks framework, including the conclusion phase.

![Figure 2. The mathematical tasks framework with a conclusion phase](image)

Although it is clear from an activity structure perspective that the task conclusion is distinct from the implementation, the question remains of whether it is necessary to make this distinction with respect to cognition. I argue that the inclusion of the conclusion phase in the framework will also add value in this respect for at least two reasons. First, the original mathematical tasks framework was deeply concerned with both the thinking processes that the students engaged in and the ways in which those processes characterized the students’ mathematical experiences. As noted by Henningsen and Stein (1997), “the nature of tasks can potentially influence and structure the way students think and can serve to limit or broaden their views of the subject matter with which they are engaged” (p. 525). Thus we must consider not only the processes themselves but how the students’ interpret and reflect upon those processes, forming a notion of what it means to “do mathematics.” It is reasonable to suppose that reflection and characterization of the thinking processes from the implementation phase takes place during the conclusion phase, perhaps not exclusively, but substantially nonetheless.

Second, though space did not allow me to report it here, there were instances in this data corpus of what seemed to the level of cognitive demand shifting in the conclusion phase. For instance, Mr. Ewing’s task enactment mentioned above involved procedures-without-connections during its implementation but descended into nonmathematical activity in the task conclusion as the baseball context became the sole focus rather than the decimal numbers (Otten, 2010). In another task conclusion, the level of cognitive demand could be argued to have descended from procedures-with-connections to procedures-without-connections as the teacher used the conclusion to emphasize only the answers rather than the variety of solution strategies. Alternatively, cognitive demand may increase during the conclusion phase. Another task enactment examined from this data corpus exhibited an implementation phase that seemed to be at the procedures-without-connections level but a conclusion phase that consisted of a rich discussion increasing the cognitive demand to procedures-with-connections. Furthermore, although I did not see it in the course of this study, it is conceivable that a task set-up and

---

implemented at the unsystematic exploration or procedures-without-connections level of cognitive demand could be modified by a masterful teacher into the doing-mathematics level as the students use their previous work as a basis for conjecturing or generalization in the conclusion phase. Therefore, since one of the primary benefits of the mathematical tasks framework is its capacity to illuminate cognitive demand trajectories, it seems that a fuller understanding of these trajectories would be possible by considering task enactments through to their conclusions.

Endnote
This data was collected as part of an NSF grant (#0347906; Herbel-Eisenmann, PI) focusing on mathematics classroom discourse. Any findings or recommendations expressed in this article are those of the author and do not necessarily reflect the views of NSF. I thank Beth Herbel-Eisenmann and the teachers, without whom this study would not have been possible.

The traditional curricular materials and pedagogical strategies have not been effective in developing conceptual understanding of statistics topics and statistical reasoning abilities of students. The statistics education reform movement has placed an emphasis on helping students develop conceptual understanding rather than a focus on mechanical calculations. This study investigated the conceptual understanding of measures of spread in an introductory statistics course centered on deemphasizing computational skills and focused rather on development of conceptual understanding. Open ended questions were developed to assess students’ conceptual understanding. A detailed analysis of the students’ responses is presented to reveal the range of students’ conceptions.

Introduction

The wide spread consensus among statistics educators and statisticians has been that the traditional curricular materials and pedagogical strategies used in introductory statistics courses have not been effective in developing conceptual understanding of statistics topics and statistical reasoning abilities of students. Much of the changes proposed by statistics education research and the reform movement over the past decade have supported efforts to transform teaching practices to include an emphasis on students’ development of conceptual understanding rather than a focus on mechanical calculations (Chance & Garfield, 2002).

In recent years, major research interest in the statistical understanding of students seemed to be focused on the measures of centers in distributions (Shaughnessy & Ciancetta, 2002). This research study was partially motivated by the future research suggestion made by Watson et al. (2003) to investigate older students’ understanding of spread. Even though there are investigative research studies available on the understanding of variation among university students in the United States by Meletiou & Lee (2002) and in Mexico by Sanches & Mercado (2006), these type of studies are considered to be very limited (Inzuna, 2006). Despite some very recent research studies investigating conceptual understanding of variability among community college students in an introductory statistics course, there are still a lot of unanswered questions regarding how we, as statistics educators, can help students develop conceptual understanding of measures of spread at community college level (Budé, 2007; Slauson, 2008). The purpose of this paper is to investigate students’ conceptual understanding of measures of spread and provide learning experiences and environments to support students in developing conceptual understandings of measures of spread.

Theoretical Framework

The guiding theory for statistics education reform is based on a learning theory arising from earlier ideas and writings of Jean Piaget on cognitive development and is referred to as constructivism (Wheatley, 1990; Garfield, 1995; Von Glasersfeld, 1995). The basic tenets of constructivism which view learning as an active process and learners as cognitively active human agents who construct their knowledge through interaction with the environment are in
stark contrast with and pose a strong challenge to the earlier conceptions of learners as passive beings whose empty minds are to be filled with information transmitted directly from and controlled by a central knower. Constructivism along with a Vygotskian perspective which takes into account social interactions and historical or cultural influences on learning have become the guiding theory for reform efforts and much research in mathematics, science, and statistics education, as well as for this study (Gordon, 1995).

The changes proposed by statistics education researchers to reform introductory statistics education can be gathered in the following four categories: changes related to content, pedagogy, technology, and assessment. The traditional content and approach to teaching statistics as a sequence of linearly and hierarchically ordered disjoint topics padded with a series of techniques is being challenged widely in the literature. Meletiou-Mavrotheris & Lee (2002) stated that presenting statistical content as a linear hierarchically ordered list of topics might lead students to view statistics as a collection of fragmented formulae and procedures taught in isolation without any interconnectedness established among the various topics. This fragmented view of statistics, created and promoted in a large part by the traditional content and approaches, tends to impress upon our students an image of statistics as a collection of specific, factual and behavioral objectives (Begg, 2004).

The changes proposed by statistics education researchers to reform introductory statistics education can be gathered in the following four categories: changes related to content, pedagogy, technology, and assessment. The traditional content and approach to teaching statistics as a sequence of linearly and hierarchically ordered disjoint topics padded with a series of techniques is being challenged widely in the literature. Meletiou-Mavrotheris & Lee (2002) stated that presenting statistical content as a linear hierarchically ordered list of topics might lead students to view statistics as a collection of fragmented formulae and procedures taught in isolation without any interconnectedness established among the various topics. This fragmented view of statistics, created and promoted in a large part by the traditional content and approaches, tends to impress upon our students an image of statistics as a collection of specific, factual and behavioral objectives (Begg, 2004).

The content related changes, which were suggested by the joint curriculum committee of the ASA and the MAA, and approved by the ASA, advocated exploring and producing data, and statistical concepts (Cobb, 1992; Moore, 1997). Since introductory statistics courses are the first, and only course for many students especially at community college level, these courses should offer opportunities for students to work with real, not just realistic, data arising from real problem settings. Interpretations of graphics, developing strategies for explorations of data, and informal inference need to be brought to the forefront of the course.

The traditional pedagogy used in teaching introductory statistics courses is, to a large extent, based on the lecture-and-listen model. We, as educators, need to remember that “we overvalue lectures” (Moore, 1997, p.125). The most common factor among pedagogical changes suggested is a move away from the traditional lecture-and-listen model toward activity-based courses which promote and support active participation, and interaction among all participants. Garfield (1993) argued that since small group cooperative learning activities might be designed specifically to allow students opportunities to actively and individually construct their own knowledge, as opposed to copying down knowledge transmitted, the use of small group activities was aligned with the constructivist theory of learning.

Among the several forms of technology related changes to support the development of conceptual understanding and reasoning abilities of students are the use of computers, graphing calculators, Internet, statistical software packages and Java applets. Using computers or calculators merely to generate statistics, to follow algorithms or to produce graphs of data are very limited views of technology use in statistics education reform. Technology use in that sense becomes a tool for doing statistics not a tool for learning statistics (Moore, 1997; Meletiou-Mavrotheris, Lee, and Fouladi, 2007).

Using technology to help students visualize concepts and understand abstract ideas is considered to be far more important than using technology solely to automate messy statistical computations (Garfield & Ben-Zvi, 2009). Technological tools such as simulations and applets have become increasingly common in introductory statistics courses to illustrate abstract concepts, simulate data, and build understanding of statistical concepts (Zieffler & Garfield, 2007; Chance & Rossman, 2006). The applets have been gaining an increasing importance

---

because of their effectiveness in illustrating various statistical concepts visually (Glencross, 1988; Chance & Rossman, 2001; Chance & Rossman, 2006). However, while software may provide the means for a rich classroom experience, computer simulations alone does not guarantee conceptual change. delMas et al. (1999) made a strong case for using technology with simulations in a predict-and-test environment to create cognitive dissonance in developing students’ understanding of sampling distributions.

The conceptual change theory had been used previously in the field of science education and is being used lately by other researchers in social studies education (Posner, Strike, Hewson, and Gertzog, 1982; Houser, Parker, Rose, and Goodnight, in review). According to the conceptual change theory of learning, students who have preconceptions need to experience an anomaly to create cognitive dissonance between their preconceptions or predictions and observed outcomes.

The traditional method of assessing student learning consists of module tests, generally with multiple-choice questions, designed for ease of grading. The traditional exam questions place a strong emphasis on the procedural or computational aspects of statistics and do not evaluate high-level cognitive and conceptual understandings of students (Cobb, 1993; Garfield, 1994; Zieffler et al., 2008). The connection of the traditional testing methods to the actual statistical practice is an unexamined assumption. The efforts of statistics education reform in assessment, which is sometimes referred to as “authentic assessment”, starts with challenging and questioning this assumption. The statistical education reform efforts have responded to this challenge and critically evaluated the traditional testing methods to offer some alternative forms of assessing students’ statistical reasoning and conceptual understandings (Garfield, 1994; Gal & Garfield, 1997; Chance, 1997; Garfield & Gal, 1999). The traditional dichotomous relationship of teaching and assessment is considered to be too narrow and too specific to provide useful information about student learning (Garfield & Gal, 1999).

The GAISE recommendations indicate that an emerging view of assessment, as an ongoing evaluation of students’ learning over the course of the semester with constant gathering of information and providing feedback, can be very valuable in informing our teaching. Among some of the alternative forms of assessment were cooperative group activities, computer lab exercises, portfolios, projects/reports, presentations, essay questions, journal entries, and open-ended writing assignments (Garfield, 1994; Chance, 1997).

Methodology

There were no general hypotheses tested in this research study. Thus, the study was primarily exploratory and qualitative in nature. A questionnaire format was developed as the main data gathering technique. The subjects of the study were community college students enrolled in two different sections of an introductory statistics course taught by one of the authors. The course required a TI-83/TI-84 graphing calculator and was taught with a teaching philosophy centered on deemphasizing manual computational skills but focused rather on conceptual understandings throughout the course. A total of 41 students, from two sections of the course, participated in the study. This particular study analyzed the responses of students and reports the results from only one of those sections. The study was, therefore, based on a final set of 20 subjects consisting of 11 female and 9 male students. The student participant group was comprised primarily of business majors with only a few students declaring mathematics as their major. Only a few student participants had studied mathematics at the pre-calculus or higher level.

An open-ended questionnaire, developed as a research instrument as well as an assessment tool, was administered after the descriptive statistics portion of the course. There were no
penalties for giving wrong responses. All the students present in class on the day of administration of the questionnaire chose to participate. The students were issued a 30 minute time limit to respond to the items on the questionnaire. Some of the items of the questionnaire were designed by one of the authors specifically for this research project. Some others were adapted and modified slightly from previous research studies such as Meletiou & Lee (2002), Inzuna (2006), and Delmas & Liu (2005).

**Results**

A simplified version of the coding scheme based on the research of Watson, Kelly, Callingham & Shaughnessy (2003) was devised to conduct an analysis of data collected. The data were coded according to the degree of mathematical and statistical correctness of the response and/or appropriateness of rationale expressed. Initially a number of different categories of responses were assigned for the data generated from each questionnaire item. Based on further analysis, common characteristics among categories were identified resulting in a consolidation of categories into fewer and more general categories of responses.

Items 7 and 8 were designed to determine if the students had an understanding of the relationship between the size of the standard deviation and the size of the spread that the data points have around the mean. The data resulting from Item 7, for example, was initially coded as five distinct categories of responses. These five initial categories were consolidated into the following more general categories: (i) appropriate responses, correct answer and appropriate rationale, such as 0, 0, 10, 10; I get the largest standard deviation because these are spread out the furthest, (ii) inappropriate responses, including no response and no rationale, wrong answer and no rationale, and misinterpretation of question, such as 0010, 0009; no rationale; and (iii) semi-appropriate response, correct answer and inappropriate or invalid rationale. An appropriate response was coded as 2 (60% of responses), a semi-appropriate response was coded as 1 (35% of responses), and an inappropriate response was coded as 0 (5% of responses).

For Item 8, initial six distinct categories of responses were consolidated into the following more general categories: (i) appropriate responses, correct answer and appropriate rationale, such as 1, 1, 1, 1; these numbers allow for the smallest standard deviation because they are closest to the midpoint, (ii) inappropriate responses, including no response and no rationale, wrong answer and no rationale, or wrong answer and inappropriate rationale, such as 0, 1, 1, 1; lower the numbers are the lower the standard deviation; and (iii) semi-appropriate response, correct answer and inappropriate, invalid or rote memorization rationale, such as 1, 1, 1, 1; when all the numbers are the same the standard deviation is 0. An appropriate response was coded as 2 (20% of responses), a semi-appropriate response was coded as 1 (50% of responses), and an inappropriate response was coded as 0 (30% of responses).

<tr>
<td>8</td>
<td>30%</td>
<td>50%</td>
<td>20%</td>
</tr>
</tbody>
</table>

As one can observe from Table 1, the percentage of appropriate responses, which was coded as 2, was drastically reduced for Item 8. The reason for this decline was attributed to the fact that...
there were seven responses with a correct answer and rote memorization rationale, such as *when all the numbers are the same the standard deviation is 0*, and these responses were coded as 1.

Items 1 and 2 explored the students’ understanding of spread shown in a pair of box plots in each item. The coding for data resultant from Items 1 and 2 initially produced several categories of responses which were then generalized into the following two categories: (i) appropriate responses, correct answer with or without appropriate rationale; and (ii) inappropriate responses, including wrong answer, no response, no rationale, and misinterpretation of question. An appropriate response was coded as 1 and an inappropriate response was coded as 0.

As one can observe from Table 2, the percentage of appropriate responses, which was coded as 1, was somewhat reduced in Item 2.

<td>1</td>
<td>0%</td>
<td>100%</td>
</tr>
<tr>
<td>2</td>
<td>15%</td>
<td>85%</td>
</tr>
</tbody>
</table>

The reason for this decline was attributed to the fact that the second box plot in Item 2 was created based on a data set in which the maximum and the third quartile were the same numeric value. This fact caused some confusion among students, such as “does not have both tails”, “unspecified maximum”, and “it is from 3 to ∞.” Prompted by this confusion, a further analysis of the given rationales for Items 1 and 2 was performed. Based on the nature of the rationales, there were four types of rationales identified: (i) a numerical rationale, such as “spread min to max or the difference between the max and min”, (ii) a graphical rationale, such as “tails extending longer”, iii) a combination of both numerical and graphical rationales; and (iv) idiosyncratic or unclear comments, such as “larger the median is more spread”, “don’t know what the spread is because does not have both tails”, “starts at 3 but has no stem”, “second box plot from 1 to an unspecified max”, “bottom one is not even on the graph”, and “bottom one is missing a whisker.” Table 3 shows the resultant summary of the analysis of rationales given by the students for Items 1 and 2.

Conclusions

This study investigated a group of community college students’ understanding of spread in a descriptive statistics setting. Although the conclusions from the study are based on a single, small group of students, the study revealed some possible common student preconceptions which should be examined closely and taken into consideration in order to promote students’ development of understanding of the concept of statistical measures of spread.

In general, the results of the analysis of student responses, which included a wide variety of rationales, justifications, and strategies, provided evidence for the students’ ability to organize concepts of spread in a way that is meaningful to them individually. It is also further evidenced by the students’ responses that despite the fact that students are taking the same course, from the same instructor using the same textbook, they do build different understandings. These findings support the need to provide environments rich in opportunities for student to construct their own understandings. Teaching methodologies more open to problem solving and supporting student construction of knowledge should be used in the teaching of statistics.

The students’ responses to Items 1 and 2 were encouraging in that the students were able to demonstrate a good grasp of spread based on box plots. Only a few (three students or 15%) students showed some preconceptions which were not aligned with the generally accepted conception when one of the data sets had the same numeric value for the third quartile and the maximum.

The students’ responses to Items 7 and 8 were not greatly encouraging in that the students mostly were unable to demonstrate an understanding of the association between the size of the standard deviation and the size of the spread that the data points should have around the mean. Mostly students were able to produce the valid arguments for their conclusions, but provided only a rote memorization rationale, such as “when all the numbers are the same the standard deviation is 0.”

As evidenced in the literature, there seems to be a great research potential in investigating how the students’ understandings of graphical representations develop. There is also a need for research on how students can be helped to improve their ability to recognize the difference between what the horizontal and/or vertical axes represent in a variety of different graphical representations, such as histograms, box plots, stemplots, and scatterplots.

A much more detailed and deeper analysis of the results from a much larger group of students could be performed using Structured Observed Learning Outcome (SOLO) Taxonomy in conjunction with a Rasch Item Response Model analysis as implemented by Watson, Kelly, Callingham & Shaughnessy (2003) to produce a variable map of student performance and item difficulty on a single scale. It is also possible to conduct in-depth, follow-up interviews of a subset of participating students. The subset of students may be identified based on either extremely weak or extremely strong reasoning abilities exhibited in the written responses to the survey.

INVESTIGATING SECONDARY STUDENTS’ EXPERIENCES OF STATISTICS

Kimberly Gardner
Kennesaw State University
kgardne9@kennesaw.edu

Data analysis, probability, and statistics have received increased emphasis in school curriculum. While much attention has been given to teaching and learning statistics at elementary and undergraduate levels, very little research has focused on secondary learners. The research discussed in this report investigates the association between secondary students’ definitions of learning and their conceptions of statistics. Using the phenomenographic approach, students in college preparatory introductory statistics courses were interviewed and observed. The findings show a hierarchical relationship between the meaning assigned and methods used by the students to acquire knowledge about statistics.

Introduction

Data analysis, probability and statistics have been researched mainly in the areas of elementary, undergraduate, and graduate levels (Groth, 2003; Watson & Callingham, 2003). The statistics literature on secondary learners has not extensively analyzed how these students tend to process and acquire meaning about the subject. Since data analysis and probability have been an integral part of the elementary curriculum, as put forth by guidelines from National Council of Teachers of Mathematics (NCTM) and the American Statistical Association, students enter high school with prior knowledge, past experiences, preformed attitudes, and beliefs that influence how they learn and what they learn (Gal & Ginsburg, 1994). With these countless variations among learners, it is unrealistic to assume that all students will understand course content in the same way, even if they tend to answer questions correctly and solve problems successfully.

We can infer that students exposed to the same instruction process the content differently, and hence they experience each course of study differently (Marton & Pang, 1999). Allowing secondary students in a college preparatory statistics course to describe their experience of learning renders some explanation as to how they assemble prior knowledge, past experiences, attitudes, and beliefs in order to develop an understanding of what is taught in regards to data analysis, statistics and probability. By investigating the role of human experience in knowledge acquisition, a collection of each person’s descriptive account of their experiences is formulated using phenomenographic methodologies. Phenomenography aims to explore how people learn and why some people learn particular subjects or domains better than others. Therefore, the objectives of the study were to: 1) categorize the various ways secondary students define statistics, 2) categorize the various ways secondary students define learning or knowledge acquisition, and 3) investigate the relationship between the students’ definition of learning and the meaning they assigned to statistics.

Theoretical Framework

The theoretical framework for the study is phenomenography, which is sometimes confused for phenomenology. Although both share the same object of research, which is human experience, they have distinct differences. Phenomenology aims to develop a single theory from the researcher’s perspective of the world based on his/her experiences. In contrast, phenomenography focuses on the perspective of others to devise a collection of categories that

---

constitute the variations in experiencing the world (Marton & Booth, 1997). The learner-
phenomenon relationship is examined to determine the process of conceptualization, but learning
is not considered to be a mental representation nor a cognitive structure (Andretta, 2007; Uljens,
1996). Instead, learning is defined as perceiving something in a new way by discerning it from
and relating it to a context (Marton & Pang, 1999; Pramling, 1996).

In addressing the question, “why do some people learn things better than others”, Marton
(1986) conducted a study on the different ways learners understood a passage of text. Based on
analyses of the learning processes used by the students, two approaches emerged: deep and
surface learning. In work by Marton and Booth (1997), deep and surface learning are defined. A
surface approach to learning is when the student's overall strategy for learning merely focuses
their attention on signs or prompts during instruction to gauge or elicit a reaction. In contrast, a
deep approach to learning is when the student moves far beyond the surface level approach to
more interpretive, comprehensive learning processes. Marton (1986) concluded that learning,
from the phenomenographic perspective, involves experiencing both the content to be learned
(referred to as “what”) and the act of learning (referred to as “how”). The “what” and “how”
aspects of learning frame the study’s focus on investigating what statistics is (content) and how
one goes about learning it (act).

The “what” aspect of learning involves assigning meaning to the content, and discerning the
interrelationships between parts of the content in how they structure the whole (Marton & Booth,
1997; Uljens, 1996). The statistics content used in the study is drawn from school curriculum
developed using the Guidelines for Assessment and Instruction in Statistics Education (GAISE,
2005), and the NCTM (2000) Data Analysis and Probability Standards. The “how” aspect of
learning has two parts: (a) the capabilities or skills the learner seeks to obtain, and (b) the
approaches used to acquire knowledge about the content (Marton & Booth, 1997). The NCTM
(2000) Process Standards, along with assessment and technology use recommendations for
statistics education (Garfield & Chance, 2000; Vellemen & Moore, 1996) were incorporated into
the statistics courses the participants took at the secondary school.

The outcome space of a phenomenographic investigation is a collective categorization of the
“what” and “how” aspects of learning. Arranged in a hierarchical structure, the outcome space
diagrams the logical link between variations in the meaning of the phenomenon and how
knowledge is attained about the phenomenon. According to Runensson and Marton (2002), even
though there are infinitely many ways to describe something, the outcome space relevantly
accounts for differences in student achievement, by uncovering conditions that facilitate the
transition from one way of thinking to a different way of thinking. By encouraging students to
vary the perceptions, approaches, and skills they use to learn will increase the observable
dimensions of the outcome space (Marton, 1986). The outcome space that emerged from the
data collected for the study constitutes the range of variation described by the participants. By
replicating the study, it is conceivable that more categories would arise.

**Methodology**

The study was conducted at a suburban secondary school in the southeastern United States.
The nine participants were recent graduates from the school who had taken an introductory
statistics course during either their junior or senior year. Data collection efforts focused on
methods that got students to reflect upon and explicitly describe their experience of learning
statistics. A questionnaire was disseminated to collect demographic information. A sixty
minute semi-structured interview with each participant was audio-recorded and transcribed. 
American Chapter of the International Group for the Psychology of Mathematics Education. Columbus, OH: The
Ohio State University.
range of questions were asked with regards to perceptions of statistics, perceptions of learning, and reflections on the experience of learning statistics. The participants also kept a two week journal in which they were asked to solve and reflect upon tasks completed in the class they took that covered data display and analysis, probability, and inference. The interviews and reflection journals represent information rich cases, in which selective quotes meeting the criteria of relevance were coded using processes adapted from phenomenography (Bowden, 1996; Marton & Booth, 1997). This iterative process continued through the deduction of meaning about the phenomenon, and was concluded when the narrowed categories of description were deemed relatively stable. Trustworthiness of data was achieved using four criteria: credibility, transferability, dependability, and confirmability. To ensure credibility, triangulation in data collection, prolonged engagement with participants and member checking were used. Thick, rich description was used to convey findings, ensuring transferability. An audit trail and securing records from the study ensured dependability and confirmability.

Results

The first objective of the study was to categorize the different ways students define statistics (“what” aspect of learning). Four definitions of statistics emerged from the group, as illustrated in Table 1.

<table>
<thead>
<tr>
<th>Experienced as:</th>
<th>Discerned attributes:</th>
<th>Statistics is:</th>
<th>Sample Quotes</th>

</thead>
<tbody>
<tr>
<td>Facts/Algorithms</td>
<td>Maintaining basic mathematics skills</td>
<td>A course focused on stating terms, evaluating expressions, solving equations, and graphing.</td>
<td>Andrew: A graphical and numerical way to represent numbers. Just like any other math[ematics] class, you basically deal with equations and graphs.</td>
</tr>
<tr>
<td>Concepts About/ Procedures for Handling Data</td>
<td>Techniques for collecting, representing, and analyzing data</td>
<td>The use of established procedures to collect and interpret data.</td>
<td>Mary: The process of gathering information on a specific topic and looking at the possible outcomes.</td>
</tr>
<tr>
<td>Inference / Prediction</td>
<td>Processes for making estimates.</td>
<td>The use of procedures to generalize or predict attributes of populations.</td>
<td>Rebecca: Statistics [are] a group of data that is gathered, combined, and analyzed in such a way that it can objectively represent the aspects of a particular population.</td>
</tr>
<tr>
<td>Restructure Knowledge/ Seek Meaning / Inform Decisions</td>
<td>Acquiring knowledge to improve quality of life, and to monitor ethical practices of research.</td>
<td>A set of norms for quality research and a set of evolving rules to inform decision making; a change agent.</td>
<td>Sally: I define statistics as the discipline of interpreting data and determining its relevance to our lives. People do studies to find out about our world, and statistics helps make sure that the studies are accurate.</td>
</tr>
</tbody>
</table>

The first column lists the ascending categories of description based on the quality and complexity. Structural aspects of statistics the students tended to focus on are presented in the column entitled Discerned Attributes. In relating the discerned attributes to a holistic view, the
meaning students assigned to the content is shown in the *Statistics is* column. The *Sample Quotes* column contains actual statements, selected from several that conveyed similar conceptions, and were used to code and describe the category. The rows of the table summarize the category. The first row, for example, should be read as follows: students experiencing statistics as *Facts/Algorithms* tended to focus on maintaining basic mathematics skills, and they viewed statistics as a course in which one states theorems, evaluates expressions, solves equations, and makes graphs.

### Table 2. Ways of Learning: Skills or Capabilities Sought

<tr>
<td>Recall information and duplicate procedures</td>
<td>Information or tasks regarded as important to instructor</td>
<td>State terms and perform simple routine task.</td>
<td>Aimee: If you know statistics you can read and understand the terms on a pretty basic level...and like if you have a school assignment that involves statistics you remember the steps and equations and how to do surveys.</td>
</tr>
<tr>
<td>Understand information and procedures</td>
<td>Finding connections among course objectives</td>
<td>Establish relationships among course objectives to assign meaning to concepts and to develop an understanding of how and why routine tasks are performed.</td>
<td>Cara: …when I fully understand how the conclusion was brought about and can reproduce the techniques used… I know I paid attention to it and…can re-use the methods to understand how they are used.</td>
</tr>
<tr>
<td>Teach / Explain</td>
<td>Being able to collaborate with others validate conjectures and self regulate.</td>
<td>Communicate understanding by teaching or explaining the concepts to someone else.</td>
<td>Sarah: …when I can fully explain it and teach it to somebody without looking at my notes… I don’t have to look at my notes and I can answer their questions or show them how to do problems.</td>
</tr>
<tr>
<td>Apply, relate and integrate information and procedures</td>
<td>Reflecting on how concepts of statistics have been encountered or how the concepts can be applied to objects of interest to validate or restructure understanding</td>
<td>Authenticate concepts of statistics by relating and integrating them with personal interest or real life to refine the existing structure of knowledge.</td>
<td>Angela: …when I can apply it outside of class or the learning experience. If I can use any information I have been taught and apply it to a different situation with some ease or without reviewing, then I know I’ve learned something.</td>
</tr>
<tr>
<td>Adapt and assimilate knowledge about analyzed surroundings</td>
<td>Exploring how concepts of statistics can be applied and adapted to phenomenon encountered in surroundings</td>
<td>Adapt and synthesize concepts of statistics with objects experienced to uncover attributes, see the object in a new way, and formulate theories.</td>
<td>Sheldon: …the most important thing I was taught was to not just accept information and that thought can be applied to whatever I do in the future to make sense of stuff I don't understand.</td>
</tr>
</tbody>
</table>

The second objective of the study was to categorize the various ways students define learning. This was investigated in two ways: 1) defining learning or specifically the skills or capabilities students sought when learning, and 2) identifying approaches to learning. Table 2 shows the qualitatively different ways the participants defined learning in the statistical context. The column headings parallel those described in Table 1. The rows may be interpreted as such:

---

students experiencing learning statistics as *Recalling Information/Duplicating Procedures* tended to focus on informational cues or tasks they perceived important to the instructor, and they sought skills needed to state terms or perform simple routine tasks. The least complex capability sought by students aligns with what Marton (1986) calls surface learning. The more elaborate capabilities require deep learning to be able to adapt and assimilate knowledge after interpreting statistical results.

The second part of the “how” aspect of learning is described in Table 3. The six approaches to learning that emerged depict activities participants engaged in when they wanted or needed to learn concepts for the course. Interpreting the first row of the table, learning about statistics through observation, means to passively receive information about the content by listening to instruction, and by watching or recording classroom events. All of the participants referred to at least two of the approaches to learning in either the interview or reflection journal.

### Table 3. Approaches to Learning: The Act of Learning

<td>Meaningful social interaction, productive collaboration, group learning goals for product construction</td>
<td>Working in collaborative groups to investigate concepts or produce a product of work; assisting and being assisted by peers and teacher.</td>
</tr>
</tbody>
</table>

The final objective of the study was to investigate the learner-phenomenon relationship. In Figure 1, the rows consist of the ways of defining statistics from Table 1, and the columns present the ways of learning statistics from Table 2. The cells within the table cross-reference the number of participants describing their experience by the row and column categories, along with the types of activities they used to learn, as described in Table 3. Referring to the Facts/Algorithm and Recall cells, two participants fell into these categories for meaning of statistics and capabilities sought. Furthermore, both students said they acquired knowledge about statistics through observation and study skills. In cells where there are more than two approaches to learning listed, one or more were indicated by the participants represented in the cell.

**Discussion**

Overall, the four conceptions of statistics that emerged from the study are consistent with findings from similar phenomenographic research. Petocz and Reid (2003) found that statistics majors’ conceptions could be characterized in three ways: a focus on technique, a focus on data,
or a focus on meaning. From research conducted with undergraduate psychology majors in a service learning statistics course, Groth (2004) categorized five conceptions of statistics: no meaning, process or algorithms, mastery of concepts and methods, tools for getting real-life results, and critical thinking. Although the research on secondary students understanding of statistics is not extensive, the findings of the study support the notion that these learners conceptualize statistics in ways similar to undergraduate students.

A 2006 study by Tempelaar investigated the relationship between statistical reasoning ability, personal background, and attitude towards learning. Introductory statistics students who deliberately planned rigorous strategies for learning content developed statistical reasoning abilities significantly faster than students without a plan. In the results illustrated in Figure 1 above, participants seeking skills categorized in lower conceptions of learning statistics (Table 2) expressed the least descriptive definitions (Table 1). Also, students in the upper left region of Figure 1 used fewer strategies for acquiring knowledge compared to students in the lower right region. Both studies suggest that students who take surface level approaches to learning statistics tend to conceptualize the content more restrictively than those taking deep level approaches. By emphasizing students’ responsibility to organize their learning processes so that they include rigorous approaches, better ways of thinking emerge and expand the outcome space.

**Figure 1. Association between the “how” and “what” aspects of learning statistics**

The various forms of assessment (tests, projects, journal writing), the use of technology, and implementing process standards (multiple representation, communication, reasoning, problem-solving) are components of the course the participants took. These strategies were used to encourage variation in perception, approaches and skills, as described by Marton (1986) to inform the hierarchical structure of the outcome space. While the outcome space for the study categorizes the conceptions of nine participants, similar secondary level statistics courses would expectedly observe similar as well as new categorizations. The outcome space may aid educators in developing strategies that foster the transformation from a limited way of thinking about statistical concepts to a more expansive way of thinking. Phenomengraphic research on...
conceptualizing statistics must continue to broadening the dimensions of the outcome space and reveal the dynamics of learning statistics.

THE IMPLEMENTATION OF A DECISION-MAKING CURRICULUM

This paper reports on a preliminary evaluation of the implementation of a new secondary level mathematics curriculum which uses engineering contexts, titled Mathematics for Decision-Making (MDM). Because the MDM curriculum is not NCTM standards-based, the authors established their own expectations for an appropriate learning environment. The research team compared data from classroom observations and teacher feedback forms to discern the level of implementation fidelity among a sample of teachers piloting the curriculum. Of the ten teachers sampled, three teachers’ implementations showed evidence of supporting the authors’ expectations and three teachers showed evidence of opposing them.

Introduction

After the release of the Curriculum and Evaluation Standards for School Mathematics (NCTM, 1989), extensive funding from the National Science Foundation encouraged significant curriculum development in the 1990’s. With the development of these conceptually oriented materials (known as standards-based curricula), researchers, policy makers, administrators, and teachers began asking the question, “Do these new materials work?” (Stein, Remillard, & Smith, 2007). The era of accountability (e.g. No Child Left Behind Act of 2001, 2002) placed further pressure on developers to prove the effectiveness of standards-based curricula. To determine if these standards-based curricula “work”, researchers looked beyond student performance and began to consider the teachers’ level of implementation fidelity (NRC, 2004). That is, researchers began studying teachers’ faithfulness to the curriculum authors’ intents as an important factor in the success of the curricula.

Additionally, most curriculum evaluators depended on the benchmarks of the Principles and Standards for School Mathematics (NCTM, 2000) to assess whether teachers created standards-based learning environments while implementing standards-based curriculum (e.g. Tarr, et al., 2008). If a curriculum was not standards-based, this may not have been the most appropriate guide to measure teachers’ implementation fidelity and success of the materials. In this paper, we discuss the implementation of a non-standards-based curriculum and investigate how closely the teachers’ implementation aligns with the curriculum authors’ intentions. In particular, we will answer the question: how do high school teachers’ implementations of a decision-making curriculum align with the authors’ pedagogical intentions?

The Development and Implementation of a Decision-Making Curriculum

The NSF-funded MINDSET (Mathematics INstruction using Decision Science and Engineering Tools) project is a five-year collaboration between mathematics educators and engineers at North Carolina State University, Wayne State University, and the University of North Carolina at Charlotte (Young, Keene, Norwood, Chelst, Edwards, & Pugalee, 2009). The objective of the MINDSET project is to create, implement, and evaluate a new high school curriculum that integrates mathematics and engineering concepts. The curriculum is intended for high school seniors who have completed two years of algebra and one year of geometry.

The MINDSET course content consists of contextual problems from business as well as from students’ lives that employ multi-step problem-solving tools and result in multiple solutions that require interpretation in the context. The MINDSET curriculum is not specifically based on the *Principles and Standards for School Mathematics* (NCTM, 2000), although its tenets do align in many ways. Instead, the emphasis of the curriculum is for students to make decisions concerning contextual problems using mathematical methods; hence, the curriculum is called “mathematics for decision-making” (MDM). High school teachers in North Carolina and Michigan are currently piloting portions of the draft curriculum. Teachers implement different portions of the MDM curriculum into an existing senior level mathematics course so that the MINDSET project team has a sampling of all materials.

**Implementation Fidelity**

For this paper, fidelity of implementation is defined as the extent to which a teacher implements a curriculum as the author intended, allowing for adaptation, supplementation, and improvisation by the teacher (Dietz & Holstein, 2009). As mentioned above, the goal of similar previous research was to investigate the implementation fidelity of standards-based curricula (e.g. Lloyd, 1999; Remillard & Bryans, 2004; Schoen, Cebulla, Finn, & Fi, 2003; Tarr et al., 2008). Thus, these researchers took into account the types of discourse, teaching methods, assessment techniques, and curricular materials expected in a standards-based learning environment.

Standards-based curriculum evaluators utilize various instruments to measure implementation fidelity. Three instruments in particular are frequently used: classroom observations (e.g. Tarr et al., 2008), surveys (e.g. Schoen et al., 2003), and teacher interviews (e.g. Remillard & Bryans, 2004). Some additional methodologies include homework assignments (e.g. Cai & Moyer, 2006), chapter evaluation forms (e.g. Thompson & Senk, 2001), textbook-use diaries (e.g. Tarr et al., 2008), and table-of-contents records (e.g. Tarr et al., 2008). Researchers use these instruments to measure several categories of implementation fidelity, including use of curriculum, teacher instructional practices, teacher background information, and teacher beliefs.

However, using implementation fidelity instruments in isolation can be unreliable (Porter, 2002). For example, teacher interviews are susceptible to self-reporting bias and classroom observations are subject to researcher bias. Since this unreliability is inherent, most researchers combined instruments to triangulate data when examining standards-based classroom environments. Research confirms that using multiple methods to measure teachers’ implementation fidelity yielded results that are more valid.

Because the MDM curriculum authors did not expect teachers to create a standards-based learning environment, the authors chose to complement this work and derive their expectations from a source other than the *Principles and Standards for School Mathematics* (NCTM, 2000). Specifically, the authors chose to utilize the Productive Pedagogy framework from the Queensland Department of Education and Training (K. Makar, personal communication, October 7, 2009; The State of Queensland, 2002). The framework outlines four overarching foci for effective pedagogy: intellectual quality, supportive classroom environment, recognition of difference, and connectedness. The MDM curriculum authors adapted focal points connected to these foci to study implementation of piloting teachers. In particular, the authors expected teachers to emphasize real-world contexts, interpret and synthesize application problems, utilize multi-step reasoning, be mathematically accurate, use technology effectively, promote student exploration, and foster an improvement in student attitudes.

Methods

Using the Productive Pedagogies framework (The State of Queensland, 2002), the authors of the MDM curriculum (one of the three researchers in this proposal is a primary author and the other two researchers are closely connected to the project) established their pedagogical intentions. In order for the teachers to implement the MDM curriculum faithfully, the authors expected the teachers to show evidence of these focal points (see Table 1 for examples of the focal points).

Approximately 40 teachers in North Carolina and Michigan piloted parts of the MDM materials during the 2008-2009 school year. The teachers implemented at least two chapters from the first semester of materials in the fourth-year mathematics course they were currently teaching (e.g. Discrete Mathematics, Advanced Functions and Modeling, or Introduction to College Mathematics). The teachers only piloted the first semester, or deterministic semester, of materials because the authors had not yet written the second semester, or probabilistic semester, of materials. During the 2008-2009 school year, ten of these teachers (all in North Carolina) were observed by at least one member of the MINDSET research team as they implemented deterministic semester materials. Some teachers were observed multiple times during their pilot, but no teacher was observed for the entire time of their pilot due to lack of resources. The observer took fieldnotes describing the learning environment.

In addition, after piloting a chapter, most teachers completed a feedback form. In this feedback form, the teachers gave detailed descriptions of the daily implementation of the chapter.

They also described whether the level of the materials was appropriate for their students, how students and teacher used technology in the classroom, and any feedback given by the students regarding the reading level.

Analysis consisted of a comparison of the chapter feedback responses to the observation fieldnotes in order to see how the information aligned. For example, a teacher wrote that he used direct instruction to cover specific material on a given day. An observer was in the classroom that same day and noted how the teacher used student-led class discussion as a way for the students to unpack the specific content. This discrepancy in the data caused us to reconsider what the teacher meant by direct instruction in his feedback form. Once we studied the feedback and the observation fieldnotes, the findings were evaluated according to the Productive Pedagogies framework to determine the ten teachers’ implementation fidelity levels.

Results

In general, three of the ten teachers showed preliminary evidence of supporting the focal points in the Productive Pedagogies framework, three teachers showed evidence of non-support, and there was insufficient evidence to make claims about the remaining four teachers. We use three of the focal points from Table 1 to illustrate the difference in teachers’ implementation fidelity: Academic Engagement, Technology, and Connectedness to the World.

Academic Engagement

The MDM curriculum authors expected teachers to encourage academic engagement in their classrooms. Based on observation fieldnotes and teacher feedback forms, two teachers (Jim and Sharon) showed clear evidence of supporting student engagement in their classroom while one teacher (Caroline) strayed from this focal point. We briefly describe the results from Jim, Sharon, and Caroline.

We observed Jim on the day he first introduced the linear programming materials. Jim used a combination of class discussion and small-group work encouraging his students to ask questions and to offer ideas regarding the contextual problem. In fact, when a student gave an idea that did not necessarily contribute to the current conversation, the teacher listed the idea on the side of the board so that the idea would not be neglected. This technique allowed the teacher to acknowledge the student and recognize the validity of the idea without spending time on an unnecessary or off-topic point. Jim fostered an open and engaging classroom this observation period. Moreover, the teacher’s chapter feedback aligned with the observer’s fieldnotes indicating that the single observation was not an anomaly. Thus, Jim’s method of student engagement corresponded with the MDM curriculum authors’ expectations of academic engagement.

Sharon was observed six times (five times with one member of the research team and once with another member) while she taught two linear programming chapters. For each observation, the observer noted students working in groups at some point during the period. Further, the teacher formally assessed students’ knowledge using a group project. The feedback provided by the teacher verified this teaching method. However, the observers found that Sharon tended to use short-answer recall questions, rather than in-depth conceptual questions, during class discussion. This type of questioning did not encourage student engagement. Nevertheless, we classify Sharon’s students as having a high level of academic engagement because they spent a large portion of class time in groups and a small portion of class time in class discussion.
Student responses on a survey provided further evidence to support the observations of high academic engagement in Sharon’s classroom. After piloting the MDM materials, Sharon gave her students a survey to discern their attitudes and beliefs about the materials. When asked, “Would you recommend that [the teacher] teach these modules in [Advanced Functions and Modeling] in the future and why?” Almost all students (21 out of 23) said “yes.” One student claimed, “[The problems] were so much fun, and [they] drew our groups closer together!” Another student stated, “Yeah, it was fun and different because I could actually see where this could be used in real life situations.” These comments, in addition to the observation data and the feedback forms, demonstrated how Sharon’s level of academic engagement aligned with the intentions of the MDM curriculum authors.

Contrary to Jim and Sharon, Caroline did not provide evidence of Academic Engagement. We observed Caroline twice while she piloted a linear programming chapter. In general, Caroline told her students answers rather than having the students discuss, explore, or conjecture on their own. For example, Caroline defined vocabulary words for the students instead of providing an opportunity for students to discuss possible definitions. At one point, the teacher completed a scaffolding worksheet at the overhead herself without any input from students to complete on their own. This contrasts to the goal of the MDM authors who created this worksheet with the intention that students would complete it in small groups. According to Caroline’s feedback form, she used “class discussion” and “group work,” but we classify the “class discussion” as lecturing to the class and “group work” as the teacher writing the answers on the overhead while many students were off task. Thus, the teacher feedback conflicted with the classroom observation fieldnotes. It is difficult to draw any definite conclusions about Caroline’s academic engagement because only two of her 16 piloting days were observed. Even so, for the two observation periods, the students were not engaged in the materials. The observer noted that Caroline’s students did not seem enthusiastic about the topics and rarely asked questions, which was a stark contrast to the behavior of Jim’s and Sharon’s students. Therefore, Caroline’s implementation of the MDM curriculum did not engage students academically as the authors intended.

Technology

One distinguishing factor about the MDM curriculum is the role of technology. Technology is not a main objective of the curriculum but is instead a means to organize, solve, or analyze real-life applications. Consequently, the MDM curriculum authors emphasize reflection and interpretation of a contextual problem during and following technology use. Using spreadsheet software, students are expected to analyze and interpret how values and solutions change and reflect on why these changes occurred, a process known as sensitivity analysis. According to observation fieldnotes and feedback forms, two teachers (Amelia and Sharon) encouraged technology reflection and interpretation through sensitivity analysis while one teacher (Bob) did not.

Two different observers visited Amelia’s class. The first observation occurred while Amelia taught sensitivity analysis and the second observation was five days after the first, during which time students had mastered sensitivity analysis. The first observer noted that Amelia lectured and used short-answer recall questions. Therefore, one may conclude that students did not have sufficient opportunity to interpret and reflect. However, the second observer noted that the students seemed to have a deep understanding of linear programming. When the second observer asked questions, students easily explained and interpreted the results of the problem. In the time

between the two observations, students were given time to reflect on the problem and analyze the
sensitivity of the numbers; hence, the teacher provided opportunities for the students to use
technology to deepen their understanding of the context. Thus, careful observation and analysis
shows that Amelia was faithful to the authors’ intentions by encouraging reflection and
interpretation during and after technology use.

Another teacher, Sharon, was observed the day before sensitivity analysis was taught and
then again a couple days afterwards by the same observer. The observer noted that she saw a
large difference in the students’ understanding of linear programming as indicated by the way the
students talked about problems. During the first observation, the students struggled to set up the
spreadsheets and interpret the problem context. After learning sensitivity analysis, the observer
noted that the students effortlessly set up spreadsheets and interpreted the constraints and
objective functions. In general, they understood the problem at a much deeper level due to their
use of technology. Therefore, Sharon, like Amelia, gave a faithful implementation of the
technology piece of this chapter.

Some teachers felt sensitivity analysis was too difficult for their students to learn. For
example, we observed Bob after teaching linear programming. Due to lack of time, limited
technology access, and teacher-perceived student ability, Bob chose not to teach sensitivity
analysis. When the observer asked the students about their experiences with the materials,
the students said they did not like typing in so many values into a spreadsheet. The students also
did not remember most of the problems in the text, even though the observation occurred
approximately two weeks after Bob taught the materials. We concluded that because the students
were not exposed to sensitivity analysis, they did not interpret and analyze problems in a
meaningful way. Consequently, they had a shallow understanding of the content as demonstrated
by their lack of familiarity with problem contexts. Therefore, Bob was not faithful to the authors’
desire to have students reflect and interpret during and after technology use.

According to observation fieldnotes, Amelia and Sharon’s students had a deeper
understanding of linear programming than did Bob’s students. We discerned that one reason for
this discrepancy was whether the teacher taught students how to analyze and interpret the
sensitivity of the data when using spreadsheet software. Teachers who used technology to reflect
and interpret contextual problems, such as Amelia and Sharon, had a high level of
implementation fidelity regarding the technology focal point.

Connectedness to the World

The authors of the MDM curriculum wrote all problems in context. Specifically, the authors
presented a real-life application followed by the mathematics needed to solve the problem.
Therefore, the authors expected teachers to teach the materials in context. If a teacher focused on
the mathematics out of context, the authors would consider this an unfaithful implementation of
the curriculum. One teacher (Jim) taught in context while another teacher (Janice) instead
emphasized mathematical procedure only.

As mentioned before, Jim was observed one time while teaching linear programming.
Throughout the observation, he kept the discourse about an introductory linear programming
problem in context. In fact, Jim avoided complex mathematical jargon and focused on students’
thinking, conjecturing, and interpreting the problem. After the observation, the observer asked
Jim why he did not introduce vocabulary such as “feasible region” or “constraint” during the
lesson. He responded that his students learned linear programming in Algebra II and he did not
want students to jump to the procedures they knew from before. By avoiding previously learned

American Chapter of the International Group for the Psychology of Mathematics Education. Columbus, OH: The
Ohio State University.
vocabulary, Jim felt that the students remained focused on the context of the problem; thereby, providing students with a fresh outlook on linear programming. Jim’s description of his class on his feedback form aligned with those characteristics observed in the classroom.

Janice was observed four times, three times by one observer and once by another. Both observers noted that Janice would “go over” the context but then emphasize the procedure. For example, when teaching shortest path problems, Janice introduced the context (transporting medical supplies) but then discussed only the procedure for the majority of the lesson. While she did not always teach algorithms out of context, this technique was typical for all four observations. Janice’s responses on her feedback form were too vague to discern whether they supported the observation fieldnotes. For example, when discussing the lesson on the shortest path, Janice noted, “Together, we found the shortest path.” This comment did not reveal how she approached the problem in class and whether she kept the problem in context. Consequently, without additional sources to validate the observation field notes, we were unable to draw a definitive conclusion about Janice’s level of implementation fidelity regarding teaching in context.

Because the authors of the MDM curriculum wrote contextual problems based upon real-life applications, they expected teachers to emphasize the context of the problems throughout the lesson. Observers noted that Janice would introduce the context of a problem, but then proceed to teach in an algorithmic manner with no reference to the context. Jim sustained the context of a linear programming problem in a lesson, but sacrificed the formal vocabulary to do so. Nevertheless, we discerned that Jim had a high level of implementation fidelity regarding the connectedness to the world focal point because his students learned about linear programming using a real-life application, not as an isolated mathematical procedure.

**Discussion**

We provided examples of teachers who showed evidence of either supporting or straying from the focal points established by the MDM authors. Interestingly, teachers who supported a specific focal point tended to support all of the authors’ focal points, and teachers who strayed from one focal point tended to stray from most focal points.

We note that teachers who are faithful to the authors’ intents are not necessarily better or more effective teachers than those who stray from the focal points. The purpose of the analysis was only to evaluate how teachers implemented the curriculum compared to how the authors envisioned the implementations, not in teacher effectiveness or student achievement.

Unlike authors of many standards-based curricula, the MDM project team has the opportunity to determine and express to teachers exactly what types of pedagogy they wish to see in the classroom because the researchers and authors have personally met the teachers implementing the materials. However, at this time, the authors had not yet explicitly informed teachers of their Productive Pedagogy focal points. Hence, we view our preliminary results regarding implementation fidelity as positive since some teachers seemed to support the focal points without any formal training on how to do so.

As this preliminary research is continued, the research team needs to examine further exactly what they expect to see in the classroom and to explain explicitly these expectations to the teachers. Additional classroom observations need to take place in order to examine whether the teachers are faithful to the authors’ intent. Moreover, the discrepancy in the data needs to be addressed; specifically, the information provided by the teachers in their feedback forms did not necessarily align with the information gathered by the classroom observations. Therefore, the
research team will need to gather more information to verify teacher-reported data using instruments such as teacher interviews and surveys.

STRUCTURES OF FINNISH AND ICELANDIC MATHEMATICS LESSONS: A VIDEO-BASED ANALYSIS

Lasse Savola
FIT-SUNY
savola@mindspring.com

For the purposes of a dissertation project, structures of 40 Finnish and Icelandic mathematics lessons were analyzed. The method of lesson structure analysis, which was developed specifically for this project, offers a means to investigate the different forms of classroom interaction teachers use to achieve their pedagogical goals. The method requires two coding passes. The first pass is inspired by the TIMSS 1999 Video Study and is used to distinguish the main pedagogical functions of lesson elements. The second coding pass, which uses ideas from the Learner’s Perspective Study as well as TIMSS, focuses on the forms of classroom participation. The coding categories are sensitive to the sample.

Analysis of videos from Finnish and Icelandic mathematics classrooms demonstrates the coding method for lesson structure. These countries were chosen in part because of their performance in the PISA studies; Finnish students have excelled in all three PISA studies, while Iceland is the only country where the girls have significantly outperformed the boys in mathematics. The recordings—two lessons from ten randomly chosen mathematics teachers of 14 and 15-year-olds in each country—were collected in 2007.

Based on this sample, there are differences in how Finnish and Icelandic mathematics lessons are structured. More than one half of the Icelandic lessons in the sample exemplify the “einstaklingsmiðað nám,” or individualized learning-strategy, the nationally endorsed pedagogical philosophy. Public instructional discourse can be missing entirely from these lessons, and, instead, the teacher tutors each student independently. This is in stark contrast with the Finnish lessons, where teacher-lead activities in which often the whole class is involved are emphasized. Based on the video evidence, Finnish teachers are rather traditional and pedagogically conservative. Their classroom practices often include a substantial social component, while many students in Iceland are getting used to learning independently, without significant collaboration with others.

The presentation of the method of lesson structure analysis as well as the results of the video study would fit well into the poster session format. The two coding passes can be explained in some detail on a poster. Statistical charts and lesson diagrams, such as the one shown below this text, can also be effectively displayed. Furthermore, copies of the finished dissertation and an article based on the study can be made available for the participants who want to learn more.

By considering the ways that children reason about integers and the difficulties they face in extending their numeric domains from whole numbers (nonnegative integers) to negative numbers, we seek to problematize the rich and nuanced understandings we in the mathematics community hold of integers. In this paper we document instances of how children’s thinking has paralleled that of mathematicians of the past, highlight ways in which children have displayed expert-like reasoning about integers, and provide possible explanations why some children are able to reason about integers in reasonably sophisticated ways.

Introduction

As adults we proficiently operate with numbers, specifically negative numbers, without the need for deep thought or reflection. Much of what we do, like rewriting $5 - (x + -3)$ as $5 - x + 3$ is automatic and beyond the level of conscious awareness. Moreover, we have a variety of understandings, metaphors, and contexts we bring to problems that allow us to think of and use numbers in multiple ways. For example, consider the number -5:

- We can interpret -5 as a directed magnitude (like owing money or debt);
- We can interpret -5 as the location on a number line (coordinate plane, etc.) 5 units to the left of or below 0;
- We can interpret -5 as the number before -4 and after -6;
- We can interpret -5 as the number that, when added to 5, results in 0;
- We can interpret -5 as an action of removing 5 from a set;
- We can interpret -5 as an action of moving 5 units left or down;
- We can interpret -5 as the difference or comparison between two quantities;
- We can interpret -5 as an element of the equivalence class $[(0,5)]$ which also includes (1,6), (-100, -95), (-2,3) and all other ordered pairs of integers satisfying the equivalence relation $(a,b) + (c,d) = (a+c, b+d)$ (where we define $(a,b)$ to mean $a - b$).

In this paper we seek to problematize the rich and nuanced understandings we in the mathematics community hold by considering the ways that children reason about integers and the difficulties they face in extending their numeric domains from whole numbers (nonnegative integers) to negative numbers. By considering the ways that children reason about integers we can enrich our own understanding and help students develop the flexibility to move back and forth between these different conceptions of negative numbers.
A Brief Historical Summary

For over 1000 years mathematicians pondered, struggled with, operated on, rejected, and eventually came to accept negative numbers. Not unlike their problematic, unwanted, and barely acknowledged cousin – the irrational numbers – negative numbers were the source of great consternation, confusion, and controversy. “Negative numbers troubled mathematicians far more than irrational numbers did, perhaps because negatives had no readily available geometric meaning and the rules of operation were stranger” (Kline, 1980, p.118). Negative numbers were theoretically plausible yet practically impossible. However, with Fermat and Descartes’s creation of analytic geometry as well as the need for more formalized and generalizable solutions to problems, mathematicians saw the rise of algebra and a corresponding acceptance of negative numbers (Freudenthal, 1983; Kline, 1980). This acceptance, though, was not without strong objections from some of the best mathematicians of their day. The philosopher Thomas Hobbes critiqued John Wallis’s book on the albegrazation of conic sections for applying algebra to geometry calling it a scurvy book and a “scab of symbols” (Kline, 1980, p. 124). Negative numbers too were rejected and described as “fictitious” (Jerome Cardan, 16th century), “absurd” (Michael Stifel, 16th century), and “false because they claim to represent numbers less than nothing” (Rene Descartes, 17th century). (See Gallardo, 2002; Hefendehl-Hebeker, 1991; Kline, 1980) The English mathematician Francis Maseres rejected negative roots in his 1759 Dissertation on the Use of the Negative Sign in Algebra saying,

... they serve only, as far as I am able to judge, to puzzle the whole doctrine of equations, and to render obscure and mysterious things that are in their own nature exceeding plain and simple ... it were to be wished therefore that negative roots had never been admitted into algebra (as quoted in Kline, 1980, p.119).

Why were mathematicians so slow to accept negative numbers? Certainly the lack of a physical, concrete, or geometrically meaningful solution contributed to the problem. Fibonacci, Chuquet, and Descartes (among others) objected to the lack of a tangible, physical or realistic interpretation of negative numbers. For example how can one have a negative number of monkeys (Bhascara I) or buy a negative amount of cloth from a merchant (Chuquet). These “impossibilities” were only accepted if a reasonable explanation for the negative solution could be generated in the given problem context (Gallardo, 2002; Hefendehl-Hebeker, 1991; Kline, 1980). In other words, a negative solution must have a magnitude-based, or positive, interpretation in order to be accepted. Second, the existence of negative numbers made the routine interpretation of addition as the joining of subsets to create a larger set problematic. Hence, the reason for Diophantus’s characterization of the equation 4 = 4x + 20 as “absurd” since the four units as the result of the summation should not be less than the addend of 20 units (Gallardo, 2002). And, finally, the attempt to remove something from nothing was seen as nonsensical. When describing the problem 0 – 4, Pascal said, “I know people who do not understand that when you subtract four from zero, what is left is zero” (Gallardo, 2002, p. 171).

Epistemologically, these reasons might point to conceptual barriers students today continue to face in understanding and operating with negative numbers (Herscovics, 1989; Thomaidis & Tzanakis, 2007). In this paper we hope to identify some of the challenges students have in understanding negative numbers and understand why those confusions exist. Moreover, we hope to identify the tacit and intuitive understandings children do have of negative numbers so that teachers, researchers and curriculum writers can better build on those strengths.
Methods

Our primary research questions were a) what are students’ conceptions of integers and operations on integers, and b) how might these conceptions develop over time. As our study is ongoing, we will present findings primarily addressing research question (a). Participants in our study include 26 elementary school students from Texas and California. Twenty of these children are in kindergarten, first, or second grade, and the remaining six are fifth graders. We have also interviewed 3 specialized adults with expertise either as mathematicians, math educators, or teachers. In addition, we have done a historical analysis of the literature to identify ways of reasoning and specific problems that puzzled mathematicians as well as the ways in which the discipline was able to overcome these problems.

Based on our historical analysis as well as our review of the relevant literature we developed sets of tasks specific to integer reasoning to be used in problem solving interviews with children and our specialized adults. Because of the range in age and understandings of our participants, we have three different interviews, one for K-2, one for 5-8, and another for specialized adults. Although many of the questions are different, the underlying constructs we sought to assess were the same across interviews. Our assessment comprises seven categories that assess children’s understandings of:

1. Number (e.g., numbers are ordinal – for counting and ordering; numbers are cardinal – they tell you “how many”) and zero (e.g., zero is nothing, zero is a place on the number line, or zero is the additive identity).
2. Number when solving counterintuitive problems (i.e., problems that contradict notions limited to positive numbers such as “addition makes larger” or “subtraction makes smaller”). The following problems are seen as counterintuitive if one’s numerical domain is only positive numbers: $3 - 5 = \_\_\_\_$, $6 - \_\_\_\_ = 8$, or $7 + \_\_\_\_ = 3$
3. Negative numbers as actions or processes (subtracting, removing, comparing, finding distance, and motion)
4. Negative numbers as objects (inverse, directed magnitudes, elements of an equivalence class).
5. Number comparisons: assessing how children think about larger and smaller when comparing negative numbers. (e.g., do they order numbers or do they reason in terms of magnitude.)
6. Symbolic proficiency: does a child recognize “–“ can be used to indicate a negative number as well as the operation of subtraction, and does a child know when to appropriately use which interpretation?
7. Contexts and tools in shifting or limiting their reasoning about negative numbers.

See the Appendix for examples of interview questions.

The interviews themselves were conducted at the children’s school sites, during the school day. They lasted between 30 and 50 minutes and were videotaped. Our analysis of the videotaped interviews began with a process of open coding (Strauss & Corbin, 1998) focusing on children’s solution strategies as well as their underlying ways of reasoning about number and operating with numbers. We used principles of grounded theory (primarily the constant comparative method) to identify emergent, distinguishing themes and features of students’ reasoning about integers (Strauss & Corbin, 1998). We balanced emergent codes from the data itself with historical and theoretical findings from the literature. As we are in the beginning

stages of the larger study, our analysis is still ongoing and will likely evolve. What we report here is a beginning framework for children’s thinking about integers and the different strands “integer sense” might encompass.

**Findings**

In the following section, we describe our findings with respect to children’s conceptions of and thinking about integers. We document instances of how children’s thinking has paralleled that of mathematicians of the past, highlight ways in which children have displayed expert-like reasoning about integers outlined in the paper’s introduction, and provide possible explanations why some children are able to reason in reasonably sophisticated ways.

First, we have found parallels in young children’s thinking about negative numbers with that of mathematicians of the past. These parallels are described in Table 1 below.

<td>2. Negative numbers as well-ordered</td>
<td>To solve the problem $3 - 5 = \square$, Jake used a counting back strategy. He counted backwards starting at three saying, “Three, two (put up one finger), one (put up second finger), zero (put up third finger), -1 (put up fourth finger), -2 (put up fifth finger). The answer’s -2.” (Jake, 1st grade)</td>
</tr>
<tr>
<td></td>
<td>When asked about numbers smaller than zero, Niki replied, “There is some but I forgot the word for them. Like something 1, something two, something 3, something 4.” And when asked to count backwards from five she used the notation displayed in Figure 1, using an “S” to stand for “something.” Note that she added a “something zero,” or S0. (Niki, 1st grade)</td>
</tr>
<tr>
<td>3. Negative number as an additive inverse</td>
<td>When solving $16 + \square = 0$ Tanner answered -16 and justified it saying, “Since this is a positive 16 you can cancel it out with it’s opposite which is -16. And then I just checked it with subtraction 16 minus 16 is zero. (Tanner, 5th grade)</td>
</tr>
<tr>
<td>4. Negative number as the action of movement (to the left or down)</td>
<td>To solve $3 - 5 = \square$, Lacy initially made stacks of 3 and 5 unifix cubes but quickly turned to a number line. She put a pointer at 3 and moved it 5 spaces to the left while counting aloud (1,2,3,4,5). She answered 02 (her invented notation for -2) and said, “That number line actually helped me a lot.” (Lacy, 1st grade)</td>
</tr>
<tr>
<td>5. Negative number as the difference (comparison) between two quantities or locations</td>
<td>Rosie is solving the “Train Problem” which says: You are taking the Polar Express from your home to the North Pole. You have one stop to make at X Elementary (insert child’s school name). Some people are on the train, but we don’t know how many. Today the train stopped at X Elementary. Four people got on the train and seven people got off the train. Does the train have more, fewer, or the same number of people when it leaves X Elementary as when it left your house? How many more/fewer people? “There would be less because if four kids get on that would be 4 more. But if 7 kids get off that would be 7 less. So 4 minus 7 would be something negative. So it would be less.” She then writes $4 - 7 = -3$ and when asked what -3 means she says, “That means 3 less than we had on the train before.” (Rosie, 2nd grade)</td>
</tr>
</tbody>
</table>
| 6. Negative number as subtraction and the equivalence between subtraction and adding an inverse (or addition and subtracting an inverse) | The following exchange occurred while Brett solved the problem $6 + \square = 4$.  

**Brett:** What is that plus for? Isn’t that supposed to be a minus?  
**Interviewer:** Is there any kind of number you can add to make it smaller?  
Brett: A negative number! I think, hmmm. Oh it’s a negative number. (He picked up the number line and moved from six to four.) Two, I mean negative two.  
**Interviewer:** How are you getting that?  
Brett: Well six minus two would equal four so six plus negative two would equal four.  
**Interviewer:** Those sound different, one is six minus and one is six plus. How do you know they are equal?  
Brett: Plussing a number, plussing a number, a negative number, would be minusing instead of plussing. (Brett, 1st grade) |
| 7. Negative number as an element of an equivalence class | While answering the Happy & Sad Thoughts Question (see appendix), Tanner said “Tuesday was a sad day, the same as Monday.” When asked to explain he said, “Because you get rid of, for this one you get rid of two (points to the 2 smiley faces and 2 sad faces he crossed out) and you have five sad thoughts left over. And on Tuesday you get rid of one (points to the 1 smiley face and 1 sad face he crossed out) and there are five sad thoughts still left over. I’m talking about what she has left over. Each one has 5 sad thoughts. (Tanner, 5th grade) |
This suggests that these are natural confusions for children to have and are to be expected given their early experiences with number. Here we see that young children can, at times, resemble early mathematicians in their struggle to understand, accept and operate with negative numbers. But this is only part of the story. We have found, perhaps surprisingly, that children as young as six can overcome these conceptual challenges that many of their peers and even mathematicians of old were unable to.

Below, we present some of the ways in which children articulated many of the “expert-like” ways of thinking about integers described in the introduction of this paper. We are not proposing that the types of reasoning outlined in Table 2 are what one would expect from an expert, but that they are precursors to reasoning about numbers in more sophisticated ways that are developmentally appropriate for children this age.

![Figure 1. Niki’s Representation of the “Somethings”](image)

**Discussion & Implications**

Why are some children able to exhibit this kind of reasoning and others not? We posit that different ways of conceiving of and using numbers more generally, might explain children’s ability to reason in relatively sophisticated ways and overcome many of the aforementioned challenges in Table 1. On the basis of our analysis of interviews, we found it useful to distinguish four ways of reasoning about numbers in general that seem linked to children’s thinking about negative numbers:

1. numbers as countable, tangible quantities or amounts,
2. numbers as well-ordered,
3. numbers as a position or location, and
4. numbers in a formalized sense.

More formally, the first three ways of thinking about numbers can be called a cardinal use of numbers, an ordinal use of numbers, and a nominal use of numbers. We believe these ways of reasoning about numbers in general have implications for how children might approach and understand negative numbers. For example, consider the problem $3 - 5 = \square$. If numbers are viewed as tangible objects (see the examples in Table 1), one could think of a context where he or she had three of something and promised five to a friend. After giving the three she had, she would still owe two. Although this idea can be represented symbolically as $-2$, one cannot represent $-2$ in a tangible way. Rosie reminds us of this when she explains why negative numbers are not really numbers in her mind: “We don’t really count with them in school, and there’s no negative one cube.” (Note that as a 2nd grader she has not been introduced to a chip model yet.) What does it mean to take something from nothing or to have $-2$ cubes? From a cardinality only viewpoint, these problems really do not make sense.

Yet, one could approach the same problem in a number line or motion context where $-2$ is a position; it is the place one lands when starting at 3 and moving left 5 (or starting at $-8$ and...}

---

moving right 6). In this view, negative numbers are seen as ordinal and sequentially related to other numbers, but not necessarily representing an amount or quantity. This way of reasoning about number is also seen in Jake’s counting back strategy. For him, there did not seem to be anything particularly special about negative numbers, they just happened to be on the other side of zero. This is in contrast to students who conceived of numbers smaller than, or below, zero but not in ways that allowed them to compare, order, and operate on numbers. We refer to this as a nominal use of number. Although not included in Tables 1 and 2, several students, when asked to identify places to the left of 0 during the Number-Line Game were unable to distinguish unique and well-ordered places to the left of zero numerically (see Appendix for activity description). BradLee initially called every place left of 0, “zero”. When asked where he would go if his teacher asked him to go to zero, he replied he didn’t know and then renamed -1 as “none” and -1 as “no numbers”. Teddy called every place to the left of 0 “negative” and described the entire left side of the number line as the “negative hallway”. He later revised his labels calling -1 the “negative classroom”, -2 the “negative playground”, -3 the “negative cafeteria” and so on until ending with the “negative principal’s office.” These children saw places to the left of zero as locations and even gave them names (negative classroom, no numbers, etc.), but they were unable to order these places numerically.

However, some children were able to approach and use numbers in a more formal, algebraic way, conceiving of negative numbers as additive inverses, noting the equivalence between subtraction and adding an inverse (or addition and subtracting an inverse), and comparing differences of differences in order to see integers as elements of equivalence classes (though their language is much less formal). We are not proposing that all children should use only a formal, algebraic way of reasoning about number, but that children should be able to approach numbers (and, also, negative numbers) from a variety of views and flexibly move back and forth between these ways of reasoning.

We found that young children can reason in powerful ways about negative numbers given the right tools and opportunities. We suspect that certain types of problems and tasks might be particularly rich sites for children’s learning about negative numbers. Moreover, these kinds of problems can provide opportunities for children to construct new views of negative numbers. As our work is ongoing, we anticipate identifying these types of generative tasks as well as developing trajectories of integer reasoning that children could pass through on their way to more sophisticated and flexible ways of reasoning.

ADDITION AND SUBTRACTION WITH NEGATIVES:  
ACKNOWLEDGING THE MULTIPLE MEANINGS OF THE MINUS SIGN

Laura Bofferding  
Stanford University  
lboff@stanford.edu

In order for students to use negative numbers in operations, they must make sense of the binary, symmetric, and unary interpretations of the minus sign. However, little is known about the extent to which children reason about these three interpretations prior to integer instruction. Through interviews, I explore the strategies 22 second graders use to solve addition and subtraction problems with negative numbers, the meanings (binary, symmetric, and unary) they assign to minus signs, and their understanding of the operations. Analysis of students’ solutions and language suggest that the second graders think comparably to students who have had integer instruction.

Introduction

Algebra is increasingly recognized as a gateway to higher mathematics and as a required skill for employment; consequently, one goal of middle school mathematics is to help students build a foundation of algebra readiness skills (EdSource, 2009). Even with the intensified focus, one reason why students still struggle with algebra concepts is they have difficulty understanding and working with negative numbers (Gallardo, 2002; Vlassis, 2004). Tatsuoka and Baillie identified 89 different rules that students use to solve integer addition and subtraction problems (e.g., subtract the smaller absolute value from the larger and add the sign of the first number); although, these rules have varying levels of success (Tatsuoka, 1983). In particular, students have trouble making sense of the changing role of the minus sign (Vlassis, 2008); they solve problems such as 8 - - 4 by ignoring the duplicate sign (Murray, 1985) or ignoring the first minus, solving, and adding the sign at the end (Fagnant, Vlassis & Crahay, 2005; Schwarz, Kohn, & Resnick, 1993; Vlassis, 2004); they claim that two minuses in a problem mean a plus (e.g., -1 + -5 = 6) (Vlassis, 2004); and they answer problems such as 6 + -2 by adding 2 and then subtracting 2 (Murray, 1985).

Children’s learning of whole numbers and whole number operations relies heavily on the use of physical manipulatives and having extended experiences with whole numbers from their toddler to mid-elementary years (Sarama & Clements, 2009). On the other hand, manipulatives for negative numbers are contrived, and according to the California mathematics content standards, students are introduced to negative numbers in fourth grade and are expected to add and subtract them the following year (California Department of Education, 1999). Some of students’ struggles with negative numbers might arise because a brief introduction to them a year before learning integer operations is not long enough or because the instruction they receive is not sufficient. If this is the case, we would expect some of their same misconceptions to also arise with students who have not had instruction. The purpose of this study was to closely explore how students solve addition and subtraction problems involving negative numbers and explain their thinking, prior to instruction. More specifically, the goal was to ascertain to what extent students before integer instruction and students post-integer instruction exhibit similar reasoning.

Theoretical Framework

Gallardo and Rojano (1994) proposed three levels of conceptualization of negative numbers which are further elaborated by Vlassis (2008). These levels include interpreting minuses as binary, symmetric, and unary functions. The binary nature of the minus sign corresponds to the subtraction operation (e.g. 5 - 3 = 2). With negative numbers, the binary interpretation is also associated with the changing meaning of subtraction as addition when subtracting a negative number. The symmetric nature of the minus sign is associated with “taking the opposite of a number” (Vlassis, 2008, p. 561-2), so – (3) = –3 and – (–3) = 3. Finally, the unary nature of the minus sign aligns with the traditional notion of negatives as a new class of numbers to the left of zero on the horizontal number line, with decreasing quantities as one moves away from zero. Students’ descriptions of how they solve integer arithmetic problems provide insight into the functions that they assign to minus signs across problem types. While we know students who have been exposed to negative integers utilize these three functions (Gallardo & Rojano, 1994; Vlassis, 2008), we need more information on younger students’ conceptions to determine if acknowledgement of the three functions arises out of instruction or not.

As Van Oers (2002) points out, “it is highly relevant to study the processes involved in symbolizing activities in a detailed way, as well as to find out the dynamics…that may influence the development of this symbolizing capacity” (p. 30). As children learn new signs, they reflect on the signs and their possible meanings. Based on his framework, students form pseudo-concepts as they take their current understanding of symbols, such as the minus sign, and apply them to new situations, such as integer problems. They also start to use language introduced by adults, although they may still attribute old meanings to the new expressions (Van Oers, 2002). The extent to which younger students acknowledge the three functions of the minus sign and the language they use to describe solutions to integer problems have implications on the timeliness of instruction students should receive on negative numbers.

Research Questions

The following questions guided my research:
1) What do second grade students’ solution strategies indicate about how they make sense of the changing nature of the minus sign? To what extent do the students acknowledge the three roles of the minus sign?
2) What do their solutions and language indicate about their understanding of addition and subtraction with negative numbers?

Methods

Subjects and Site

This exploratory study was conducted at an elementary school in a district in northern California which has a low percentage of English language learners (only 2.3% of the students compared to 25% statewide and 9% nationwide) (Education Data Partnership, 2010). It was important to interview children with a strong grasp of English to get more detailed descriptions of students’ solution explanations without confounding the difficulty of explaining problem interpretations with the difficulty of using the language. A total of 22 second graders (8 male, 14 female) from two classrooms agreed to participate in the interviews.

Materials and Data Collection

Individual interviews lasted for 16 minutes on average. During the interviews, students answered 18 negative number addition and subtraction problems presented one at a time and--

except for the first two questions--in random order. Before moving on to the next question, students had to explain how they came to their answer. Siegler (1996) found that this method is accurate and reliable.

Based on the position of the signs and numerals in the problems there are 32 possible integer addition and subtraction problem types. Two test forms were created in an effort to cover more of the problem types without overwhelming students with too many questions; students’ first two questions were the same across forms and four other questions were repeated on both forms. Aside from the first two problems, the order of the questions was randomized on each test, and students were randomly assigned to test form. Students taking Form A saw either the first or second half of their problems with boxes around the numerals to see if this format changed the ways they talked about the negative signs (see Table 1 above).
Analysis

Students’ solutions were coded for accuracy, and their verbal reports were transcribed and coded for each question. Solutions were coded for the strategies students used to set up the problem (e.g., ignored all negatives, reversed the numerals, changed the operation), strategies students used to compute the answers (e.g., recall, count the distance between numbers, use a related fact), and manipulations of the answer (e.g., added a negative sign). Student responses that reflected one of the three meanings of the minus sign (binary, symmetric, and unary) were identified based on the codes. Students’ responses were also coded for references to their descriptions of addition and subtraction in comparison to how they solved the problems.

Results

Three Meanings of the Minus Sign

All students correctly solved the first question, 6 - 6, so this problem was dropped from analysis. Overall, the average number correct score was 3 out of 17 (20%); however individuals’ scores ranged from 0 to 9 out of 17 (0% - 53% correct). Among the group of 22 second-graders and 17 problems, students acknowledged all three roles of the minus sign. Together, they used the binary function on 198 out of 374 questions (53%), the symmetric function on 74 out of 374 questions (20%), and the unary function on 38 out of 374 questions (10%).

Binary. On average, students used the minus sign as an operator or binary function on 9 of the 17 problems (53%), but the range was large: two students used the binary interpretation on only 2 of 17 problems (12%) and two used it on all 17 problems (100%). However, students frequently ignored negative signs in order to subtract or interpreted negative signs as minuses in interesting ways. Table 2 provides examples of students’ binary responses and their corresponding codes. Notes in “< >” describe students’ actions during the interview and those in “( )” describe my interpretation of their solutions.
The problem 4 - 9 presents an interesting case because all students used the binary interpretation of the minus sign, but 15 of the 22 students (68%) reversed the numerals and solved 9 - 4 = 5. Surprisingly, none of these fifteen students explicitly stated that you cannot subtract a larger number from a smaller one, a claim which often persists through middle school regardless of whether students solve other negative problems correctly (Ball, 1993; Murray, 1985; Vlassis, 2004). Instead, they commented that it was easier to think about the problem with the larger number first or said they just knew the answer. Three additional students (14%) said there were not enough to subtract and produced answers of zero (Peled, Mukhopadhyay, & Resnick, 1989), and four students (18%) crossed the zero point and reached negative answers.

**Symmetric.** While all students acknowledged the binary nature of the minus sign, only 8 out of 22 students (36%) used the symmetric format of the minus sign. However, when they did use the symmetric format, they did so for an average of nine problems. Students’ symmetric responses fall into one of two categories: 1) solving problems as positive and adding a negative sign to the answer because the problem contained negatives and 2) drawing comparisons between the positive and negative forms of the problem, calculating using positive numbers, and adding a negative sign. This distinction may be subtle but represents advancement in students’ thinking. Amelia belongs to the first category; after solving -7 - -7 = -0, she explained, “It has negatives in it, and seven minus seven is zero.” In contrast, Bryan changed the original problem, 9 - -1, into a new problem, -9 + -1, and solved it by reasoning, “Nine plus one equals ten, so if it was minus nine plus minus one, it would equal minus ten,” which illustrates category 2.

**Unary.** Finally, 8 out of 22 students (36%) used the unary interpretation of the minus sign and talked about and operated on negative numbers as separate from positive numbers. These students used the unary interpretation for an average of five problems. For instance, when solving -2 - 1, one student, Emily said, “It’s one less than negative two, so it’d be negative three.” While the unary interpretation was not used as often when students solved problems, 14 of the 22 students (64%) read negative numbers using language that distinguished them from positive numbers, such as “minus five,” “below zero five,” or “negative five.”

Overall, 7 out of 22 students (32%) used all three meanings of the minus sign, 1 out of 22 students (5%) used the binary and symmetric formats, 1 out of 22 students (5%) used the binary and unary formats, and 13 out of 22 students (59%) used only the binary format. Additionally, use of the boxes around the numbers on Form A did not make a significant difference on their strategies.

**Interpretation of Addition and Subtraction**

Especially for students who acknowledged the unary or symmetric interpretations of the minus sign, the language they used to describe their solution processes reveals conflicting conceptions of addition and subtraction. When operating with natural numbers, addition results in a number that is larger than either addend and that is further to the right on the number line. With negatives, however, adding a smaller positive to a larger negative number (e.g., -8 + 4) results in a larger number further to the right on the number line but which has a smaller absolute value. Likewise adding a negative to a negative number (e.g., -2 + -5) results in a number with a larger absolute value but which is further to the left on the number line.

While all students who took form B of the test got a larger absolute value for problems such as -4 + -8 (answers were -12 or 12), responses to problems such as -8 + 4 show that several students were uncertain whether to focus on moving to the right on the number line or on reaching a larger absolute value. Furthermore, when using the binary meaning of the minus sign,
students either ignored the negative signs and/or reversed numbers so they could do positive number subtraction or they wavered between moving left on the number line and getting a number with smaller absolute value. Table 3 provides examples of how students’ answers changed between number line and absolute value-based answers for addition and subtraction.

### Discussion and Conclusions

The results of this study have a few implications toward curricula and task design in the broader frame of optimizing student understanding. First, merely looking at students’ number correct scores on integer tests will not provide sufficient information on how students interpret the negative signs or order and quantity of the negatives. Second graders in this study supplied incorrect answers on many of the problems but demonstrated insightful and complicated reasoning about them. For example, when solving -8 - -8, one student, Mollie said, “Well, if that one wasn’t negative <points to the first negative>, then it would have been sixteen, but it’s negative, so I think it’s eight,” which is 8 less than the 16 it would have been. Additionally, some of the students obtained correct answers through incomplete reasoning, which would not be captured through written tests alone. Therefore, we need to pay more attention to the answers students provide and select questions which will supply the most contrast and highlight how they are thinking about the problems. Furthermore, the interviews revealed that students are trying to make sense of how operations with the negative numbers align with their previous ideas of addition and subtraction, so future measures should aim to uncover how students think about these concepts together with the multiple meanings of the minus sign.

Brown and Borko (1992) explain, “Learning involves making connections between new information and existing systems of knowledge; teaching should facilitate making these connections by helping students to relate new knowledge to knowledge they have already developed” (p. 211). Children in second grade are already forming ideas about the multiple roles of the minus sign or what problems like 4 - 9 mean, and in many cases, they use the same strategies identified by researchers who have interviewed students after they have had instruction in negative numbers (e.g., Fagnant, Vlassis & Crahay, 2005; Murray, 1985). Since over half of the children in the study were willing to explore more than the binary function of the minus sign, negative numbers can be introduced earlier, and curricula could address their emerging and
conflicting conceptions so that children have more time to become familiar with negatives. One area which instruction could target is illuminating the lack of the commutative property holding for subtraction and guiding students to acknowledge the possibility of solving problems like $4 - 9$ without feeling the urge to reverse the numerals. Students should also have the opportunity to explore the multiple meanings of the minus sign. Earlier and extended experiences with the concepts of negatives may help prepare students for operations with them later.

Aside from instructional implications, these results also suggest future areas of study. In the case of students who ignore all negative signs and operate with only the binary meaning of the minus sign, we should explore what experiences influence them to acknowledge the other functions of the minus sign. Further studies should also compare how students approach the three meanings of the minus sign and the changing nature of addition and subtraction both before and after instruction to determine if current instruction helps students progress in their thinking on these topics. Finally, we should further explore the language teachers use to talk about whole number addition and subtraction and investigate its impact on students’ reasoning when adding and subtracting with negatives.

DIFFERENT LEVELS OF REASONING IN WITHIN STATE RATIO CONCEPTION 
AND THE CONCEPTUALIZATION OF RATE: A POSSIBLE EXAMPLE

Gulseren K. Akar
Bogazici University
gulserenkaragoz@yahoo.com

In this study I studied the nature of the conception of within-state ratios. Fourteen prospective elementary and secondary mathematics teachers participated in two, one and one half-hour long written sessions followed by an hour-long clinical interview. This paper presents one of the prospective elementary mathematics teacher’s, Mark’s use of strategies and justifications behind those strategies in the context of ratio. Data on Mark’s justifications showed different levels of reasoning in within-state ratios at the beginning of the interview as compared to the end of the interview. Whether or not different reasoning patterns indicate learning or only a reorienting to something previously learned, data might be an example of a student who possibly had the understanding of particular ratios [internalized ratio] at the beginning of the interview, and came to an understanding of rate [interiorized ratio] by the end of the interview.

Introduction

Noelting (1980b) claimed that a student might approach a proportion such as \( \frac{a}{b} = \frac{c}{d} \) by comparing the first set of ratios \( \frac{a}{b} \) and \( \frac{c}{d} \) or the second set of ratios \( \frac{a}{c} \) and \( \frac{b}{d} \). In the first case, he called the ratios \( \frac{a}{b} \) and \( \frac{c}{d} \) as within (state) ratios, where the ratio represents the original quantities, within one state, and the quantities come from two different measure spaces such as distance and time in uniform motion. In the first case, he called the ratios \( \frac{a}{c} \) and \( \frac{b}{d} \) as between (state) ratios, where the ratio represents quantities between two situations and so the quantities come from the same measure space such as the comparison of distance to distance or time to time in two situations of the uniform motion (Noelting, 1980b). Noelting and some other researchers emphasized that these two types of ratios originate from different cognitive processes (Karplus, Stage & Pulos, 1983b; Noelting, 1980b; Schwartz, 1988; Vergnaud, 1994). In this study, the focus was on the cognitive processes that make one pay attention to within state ratios at different levels of reasoning.

Kaput & West (1994) defined the particular ratio of “3 pounds per 4 dollars” as a particular substitution of x and y values, meaning a particular purchase; on the other hand, defined the rate-ratio as the linear function defined between two measures (Kaput & West, 1994) ---the function that determines the relationship between the two quantities. In addition, researchers argued that experience with the particular ratio (internalized ratio) situations as a mental operation, relating a particular pair of quantities and realizing the homogeneity, must yield to the conceptualization of rate intensive quantity, rate-ratio (interiorized ratio) (Kaput &West, 1994; Thompson, 1994). This study also focused on possible conceptualization processes involved in the understanding of rate- ratios building on particular ratio situations. Several researchers have studied different conceptions of ratio. Simon & Blume (1994) introduced ratio-as-measure as an intensive quantity that is a measure of the attribute in the situation. Thompson (1994) focused on the
conceptualization process for the abstraction of a specific case of ratio as measure, speed. His analysis for the conceptualization process of speed proposed different stages of knowing. Those stages included 1) an image of two quantities covarying, 2) an image of two segments, one for distance and one for time, partitioned proportionally according to units of time, and 3) ‘an image of segmented total distance in relation to a segmented total amount of time’ (Thompson, 1994; p. 204). Heinz (2000) studied identical groups conception in which ratio is understood as a representation of association between two extensive quantities. Similar to the conceptualization process claimed by Thompson (1994) for speed, Heinz (2000) proposed a detailed sequence that students would go through in conceptualizing ratio as an intensive quantity. The sequence is also aligned with the building-up processes, a precursor to the understanding of rate conception (Heinz, 2000; Kaput & West, 1994; Thompson, 1994).

**Purpose**

This study expands previous research on the conception of ratio (e.g., Heinz, 2000; Kaput & West, 1994; Simon & Blume, 1994; Thompson, 1994) in two important ways: First, in light of the data, using different tasks, reasoning patterns involved in within state ratio conception as an intensive quantity are compared to the reasoning patterns involved in an understanding of ratio as a representation of the association between two extensive quantities. In addition, a student’s use of different representations in those different reasoning patterns in within state ratio situations was documented. Second, whether data showed learning on the student’s part or only a reorienting to something previously learned, an example of a student who possibly had the understanding of particular ratios [internalized ratio] at the beginning of the interview, and came to an understanding of rate [interiorized ratio] by the end of the interview was shown. Such work is likely to shed light on the learning of ratio as a measure of an attribute (Simon & Blume, 1994) that researchers claimed to develop on the building-up processes students use in particular ratio situations (Heinz, 2000; Kaput & West, 1994; Thompson, 1994).

**Methodology**

This study embraces the idea that knowledge is not independent of the knower; researchers can only create models of knowledge of others by observing their behavior (e.g., Clement, 2000). In this study several tasks in the context of ratio were given to fourteen prospective mathematics teachers to investigate the nature of the understanding of within state ratios. Observations were made by asking the students to justify their reasoning in two, one and one half-hour long written sessions. Then, a one hour-long clinical interview was conducted with the students, using both the same tasks and some additional tasks. Some of the tasks were adaptations of tasks used in previous research. And I created several other tasks such as The Mosaic Problem (adopted from Vergnaud, 1994), the Hair Color-2, the Mixture and the Ice-Cream Problem (presented in results section) by taking into consideration previous research results on ratio (e.g., Heinz, 2000; Simon & Blume, 1994; Thompson, 1994; Kaput & West, 1994). For instance, I knew that students without the necessary knowledge base in ratio might revert to primitive stages of knowing when reasoning on problems with numbers whose magnitudes are relatively close to each other (Kaput & West, 1994) and also students with the necessary knowledge base in ratio can reason through the problems regardless of the difficulty of numbers they encounter (Heinz, 2000). Based on these results, I included non-integer multiplies and some difficult numbers in some tasks to distinguish different levels of reasoning in within state ratios. I also paid attention to the fact that the problem solving process assumes the integration, elaboration and the entailment of the
previous states into the current state of mathematical knowledge such that necessary previous states of knowledge can be called upon into the current knowing actions (Kieren & Pirie, 1991).

In both written problem solving sessions and interviews, I examined Mark’s strategies, solution processes and justifications with the goal of determining what underlying conceptions of ratio he might be revealing through the strategies, processes and justifications. To make sure that hypotheses and conclusions drawn from the data were plausible, other researchers were consulted to challenge the conjectures and/or to affirm their reasonableness. Also, previous research results were visited frequently. As shall be seen in the following sections, discomforting data were also under scrutiny such that based on researchers’ opinions on the initial hypotheses about the student’s thinking, either the alternative hypotheses were created or more than one interpretation of the data were suggested. To do this, I used the results of an important study done by Tzur & Simon (2004). These researchers introduced two stages of abstraction: participatory stage and anticipatory stage. Participatory stage refers to the understanding level such that the student has access to the knowledge only if participating in the context of the activity through which the knowledge is developed. They asserted, “In the context of the activity means either the learners are engaged in the activity or are somehow (e.g. chance, social interaction) prompted to use or think about the activity” (p. 15). Anticipatory stage refers to an understanding level such that the student is able to call upon the knowledge without being in the context of the activity through which it is developed.

The following sections present excerpts from transcripts of the interview conducted with Mark. Data showed different reasoning patterns and use of representations revealing different levels in the understanding of within-ratios at the beginning of the interview compared to the end of the interview. Though, Mark’s initial thinking on the Mosaic Problem showed the same patterns as the beginning of the interview, after he reasoned through an alternative solution to the Mosaic Problem, his reasoning about the ratio as measure situations changed significantly. In particular, his understanding of ratio at the beginning of the interview showed characteristics of an understanding of ratio as a representation of two extensive quantities; whereas, the line of reasoning at the end of the interview showed characteristics of the understanding of ratio as an intensive quantity measuring the attribute in the situation.

**Results**

**Mark’s Understanding of Within-State Ratios**

As mentioned, Mark’s reasoning and use of representations about within state ratio situations changed drastically after his engagement in the Mosaic Problem. For that reason, each section is labeled either “Beginning of Interview” or “End of Interview”. Beginning of Interview refers to before Mark reasons about the Mosaic Problem, and End of Interview refers to Mark’s reasoning about the Mosaic Problem and after.

**Beginning of Interview**

At the beginning of the interview, when Mark reasoned through The Hair Color-2 Problem and the Mixture Problem, his explanations and representations resembled an understanding of ratio as an expression that represents the association between two extensive quantities (Heinz, 2000). That is, ratio is made up of two extensive quantities.

**The Hair Color-2 Problem:** Kelly likes to color her hair with a mixture of red and brown dye. When her hair was shorter; she used 15 grams of red and 17 grams of brown dye. Now, her
hair is longer. She knows that the original mixture will not be enough to color all of her hair. She intends to add 7 grams of red dye to the original amount of red dye and some amount of brown dye to the original amount of brown dye. How much brown dye does she need to make sure that she has the original color?

In a group of seventh graders, the following two solutions were given:

- a) The amount of brown dye Kelly needs to add to the original amount is $17 \times \frac{22}{15}$.
- b) The amount of brown dye Kelly needs to add to the original amount is $22 \times \frac{17}{15}$.

Explain how each answer fits or does not fit the story? Depending on the choice of your answer, explain what $\frac{22}{15}$ represents and/or what $\frac{17}{15}$ represents.

In the written sessions, Mark had solved the Hair Color-2 Problem using cross multiplication procedure instead of explaining how the answers fit the story and what the ratios represented. At the beginning of the interview, I asked Mark to account for the solutions provided to him. Mark explained what $17/15$ ratio represents and he said “So, for every 15 grams of red dye, she needs 17 grams of brown dye”. Then, I asked him to comment on that more:

R: Can you show to me you can put into mathematical terms or, is there a way you can show me for every 15 grams of red there will be 17 grams of brown dye?

M: For every gram of red dye it is going to be 1.15 for brown.

The excerpt shows that Mark knows that the ratio $17/15$ represents the relationship between red and brown dye as “for every 15 grams of red, there would be 17 grams of brown.” He also offered that the result of the division tells how many grams of red dye are needed for 1 gram of brown dye. Then I asked him to show 1.15, the result of the division of 17 by 15, using any kind of graphs, diagrams or shapes, he drew two bars and said:

M: This for every one gram of red there is going to be one a little bit more brown [He made two bars, one of them is for R and the other is for B where Brown is bigger than the Red one]

The excerpt shows that Mark knows that 17 grams of brown dye and 15 grams of red dye are related to each other such that when he partitioned 17 grams of red into 15 equal parts, the result would be “for every gram of red, there will be 1.15 grams of brown” and he can represent the result of division as two different bars because he is thinking that the result of division, 1.15, represents two quantities: 1 gram of red and 1.15 grams of brown. That is, Mark engaged in approaching the Hair Color-2 Problem using a per-one strategy [unit-factor approach]. Heinz (2000) stated that students with the understanding of ratio as a representation of extensive quantities (identical groups conception) would utilize per-one strategy to associate the quantities in the original ratio situation.

Then he commented on what he wrote above as $R \times 15 = 15$ and $B \times 15 = 17$.

M: Right, yeah, and then there is 15 of those whatever you need for red, and then 15 of those will be what you need for brown, or if for brown that is bigger, so you need 15 here and 17 of there.
The excerpt shows that Mark knows that the two original quantities of 15 grams of red dye and 17 grams of brown dye can be partitioned into 15 equal parts such that the result of the partition is 1 gram for red and 1.15 grams for brown. He knows that he can accumulate those 1 grams to make up the original 15 and at the same time he has to accumulate 15 portions of 1.15 grams of brown because of the specific combination they make up, i.e. the original color. Thus he knows that “1.15 grams of brown dye and 1 gram of red dye” have the same color as “17 grams of brown dye and 15 grams of red dye.” Another important point is that, Mark is able to think about how many times both quantities need to be iterated. In other words, since he knows that 1 gram of red dye becomes 15 grams of red dye at the end and 15 is 15 times bigger than 1, and he needs to iterate both quantities at the same time, he knows that the other quantity needs to be iterated the same number of times.

Also, Mark’s thinking on the “b” option and “c” option of the Mixture Problem showed the same characteristics of his thinking on the Hair Color-2 Problem.

**The Mixture Problem:** A group of fifth graders will mix two types of juice mixture and will put them into jars so they can serve them to the kindergarten students during the week. In the first jar, they put 36 grams of lemon juice and 32 grams of lime juice. In the second jar, they put 20 grams of lemon juice and 15 grams of lime juice. To label the jars, the fifth graders wanted to use one number to accurately represent the lemon-lime flavor in that jar. They considered the following three ideas for labeling the jars:

- a) There is 4 more lemons in the first mixture so put 4 on the first label. There are 5 more lemons in the second mixture, so put 5 on the second label.
- b) The ratio of 36/32 for the first type of mixture and the ratio of 20/15 for the second type of mixture.
- c) 1.125 (the result of dividing 36 by 32) and 1.33 (the result of dividing 20 by 15).

Which idea(s) would accurately indicate the mixture’s lemon-lime flavor? Why? Provide an explanation for the reason(s) that each of these options would or would not indicate the mixture’s lemon-lime flavor.

Mark said, “That is also another ratio, because that is like if you take 36 to 32, 1.125 means for every 1 gram, 1 ounce or whatever of lime juice there will be 1.125 lemon juice in the mixture. 1 and 1.125 so whenever you have like 2, 2 times 1.125, 3 will be 3 times 1.125, four whatever and when you get to 32 then it will be 32 times 1.125”. His initial thinking on the Mosaic Problem also showed the same characteristics of his thinking on the Hair Color-2 problem. [To be shared during the conference]

**End of Interview: Mark’s Reasoning on the Mosaic Problem**

This section provides data on Mark’s reasoning on an alternative solution of the Mosaic Problem provided to him during the interview. It is important to reemphasize that Mark’s initial thinking on the Mosaic Problem resembled his reasoning on the Hair Color-2 Problem and the Mixture Problem.
Can you provide multiple solutions to this problem? Explain how your solutions make sense in terms of the problem context.

During the interview, I provided the following to Mark “Somebody solved the problem as follows: They divided 36 by 16, 36/16=2.25, and multiplied that by 40, so 2.25*40=90. Can you account for the solution? What does 2.25 represent? Why does it make sense to multiply it with 40?” Mark explained his reason for how he was able to multiply 2.25 with 40 by saying “they worked 2.25 times as long”. Then, to make sense of what 2.25 represented he engaged in adding the amounts of 16 minutes and 40 square cm repeatedly to reach the result. At this moment the interview became much more interesting because of Mark’s line of reasoning.

M: They originally worked for 16, this is 16 minutes, and they worked then 40 cm, so if you know 36 over 16 is, going from 16 to 36, would be like one, two and two five so they are staying at the same rate so it will be 40, 80 and a fourth of that”
R: A fourth of that
M: Because point 25 is one fourth, so like 16, 32 and a 4\textsuperscript{th} of 16 and so then 40, 80 and a fourth of it is 10 so it is
R: Fourth of what
M: The area
R: The fourth of which one, like 16, 32.
M: 40, 80 and 90
R: A fourth of what
M: fourth of the 40
R: Then are you going to add that to and you know you can get 4\textsuperscript{th} of 40 because
M: Because you went from 16 to 32 and 4\textsuperscript{th} of 16 is 4 to get 36 and then 40, 80 and 4\textsuperscript{th} of 10, 4\textsuperscript{th} of 40 is ten so then you have the 80 and then 90.
R: So you know that the remaining 4 are 4\textsuperscript{th} of 16 why you are using that.
M: Because it is 2.25
R: Why are you allowed to find 4\textsuperscript{th} of 16 in the context of the problem, why does it make sense?
M: You can use a 4\textsuperscript{th} because 36 is not a multiple of 16 it is more than that so it is, it is not like 32 and then only a fraction of that so that is why you can use one 4\textsuperscript{th} for 16 and get 4, it was just like it was 32 minutes so 16 minutes to 32 minutes would be 40 cm to 80 cm since this is 36 it is going to be a 4\textsuperscript{th} a 4\textsuperscript{th} more, a 4\textsuperscript{th} as much so from 16 to 36 it will be 40 to 90, but without using ratios, you can wrap all these
R: How?
M: [The student draws a graph] so it starts here at 16 over here you are at 40 so it is about there and than 36 it is about 90, [inaudible] rate, it is going to be the it is going to be the constant line.
R: What does that line represent?
M: It tells you how much they will do in a time period, so instead of doing proportions, it would be like if they worked 10 minutes it is going to be about 30 around or it will be around 25 because 2.5 you can’t tell from the graph but you can tell it is going to go up it is like rise over run so 2.5 over 1 right so there will be 2.5 cm square.

Mark’s reasoning and use of representations seems to be more sophisticated after the
Mosaic Problem. Mark’s description of a line graph contrasts with his earlier use of a bar graph to show the relative size of two quantities.

![Figure 2. The graph Mark drew for the Mosaic Problem](image)

Thompson (1994) claimed that “as soon as one reconceives the situation as being that the ratio applies generally outside the phenomenal bounds in which it was originally conceived, then one has generalized that ratio to a rate…rate is (from my point of view) a linear function that can be instantiated with the value of an approximately conceived structure” (p.192). In that sense, data show that Mark is able to use the line representation as a representation of constant ratio which represents the invariant relationship, “2.5 square cm for 1 minute,” among all the cases outside the phenomenal bounds of the Mosaic Problem. Thompson further claimed “…To say that an object travels at 50 miles/hour quantifies the objects’ motion, but it says nothing about a distance traveled nor about a duration traveled at that speed (Schwartz, 1988, cited in Thompson, 1994). However, conceiving speed of travel in relation to an amount of time traveled produces a specific value for the distance traveled” (p.192). In that sense, the last excerpt shows that Mark could think of 10 minutes as worth 2.5 times as much work, which is 25 square cm. Thus, he was able to think of 10 minutes and 25 square cm of work producing a specific value for the invariant relationship of 2.5 square cm per minute among all the cases with the same rate. After this point, when I asked him to comment on the problem below, the Ice-Cream Problem, he could reason about it using within state ratios.

**The Ice-Cream Problem:** In an Ice-Cream factory 12.7 liters of milk and 10.5 pounds of sugar is needed for one gallon of ice-cream. The producers realized that they had 11.4 pounds of sugar for the new gallon and wanted to produce the same Ice-Cream with what they have. How much milk do they need to use?

Kelly solved the problem above and found the answer as 13.7 liters of milk. She then claimed that the ratio of 12.7 to 10.5 is the same as the ratio of 13.7 to 11.4. Then, she wrote:

\[
\frac{12.7}{10.5} = \frac{13.7}{11.4}
\]

Why should I believe her that this is a true statement? Can you convince me that this is a true statement?

Mark reasoned through that problem using the same argumentation and the graph [To be shared during the conference]. That is, Mark calculated 12.7 divided by 10.5, made a graph to communicate his thinking and claimed the following:

R: What does that line tell you, what is that line?
M: That is, it will be 1.21 over divided by 1. for 1.21 liters of milk there is one pound of sugar.
The above excerpt shows that the line is the relationship between the two quantities that make up the ratio, such that no matter what amount constitutes the mixture, the relationship between the quantities does not change. The invariant relationship is a multiplicative relationship such that the quotient, the result of division of the quantities in within-ratios, represents that.

**Mark’s Understanding of Between-State Ratios**

Data showed Mark’s limitation on the Hair Color-2 Problem, option “a”, at the beginning of the interview. When I asked Mark to reason about option “a”, the meaning of the ratio of 22/15, he said “…I do not know that one…” . However, he was able to reason about the alternative solution to the Mosaic Problem, which involved a between ratio solution process, depended on the quotitive division. Tzur & Simon (2004) in their postulation of participatory and anticipatory stages of understanding provided a way to make sense of Mark’s different responses to the two problems. At the participatory stage of understanding, the student needs to be able to be thinking about or be involved in the activity through which the understanding developed. For Mark, he was able to solve the Mosaic Problem because it cued him to his activity of solving missing-value problems by multiplying each quantity by the same number, which also cued him to use quotitive division. At the anticipatory stage, the student no longer requires a focus on the original activity. He is able to call on the understanding when needed. Thus, for Mark, the Hair Color-2 required an anticipatory level of understanding, because it did not cue him for the activity of solving missing-value problems by multiplying each quantity by the same number.

**Conclusion and Discussion**

The line of reasoning data corresponds with ratio as being the expression of specific situations, particular ratios, and rate as being the constant ratio, which is reflectively abstracted from ratio, through generalized situations (Thompson, 1994). Building on Thompson’s (1994) analysis for the conceptualization process of speed and Heinz’s (2000) hypothetical sequence, I propose the following as an explanation for how Mark came to an understanding of rate building on particular ratios. Mark already had gone through the accumulation of the quantities of 16 minutes and 40 square cm until he reached the targeted quantity of 36 minutes. His focus was first on the specific amounts of 16 minutes and 40 square cm, 32 minutes and 80 square cm and 36 minutes and 90 square cm. Once he made the segments of 16 minutes until 36 minutes – between state ratios—and 40 square cm until 90 square cm—between state ratios—, his focus was on both the whole segment and the specific amounts of that segment, such as 16 to 40, and 32 to 80 and 36 to 90—within state ratios. Mark knew that each of those pairs of quantities have a particular multiplicative relationship. Since he already knew that 16 and 40 are related to each other by 2.5 square cm for 1 minute, this made him realize that each of those specific quantities, 16 to 40, 32 to 80, 36 to 90, are all related to each other by the same relationship of 2.5 square cm per one minute (an image of an accumulation of two quantities that carries the image that the values of both quantities can vary, but only in constant ratio to the other). At that moment, he claimed that, “You can wrap all these,” because he realized that the ratio is a constant ratio, invariant for all cases with the same property. His use of the line graph and explanation of it demonstrated his reasoning about an interiorized ratio or rate.

In sum, Mark’s reasoning and use of representations in within state ratio situations at the beginning of the interview was different from his thinking at the end of the interview. More interestingly, Mark’s reasoning on the Mosaic Problem presented somewhat different levels of reasoning about within state ratios. Particularly, Mark used a unit-factor approach to reason for...
about the problem, at first. Later he was able to think about the within state ratios as an intensive quantity that quantifies the quality of interest in the situation. Also, at the beginning of the interview, Mark’s reasoning on the Hair Color-2 Problem “a” option contrasted his reasoning on the alternative solution to The Mosaic Problem at the end of the interview. It seems that Mark’s activity with the Mosaic Problem led either to learning or to a reorienting to something previously learned. In either case, his explanations and representations were more sophisticated following his work on this problem.

This study presents an analysis of a nine-year-old student’s mathematical activity constructing and extending fraction ideas in a fourth-grade classroom teaching experiment. The researchers, supported by the students’ teacher and principal, facilitated forty-eight open-ended sessions over the course of the school year. The students, working in pairs, invented strategies and constructed models of their solutions to problems involving fractions and rational numbers. Solutions were shared and questioned by the students as they justified their ideas. Results provide important documentation that students can demonstrate deep understanding of complex ideas before their introduction in the traditional curriculum.

Introduction

This study is part of a larger National Science Foundation funded research project1 based on data collected from a year-long teaching experiment in a rural/suburban public school. The mathematical ideas introduced in the fourth grade classroom took place before procedural ideas about equivalence and operations with fractions were introduced in the school’s curriculum. The study included forty-eight sessions implemented throughout the 1993-1994 academic year. This paper focuses on a six-week interval early in the year and includes three consecutive sessions on September 27, September 29, October 4 and a fourth session several weeks later on November 10. During the first three sessions the students were presented problems about fractions in reference to a particular unit comparison of fractions and equivalence. They were asked to model their solutions to each problem with Cuisenaire rods and develop justifications for their reasoning that could be shared with the class (Steencken, 2001; Yankelewitz, 2009). The conceptual understanding demonstrated by the students concerning the meaning of fractions as numbers rather than simply as operators and the subsequent existence of an unlimited number of equivalent names for each fraction (Steencken, 1998) served as a foundation for extending equivalence notions to integers and rational numbers in the fourth session, November 10, 1993. In that session, the students, based on their work with their partners, were invited to place positive and negative numbers on a large number line written on the dry erase board at the front of the class. As they shared their reasoning about each entry, the class debated a variety of issues and disagreements about what was posted (Schmeelk, 2010). The four sessions analyzed and reported in this research build from the first time the nine and ten year old students encountered two distinct names for the same fraction. They concluded with the students’ consideration of where to position those names for positive and negative integers and proper and improper fractions on a number line. In particular, students express concern and engage in discussion about the referent unit on the line for each rational number being considered. Our case study specifically examines Meredith as she builds solutions to the problems and interacts with her classmates and the researcher/facilitator over the six-week interval. The research is guided by the particular question: “How does Meredith’s understanding of equivalent fractions extend to rational number?”

Theoretical Framework

The notion of students building and restructuring their thinking based on previous experiences has been discussed in detail by Davis (1984). In the process of building personally meaningful experience, the learner assimilates earlier knowledge into new frames. This process is referred to by Davis as an assimilation paradigm. Davis and Maher (1990) refer to these new frames as a set of internal mental functions where a learner sees a new experience to be “just like” or as “similar to” earlier experiences. The properties that make an activity serve as an assimilation paradigm, according to Davis, deal with new ideas for which students have “powerful representations” and “reliably accurate isomorphic images” for all operations that apply. These images, according to Davis, are what guides learners to build solutions to new problems. He suggests, further, that the frames that are built and applied to new problems make building the solutions “simple” for the student. This suggests that learning with meaningful experience in which properties can be recognized and assimilation paradigms can be built constitute conditions for the growth of knowledge.

According to Davis and Maher (1990), the process by which knowledge is assimilated is cyclic (p. 65). It includes building a representation, carrying out memory searches to retrieve or construct a representation, constructing a mapping between the data representation and the knowledge representation, checking the mapping for correctness, and using technical devices associated with the knowledge in order to solve problems. The powerful representations described by Davis (1984) help students to construct mappings between the external and internal representations.

The Rational Number Project (RNP), over more than two decades, has provided seminal foundational research about how students think about fractions and rational numbers (Behr, Harel, Post & Lesh 1992; Behr et al., 1993; Lesh, Post & Behr, 1988). More recent RNP research studies, such as Cramer, Post and del Mas (2002) and Cramer and Henry (2002), show that students, when encouraged to construct their own conceptual understanding of rational numbers, relied less on rote procedures when solving mathematical tasks. These studies showed that the students who emerged from the RNP curricula scored significantly higher and exhibited a better quality of thinking and estimation on tasks given during interviews than comparison group students who did not use the RNP materials. Further, Cramer and Henry (2002) examined the role of using manipulative models to build number sense for addition of fractions and noted that teachers often transition to symbols from manipulatives too soon. Their results show evidence that the RNP students developed an understanding of fraction size as they successfully ordered fractions and were able to estimate answers to problems and verbalize their thinking. Overall, the Rational Number Project materials when used correctly appear to improve characteristics of students’ number sense.

Freudenthal (1983) describes equivalent rational numbers in terms of representing the “same thing.” He gives the example, “2/3 = 4/6 = 6/9 = …” and states that each fraction in the example is an alias for the same rational number. Freudenthal uses whole number aliases as a metaphor to describe rational number aliases. He states that, “One prefers for the number 5 the expression 5 rather than 3+2, 10-5 and so on, though the others are equally well admissible” (p.133). Steencken and Maher (2003) describe the students’ process of gradually replacing their physical models constructed from the rods with symbolic fraction number names as they built solutions for fraction problems, exemplifying Davis’s idea of an assimilation paradigm. “Eventually they referred to the comparisons without physically using the rods” (p.130).
Context of the Study
The study took place in a suburban New Jersey district over a one-year period with a heterogeneously grouped fourth grade class of twenty-five students aged nine and ten. The group included fourteen girls and eleven boys. All sessions were videotaped with one to three cameras during extended classroom sessions lasting from fifty to seventy-five minutes. The teacher was present throughout the sessions as well as other observers including: graduate students, the principal, graduate student observers, and the camera crew.

Data and Methodology
Triangulation of data occurred with video data and their full transcripts, observation notes, student overhead transparencies produced for sharing and other student work. The data combination (Pirie, 1996; Lesh & Lehrer, 2000) was designed to optimize the possibilities of examining in detail the students’ mathematical activities while reducing human and technological biases (Powell, Francisco & Maher, 2003).

The data were analyzed based on components of the Powell, Francisco and Maher (2003) method, evolved from the longitudinal research video studies of the Robert B. Davis Institute for Learning (RBDIL). Their method includes several stages for the analysis of video data including: viewing, transcribing, coding, writing analytical commentaries and summaries, and developing a narrative. We elaborate on four main phases that were used. Firsts was viewing each of the CDs multiple times, which was followed by transcribing and verifying each of the CDs. The verification process entailed having another viewer watch the CD to verify that the CD was properly transcribed. Transcription consisted of four components including: line number, time code, speaker, spoken words and actions. The line numbers were used for reference. The time stamp usually was noted in five minute intervals. Transcriptions then listed the speaker’s name followed by both spoken words and actions that are not verbally expressed. Particular camera views also were noted within the session transcriptions. The third phase, coding, was where critical events were flagged, traced, compared and categorized. The codes were placed on the transcript in a new column to facilitate scanning of the transcript while analyzing critical events. During the last phase, a summary of the findings and a narrative emerged. The narrative tells the story of what took place during the sessions and references the actual critical events in the transcript by line number.

Earlier Research Results
During the first three sessions, September 27, 1993, September 29, 1993, and October 4, 1993, students, for the first time, encountered different number names for the same fractions. A comprehensive list of the tasks during the first three sessions is in Table 1. A summary of the fraction ideas that were investigated by the children who built a variety of models using rods and drawings of rods to represent their solutions is also given. Details about the reasoning of the students and the processes by which they challenged each other and built on the ideas of others are given elsewhere (Yankelewitz, 2009). The collection of tasks and the fraction ideas that were considered by the children are central to better understand the sequence of ideas that evolved. The students offered models to support their solutions and made revisions in order to accommodate the input of others. Consequently, their sharing and arguing about ideas generated multiple justifications that were backed with multiple models.

On September 27, when asked by the researcher, “If we are calling the orange rod one, the number name one, what would you call the number name for the red rod?” Gregory stated, “one-fifth.” When asked why, Gregory replied, “Because five of the red blocks equal up to one orange block.” The researcher then asked, “What number name would I give to two of the whites? Two white rods?” Erik exclaimed, “Two of the white rods? That’s a red rod.” The researcher called on Mark who responded, “One-fifth.” Andrew explained why they had chosen one-fifth. Meredith stated, “I think it’s two-tenths.” Meredith explained, “When we did it before, we said that, we said that orange has ten whites, it measures up to ten whites. And if you put the whites up it would have ten. And two of ten is two-tenths.” Two minutes later, the researcher asked the class, “What do the rest of you think of that?” The class remained quiet.

On September 29, the researcher asked the class, “Is one-fifth equal to two-tenths?” Meredith explained that ten white rods equal up to an orange rod so two white rods would be two-tenths. She, then, showed that five red rods equals up to an orange rod, so one of them would be one-fifth. She finished by saying that if you take one of the red rods and put it above two of the white rods, they’re equal. The researcher asked other students in the class what they thought. Brian and Erik agreed.

On October 4, the students were asked which fraction, one-half or two-thirds, is bigger. They were asked to build models to support their ideas. After the students had finished building their models, the researcher asked the students again which fraction is bigger. The students stated that two-thirds is bigger. The researcher asked the students how much bigger two-thirds is was than one-half; they replied one-sixth. The researcher asked the class if anyone had made a second model, to which Meredith eagerly exclaimed, “Oh! Oh!” Meredith, then, went to the overhead projector and placed twelve white rods beneath the two dark green rods. She, then,
showed that two white rods (two-twelfths) was the difference between two purple rods (two-thirds) and one dark green rod (one-half). Michael exclaimed, “No. They can’t do that because the two-thirds are bigger than the half by a red; so, they can’t use those whites to show it.”

Results

The earlier sessions provide a background for the flow of events that occurred during the fourth session, November 10. The activity ranged from a discussion of Meredith’s five lines on the number line, which she had constructed to parallel her rod constructions, to marking fractions on a big number line on the dry erase board at the front of the class. The session opened with a discussion of five stacked lines Meredith had drawn to where each line represented a different aspect of the number line as seen in Figure 1.

![Figure 1. Meredith’s number line](image-url)

Specifically, the top line consisted of a complete number line: the second line showed two half regions and the number one-half labeled: the third line showed three thirds regions with both numbers one-third and two-thirds labeled: etc. Meredith had labeled the number fractions under the line and the region fractions above the line. Some students expressed concern about the numbers Meredith had placed above the line; for example, Michael stated, “Why are you calling two-thirds, a half? It is not half. It is bigger than half, two-thirds is bigger than half.” Meredith replied that she knew but was unsure “where to put it.” The class debated the two ways to represent fractions (operator and number) for approximately fourteen minutes. Later, students worked on marking numbers on a number line on the overhead projector. A discussion about how many third could be fit in the interval between zero and one triggered the question about where four-thirds would go. The researcher asked to hold the question about the placement of four-thirds; however, Meredith exclaimed that the interval would need to be six-thirds. Meredith continued, “If you made it to two, you would have six-thirds and, then, you could place four-thirds.” The class discussed this idea as Meredith worked on her own at the overhead projector. Two minutes later, the researcher asked to see what Meredith was writing on the overhead projector. The camera captured Meredith’s line where thirds were marked on the interval.

between zero and two. Under the number named one, Meredith had written in the corresponding fraction three-thirds. Under the number named two, Meredith had written in the corresponding fraction one and three thirds.

**Figure 2. Meredith places thirds on the number line**

Fifty minutes into the session, the class was working on placing numbers on a big number line on a dry erase board at the front of the room. The students were asked to select a number to place on the large number line. The first student, Audra, placed the number one-half under the number named zero. A lively discussion resulted about the placement of one-half, where arguments pro and con were offered; it apparently focused on whether the entire line should considered as the unit and the fraction as operator. Later, Meredith addressed this issue by disagreeing with the way the boys would have labeled fourths, operating on the entire line, and, one-fourth, two-fourths, three-fourths, four-fourths, one and one fourth, one and two fourths and one and three fourths correctly. The researcher asked Meredith about the earlier placement of one half by another student, to which Meredith replied that that is not how the line would be divided.

Two minutes later, the researcher stated that she was curious where Meredith would place negative one-fourth, negative two-fourths, negative three-fourths and negative four-fourths. Meredith walked up to the board and correctly placed the numbers between zero and negative one. A student in the class exclaimed, “She is like cutting the number line”.
